The star α Piscis Austrinus, 'the Mouth of the Fish', apparent magnitude 1.17, spectral type A3V. Situated at a distance of 25.1 light-years (parallax 0.130″), the star has an absolute magnitude of 1.7. Although a white star, it often appears reddish to northern hemisphere observers, due to a combination of its low declination (-29.6°) and atmospheric pollution. It is notable for observers in the British Isles as the southernmost first-magnitude star visible to them, just above the southern horizon in September and October. From southern England it reaches a maximum meridian altitude of about 10° at the end of September.

Force-Free Magnetic Fields

In MAGNETOHYDRODYNAMICS (MHD), which describes the fluid behavior of PLASMAS, the magnetic field $\boldsymbol{B}$ exerts a force, the Lorentz force, given by $\boldsymbol{F} = (1/c)\boldsymbol{J} \times \boldsymbol{B}$, in terms of the field and its electric current density $\boldsymbol{J} = (c/4\pi)\nabla \times \boldsymbol{B}$, where c is the speed of light. In many circumstances, the electrical conductivity of the plasma is so large as to be taken infinite, in which case electric currents change only by the inductive effect of the flowing plasma, with negligible Ohmic decay. In the absence of plasma motion, electric currents, once set up, persist with no decay. A particular form of such an equilibrium state is one in which the current density is parallel to the magnetic field, as described by the equation

$$\boldsymbol{\nabla} \times \boldsymbol{B} = \alpha \boldsymbol{B}. \tag{1}$$

The Lorentz force vanishes in the plasma and the magnetic field is said to be force free. In equation (1), the proportionality factor α is allowed in general to vary in space, subject to the condition

$$\boldsymbol{B} \cdot \boldsymbol{\nabla}\alpha = 0 \tag{2}$$

requiring α to be constant on a line of force, in order that Maxwell's equation

$$\boldsymbol{\nabla} \cdot \boldsymbol{B} = 0 \tag{3}$$

is satisfied.

Force-free fields are expected in the outer solar atmosphere where the plasma is electrically highly conducting but is so tenuous that its pressure and other body forces may be neglected compared with the typical strength of the Lorentz force that the magnetic field and its electric current are capable of producing. The Lorentz force $\boldsymbol{F}$ may be written as $\boldsymbol{F} = -\nabla(B^2/8\pi) + (1/4\pi)(\boldsymbol{B} \cdot \nabla)\boldsymbol{B}$, in terms of a pressure force and a tension force, which mutually cancel when the magnetic field is force free. The magnetic pressure $B^2/8\pi$ is a measure of the magnitude of the Lorentz force the field is capable of exerting. Force-free magnetic fields are therefore expected when the ratio of the gas pressure to the magnetic pressure, denoted by β in the plasma physics literature, is much smaller than unity.

Equations (1) and (2) pose a nonlinear problem for the magnetic field except when the function α is a constant. In this exceptional case, equation (2) is trivially satisfied, and solving equation (1), for some constant value of $\alpha = \alpha_0$, may be transformed to solving the vector Helmholtz equation

$$\boldsymbol{\nabla}^2\boldsymbol{B} + \alpha_0^2\boldsymbol{B} = \boldsymbol{0} \tag{4}$$

subject to suitable boundary conditions formulated for a physical problem. The astrophysical and plasma physics literature contains many works on the solutions to this linear problem. The general nonlinear problem is not readily treated, with few known solutions. In the following, we describe briefly some of the general physical properties of force-free magnetic fields.

The nature of the Lorentz force is such that the magnetic pressure force may be balanced by the magnetic tension force only in some bounded region of space. The magnetic pressure has an outward exertion which cannot be globally confined by the magnetic tension force alone. This is a fundamental property expressed by Chandrasekhar's virial relation:

$$\int_V \frac{B^2}{8\pi}\,\mathrm{d}V = \frac{1}{4\pi}\int_{\partial V}\left[\frac{1}{2}B^2\boldsymbol{r}\cdot\,\mathrm{d}\boldsymbol{S} - (\boldsymbol{B}\cdot\boldsymbol{r})(\boldsymbol{B}\cdot\mathrm{d}\boldsymbol{S})\right] \tag{5}$$

valid for any force-free field $\boldsymbol{B}$ in some volume V with boundary surface ∂V. If the force-free field is self-confining, we could take the volume V to be all space, in which case the surface integral in equation (5) would vanish since the field intensity would fall with distance as fast as a dipole magnetic field. A contradiction then arises from equation (5) unless $\boldsymbol{B} = \boldsymbol{0}$. This classical result implies the impossibility of creating a magnetically self-confining plasma without rigid walls in the laboratory. In the astrophysical context, this property shows that force-free magnetic fields need to be anchored to regions where the magnetic field exerts nonzero Lorentz force on the embedding plasma.

In the solar atmosphere, only the magnetic field in the thin layer called the photosphere can be measured with any useful spatial resolution. Equation (5) offers a means of estimating the energy of the magnetic field in the atmosphere above, taken in the force-free approximation, in terms of the measured vector field at the photosphere. In this popular model, the volume V is often taken to be the space above the photosphere treated as an infinite plane. A basic motivation of this modeling work is to demonstrate the amount of free energy that can be stored in the parallel electric currents of a force-free field. The stored energy is believed to be the origin of the enormous amount ($\sim 10^{31-32}$ erg) liberated in a large SOLAR FLARE. The application of force-free fields to the solar atmosphere has served to illustrate observed magnetic structures and to illuminate basic physical points. Application with the use of measured photospheric vector fields as inputs is an involved and difficult numerical simulation effort, as a result of nonlinearity, difficulties associated with the proper posing of the boundary conditions and the ill-posed nature of the mathematical problem.

In a perfect electrical plasma conductor, the magnetic flux is frozen into the plasma so that the field topology cannot change in time. If a magnetic field, not necessarily in force equilibrium, is taken to be given and is then deformed by displacing the embedding perfectly conducting plasma to an extremum in its total magnetic energy, the result would be the force-free field as described by equations (1) and (2), where the scalar function α takes a distribution in space that renders the solution $\boldsymbol{B}$ topologically identical to the given initial field.

The variational problem stated above is difficult to treat but has very interesting physical implications.

The solution to the variational problem may not be unique, in which case the nonunique solutions may be distinguished between the force-free fields which are linearly stable and those which are linearly unstable (see MAGNETOHYDRODYNAMIC INSTABILITIES). Linear magnetohydrodynamic stability of force-free magnetic fields has been treated extensively in the literature, with the general result that the rigid anchoring of the force-free field lines to the base of an atmosphere provides some degree of stability so long the lines of force are not too lengthy within the atmosphere. Most of the force-free fields studied in linear stability analyses are one- or two-dimensional fields. Extension to non-trivial variation in three-dimensional space, except for the case of constant α fields, is limited although some simple examples have been found, including some with realistic geometry suggestive of observed solar magnetic structures. These examples were found to be linearly stable.

More interesting is the possibility that an extremum in magnetic energy corresponds to a force-free field which necessarily contains magnetic tangential discontinuities in order to satisfy the requirement that the force-free field has a prescribed field topology. Mathematically, this is related to the fact that, in variational problems, the set of smooth minimizing functions to approach an extremum is not necessarily compact. If the extremum magnetic field must have a tangential discontinuity and is a minimum in energy, a magnetic field having the same magnetic topology may physically relax into such a state with the formation of the inevitable tangential discontinuity. Physical plasmas have large but finite electrical conductivities so that the formation of the tangential discontinuity in such a plasma would proceed until the thickness of the discontinuity is small enough for the electrical resistivity, however weak, to dissipate the sheet. This process is a consequence of high electrical conductivity, which, remarkably, creates the physical circumstance for inevitable dissipation of electric currents. The idea was proposed by E N PARKER as the origin of plasma heating under astrophysical conditions.

The turbulent MHD relaxation of plasmas at large magnetic Reynolds' numbers proceeds by the formation of magnetic tangential discontinuities which dissipate by MAGNETIC RECONNECTION (see also MAGNETOHYDRODYNAMICS: MAGNETIC RECONNECTION AND TURBULENCE). With resistive effects important only at these reconnection sites, the change in magnetic field topology proceeds in such a way that, as a measure of the complexity in the field topology, the MAGNETIC HELICITY is conserved in the global volume of the plasma, as opposed to the more stringent requirement of no change in field topology. This global conservation of magnetic helicity is a constraint that sets the extremum in the total magnetic energy to be one of a force-free field having a constant $\alpha = \alpha_0$, described by equation (4). The value of α_0 is then fixed such that the linear force-free field has the conserved amount of total magnetic helicity. This provides a physical basis for singling out the linear force-free fields from the nonlinear ones. Application of this theory due to B Taylor to the laboratory plasmas has been very successful. Extending the application to solar and astrophysical magnetic fields is not straightforward because of the problem of gauge dependence of magnetic helicity in the case of magnetic fields which thread across the boundary of its physical domain.

Fornax

(the Furnace; abbrev. For, gen. Fornacis; area 398 sq. deg.) A southern constellation which lies between Sculptor and Eridanus, and culminates at midnight in early November. It was introduced as Fornax Chemica (the Chemical Furnace) by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2. The shortened form was adopted by the IAU in 1922.

A small, inconspicuous constellation, the brightest star in Fornax is α Fornacis, a binary with pale yellow and yellow (F6 and G7) components, magnitudes 3.8 and 7.0, separation 4.5″, period 314 years (?). There are no other stars brighter than fourth magnitude. Interesting objects include the Fornax Dwarf Galaxy (ESO 365-G4, also called the Fornax System), a dwarf spheroidal galaxy in the Local Group, about 540 000 light-years distant, NGC 1365, a ninth-magnitude barred-spiral galaxy, and NGC 1316, another ninth-magnitude spiral which is the optical counterpart of the strong radio source Fornax A. The last two are members of the conspicuous Fornax Cluster of galaxies.

Foucault, Jean Bernard Léon (1819–68)

Physicist, born in Paris. Became professor at the Paris Observatory and member of the Longitude Institute. Collaborated with FIZEAU in the measurement of the velocity of light using the Fizeau wheel. After they quarrelled, independently of Fizeau he measured the speed of light in water, and found it to be slower than in air, as predicted by the wave theory of light, and against the corpuscular theory. First scientist (with Fizeau) to photograph the Sun (on a daguerreotype). Developed the *Foucault pendulum*, at first hanging a 2 m long pendulum in his basement, and a 10 m one in the Paris Observatory, so watching the rotation of the pendulum's oscillating path and confirming the rotation of the Earth. After this he carried out a demonstration with a very long pendulum (60 m) in the dome of the Pantheon, causing a public sensation. Showered with honours, and appointed to the staff of the Paris Observatory, he set about improving its telescopes, in the course of which he invented the knife-edge test for the figure of a mirror, the process of silvering glass mirrors (replacing the speculum metal mirror), and pneumatic mirror support systems.

Foucault's Pendulum

A freely swinging pendulum mounted in such a way as to reduce its physical contact with the Earth to an absolute minimum. An ideal pendulum of this type would, if set swinging in a particular plane at one of the Earth's poles, continue to swing in that same plane relative to the 'fixed stars', and the Earth would rotate underneath it. To the observer on the Earth's surface, the pendulum would be seen to rotate its plane of swing through 360° each day. The period of rotation of the plane of the pendulum increases with decreasing latitude on the Earth's surface. No rotation is observed for a pendulum at the equator. Observation of the behavior of such a pendulum is direct evidence of the fact that the Earth rotates on its axis. This type of pendulum is named after the French physicist, Léon Foucault (1819–68).

Fowler, Alfred (1868–1940)

Professor at the Imperial College of Science and Technology, in South Kensington, London, a master of spectroscopy, especially for solar phsyics. He identified titanium oxide in cool stars, magnesium hydride in sunspots, carbon monoxide in comets and ozone in the Earth's upper atmosphere. When the Bohr theory of the atom appeared, he made contributions to atomic physics, identifying the spectrum of ionized helium and determining the value of the Rydberg constant and the proton–electron mass ratio. Organized, and became the first Secretary of, the International Astronomical Union.

Fowler, William Alfred ['Willy'] (1911–95)

American nuclear physicist, born in Pittsburgh, PA, worked at CalTech. Nobel prizewinner (1983). While at the Kellogg Laboratory studied the nuclear reactions of protons with the isotopes of carbon and nitrogen, the very reactions in the CN cycle identified at that time by HANS BETHE as occurring in the stars. Established the science of nuclear astrophysics. Found that there was a gap in the sequence of stable nuclei at mass 8, as at mass 5. These mass gaps spelled doom for GEORGE GAMOW'S brilliant idea (the alpha-beta-gamma theory) that all nuclei heavier than helium (mass 4) could be built by neutron addition, one mass unit at a time, in the Big Bang. Measured the rates of nearly all nuclear reactions of astrophysical interest, and co-authored, with Margaret Burbidge, Geoffrey Burbidge and FRED HOYLE, the famous 1957 paper, 'Synthesis of the elements in stars', known as B^2FH. They showed how the cosmic abundances of essentially all the nuclides from carbon to uranium could be explained as the result of nuclear reactions in stars, using hydrogen and helium produced in the Big Bang. After 1964 Fowler worked on theoretical problems involving supernovae, gravitational collapse and nucleo-cosmo-chronology.

Fraunhofer Lines

Dark lines in the spectrum of the Sun, first studied by Joseph von Fraunhofer (1787–1826) in 1814. He labeled the most prominent of these by the letters A to K, ranging from the red end of the spectrum to the violet. Most are absorption lines due to the absorption of light by atoms in the outer regions of the Sun; for example, a prominent pair of close dark lines in the yellow part of the solar spectrum is the 'D' lines of the element sodium. A few Fraunhofer lines orignate in molecules in the Earth's atmosphere.

Fraunhofer, Joseph von (1787–1826)

Instrument-maker, born in Straubing, Germany, began life as a wood turner then as a glazier, educated himself in optics. Joined the instrument workshop of Georg Reichenbach and Joseph Utzschneider making and developing lenses, and taking up optical glass making for the microscopes, opera glasses, loupes and the small and large astronomical telescopes and heliometers which the company built. Fraunhofer calculated, designed and tested every instrument, wrote the manuals and watched the disassembling and packaging process for the bigger telescopes, including the big refractor for the Russian observatory in Dorpat, used by STRUVE to measure 3000 double stars. This was the first telescope mounted equatorially and driven about the polar axis with a clock. Around 1813 Fraunhofer began to research the chromatic properties of different sorts of glass and rediscovered the dark lines in the Sun's spectrum, as first seen by WILLIAM WOLLASTON and now known as *Fraunhofer lines*. Fraunhofer identified and measured the wavelengths of 574 lines, cataloging them with letters (A to Z for the strong ones, as for example the 'sodium D-lines', lower case letters for the weaker, e.g. the magnesium b-line), which are still used today. His motivation for the study seems to have been to provide wavelength standards to make refractive index measurements although his work is remembered as pure science. He followed up this work with studies of the spectra of the light of electric sparks, different light sources and stars. Fraunhofer sold his firm to Merz.

Frequency

The rate at which specific events occur. In the context of electromagnetic radiation, the term is taken to mean the number of wavecrests per second passing a particular point. For light of wavelength λ, since the speed of light $= c$, the frequency, $f = c/\lambda$.

The SI unit of frequency measurement is the hertz (Hz), measuring the number of waves passing a fixed point per second. Thus, 1 wave per second would correspond to a frequency of 1 Hz, 100 000 waves per second to 100 000 Hz, etc. Common multiples are kilohertz (kHz) = 1000 Hz, megahertz (MHz) = 1000 000 Hz, and gigahertz (GHz) = 1000 000 000 Hz. An older unit of frequency is cycles per second (c/s); 1 Hz = 1 c/s.

Friedmann [Fridman], Aleksandr [Alexander] Aleksandrovich (1888–1925)

Mathematician, born in St Petersburg, Russia, where he studied and first worked. After exciting war-time and revolutionary experiences he returned to Petrograd (as it had been re-named, before becoming Leningrad and now St Petersburg again) where he taught mathematics and mechanics. Friedmann took up an interest in EINSTEIN's general theory of relativity, and showed in a classic paper 'On the curvature of Space' that the radius of curvature of the universe can be either increasing or a periodic function of time. Einstein and de Sitter had considered a stationary type of universe, and Einstein at first claimed that Friedmann's solution does not satisfy the field equations, but conceded after further study that Friedmann was right. Friedmann's solution foreshadowed the concept of the expanding universe. Just as COPERNICUS made the Earth orbit round the Sun, so Friedmann made the universe expand.

Frost, Robert (1874–1963)

American lyrical poet, born in San Francisco, amateur astronomer. His poetry contains numerous astronomical images, including the image of the farmer who, unknowingly, picked up a meteorite and built it into a prosaic stone wall. He had a telescope in his farmhouse in Derry, New Hampshire and each of his children was given the task of following one star (cf. his poem, *Choose Something Like a Star*).

Fuertes Observatory

Located on the North Campus of Cornell University, Ithaca, New York, it contains a 30 cm refractor. Earlier in the twentieth century, the observatory was used to tell the time by noting when certain stars passed overhead. Today it is used largely as a teaching facility for introductory astronomy classes. It is also used by the Cornell Astronomy Club.

Fundamental Catalogs

Catalogs that list stars whose positions and proper motions have been very accurately determined over many years by positional measurements relative to telescopes, rather than to other stars. A number of early catalogs are still of value because the determination of positions and proper motions is an on-going exercise in which old observations are combined with the latest measurements; a notable example is the *General Catalog of 33 342 Stars* (*abbrev.* GC) compiled by the American astronomer Benjamin Boss (1880–1970) and published in five volumes in 1936–7.

The most important fundamental catalogs are the FK series, begun in Berlin in 1879. The third of these, the *Dritter Fundamentalkatalog des Berliner Astronomischen Jahrbuchs* (*abbrev.* FK3), published in 1934 contained the positions of 1535 stars with a limiting magnitude of about 7.5, for the epoch 1950.0. It was adopted as the standard list of fundamental stars by the International Astronomical Union (IAU) in 1935, and a series of annual volumes of *Apparent Places of Fundamental Stars* was commenced in which the predicted positions of the fundamental stars are tabulated at 10 day intervals, using the FK data.

Succeeding catalogs, the FK4 and FK5, were published in 1963 and 1988 respectively by the Astronomisches Rechen-Institut, Heidelberg, on behalf of the IAU. The catalog positions are calculated for a standard epoch, so that they provide a fundamental reference frame to which observations of the positions of all other bodies may be referred. Precise positional observations of the fundamental stars made at many observatories around the world, mainly with transit circles (and, in more recent years, photographic zenith tubes and prismatic astrolabes), are combined to update and improve the catalog positions and proper motions for this list of fundamental stars.

Fundamental Forces

The forces that govern the various interactions between particles. The four fundamental forces, or interactions, are: gravitation, the electromagnetic force, the strong nuclear force, and the weak nuclear force.

The gravitational force acts between all particles and is always attractive; it pulls matter together. Gravitation is the force that binds together the solar system, the galaxies, and clusters of galaxies. The electromagnetic force controls the behavior of electrically charged particles (particles of like charge repel, whereas opposite charges attract). The electromagnetic force is the binding force of atoms; the electromagnetic interaction between its positively charged nucleus and its surrounding cloud of negatively charged electrons holds an atom together. The electromagnetic force also controls the absorption and emission of electromagnetic radiation. The strong nuclear force binds together the nucleons (protons and neutrons) in an atomic nucleus and prevents the like-charged protons from flying apart. Particles that are acted on by the strong nuclear force (including protons and neutrons) are known collectively as hadrons. The strong nuclear interaction between individual hadrons is believed to be a remnant of a more powerful color force that acts between quarks inside hadrons. The weak nuclear force causes the radioactive decay of certain atomic nuclei. In particular, it governs the process called beta decay whereby a neutron breaks up into a proton, an electron and an antineutrino.

The strong and weak nuclear interactions are short-range forces that are effective only within the nuclei of atoms, the range of the strong force being about 10^{-15} m and that of the weak force about 10^{-17} m. The electromagnetic and gravitational interactions are long-range forces, their strengths being inversely proportional to the square of distance (if the distance is doubled, the force is reduced to a quarter of its previous value). Thus, in principle, the gravitational attraction between two masses, or the electromagnetic force between two charged particles, does not decline to zero until the separation between them becomes infinite. Although in terms of interactions between individual particles, gravitation is far weaker than the electromagnetic force, because matter on the large scale tends to be electrically neutral, gravitation controls the overall dynamics of planets, stars, and galaxies.

In the present-day universe, at everyday energy levels, the four forces are distinct from one another and have different strengths (in order of decreasing strength: strong nuclear, electromagnetic, weak nuclear, gravitation). At very high energies (particle energies in excess of about 10^{11} eV) the weak and electromagnetic forces merge into a single 'electroweak' force. According to Grand Unified Theories (GUT), the strong and electroweak forces will lose their separate identities and behave as a single unified force at particle energies in excess of about 10^{24} eV (about 10^{12} times higher than can be achieved in present-day particle accelerators). Although a complete theory (a 'theory of everything') that embraces all four forces has not yet been achieved, it is widely believed that at still higher energies, gravitation will unite with the others into a single 'superforce'. If this hypothesis is valid, the universe was dominated by the superforce in the first microscopic instant of the Big Bang. Thereafter, as the universe expanded and cooled (and particle energies decreased), the unified force broke up into the four separate forces.

According to modern quantum theories, the various fundamental forces are conveyed between real particles by means of 'virtual' particles (particles that are permitted temporary existence by the Heisenberg uncertainty principle). The force-carrying particles, or 'gauge bosons', for each of the forces are as follows: electromagnetic force, photons; weak nuclear interaction, intermediate vector bosons; strong nuclear interaction between hadrons, pions (strong interaction, or 'color force', between quarks, gluons). The existence of the hypothesized force-carrying particle for gravitation (the graviton) remains unproven.

According to Kaluza–Klein theory, which is named after physicists Theodore Kaluza and Oscar Klein, the universe began with more than four dimensions (current versions of this kind of theory require at least ten dimensions), of which only four expanded to form space (which has three dimensions—length, breadth, height) and time, the others remaining so tightly 'curled up' on themselves that they are not directly perceptible. Theories of this kind suggest that the fundamental forces are manifestations of these hidden dimensions.

Fundamental Particles

Subatomic particles that cannot be divided into smaller components. The fundamental particles include leptons (electrons, muons, tau particles, and neutrinos), quarks and gauge bosons particles which, so far as is known at present, do not have an internal structure composed of other, more basic, particles.

See also: elementary particles, gauge bosons, leptons, quark, subatomic particles.

Fundamental Stars

A definitive list of 1535 stars, adopted by the International Astronomical Union in 1935, whose positions and proper motions have been very accurately determined over many years and are regularly updated by positional observations of very high precision. The data are regularly published in fundamental catalogs and provide a reference-frame for position- and motion-determining observations of all other bodies.

See also: fundamental catalogs.

Fusion

The process in which two lighter atomic nuclei are combined to form a heavier atomic nucleus. Very high temperatures are normally required in order for atomic nuclei to collide with sufficient energy to overcome their mutual electrostatic repulsions (each atomic nucleus has a positive charge, the magnitude of which depends on the number of protons it contains). Fusion that occurs under high-temperature conditions is called thermonuclear fusion.

Fusion reactions involving light elements release large amounts of energy. The mass of the resulting nucleus is less than the combined masses of the two original nuclei, the difference in mass, Δm (which is known as the mass defect) being released as energy (E) in accordance with Einstein's relationship, $E = \Delta mc^2$, where c denotes the speed of light. The fusion of elements up to iron (atomic mass 56) results in the release of energy. The fusion of elements heavier than iron requires an input of energy. Thermonuclear fusion provides the energy that powers stars. In main sequence stars, such as the Sun, fusion reactions (the proton–proton reaction or the carbon–nitrogen–oxygen cycle) convert hydrogen to helium. In red giants, helium is converted to carbon by a process called the triple-alpha reaction and, in highly evolved high-mass stars, fusion reactions synthesize a succession of elements up to iron.

Gagarin, Yuri Alekseyevich (1934–1968)

Russian cosmonaut, born in Gzhatsk, Russia (renamed Gagarin after its favourite son). Trained in the Soviet air force, in 1961 he became the first man to travel in space, completing an orbit around the Earth in the Vostok spacecraft.

Galactic Astronomy *c.* 1900–*c.* 1950

By the early years of the 20th century it was widely believed that the great majority of the objects in our stellar system were close to the Galaxy's center, that the Sun was near its center, that the stars moved randomly in space and that the Galaxy included all the objects in the visible universe. There was, however, no general agreement on the Galactic system's size and detailed shape. Also, while some astronomers were prepared to accept in principle that external galaxies existed, they placed these other galaxies beyond the reach of even the most powerful telescopes.

Half a century later a very different conception of the Galaxy had been fashioned. In the early 1950s the orthodox view was that the Galaxy had a diameter of 30 000 pc and was a disk-like system with a central bulge. It also possessed a spiral structure with the Sun placed about 8500 pc from the center. All astronomers now accepted that the Galaxy rotated differentially and that it was only one of a multitude of galaxies.

Galactic models in the early years of the century

There were two principal models of the Galaxy in the first decade of the 20th century: the spiral and the ellipsoidal. The hypothesis that the stars in the Galaxy are arranged in a spiral pattern, which had first been proposed, in the middle of the nineteenth century, owed most to the Dutch astronomer Cornelis Easton (1864–1929). In 1900 he had described 'A new theory of the Milky Way' in which he had noted that the latest observations of nebulae had demonstrated the spiral to be a much commoner form than had previously been supposed. Might the spiral structure, Easton asked, be the plan on which the Galaxy was designed?

A principal aim of some astronomers in the 19th century had been to discover the actual distribution of the stars in space and hence the size and structure of the Galaxy. To succeed they judged they would have to disentangle the two causes of a star's apparent brightness: its distance and its luminosity. For want of anything better, these pioneers had sometimes been driven to employ the assumptions of constant absolute magnitudes and constant spatial densities for the stars, but both were by 1900 long accepted as grossly inadequate. At the end of the 19th century and in the early years of the 20th, however, astronomers forged novel methodological and conceptual tools in their attempts to discern the nature of the Galaxy. These tools gave rise to 'statistical astronomy' which many hoped would eventually enable them to discover the true arrangement of the stars. As the astronomer–historian A Pannekoek expressed it, 'here [is] a new kind of astronomy, which may be called "statistical astronomy". It appears where we have to deal not with stars individually but, with hundreds or thousands or even millions of them. Then the nature of the problems has changed with the object; we do not ask which stars, but how many stars have certain characteristics (color, spectrum, duplicity) or certain values of the parameters (temperature, density, luminosity, magnitude). Counting supplies the measuring. The positions (in the sky or in space) do not matter, but the densities of distribution (over the sky or over space). Statistical laws of distribution are the objects and the working instruments of the astronomer who is dealing with thousands and millions of the heavenly host'.

In the early years of the 20th century the three most notable exponents of, and innovators in, statistical astronomy were C V L CHARLIER (1862–1934) at Lund, Hugo von Seeliger (1849–1924) at Munich and J C KAPTEYN (1851–1922) at Groningen. Seeliger's approach consisted basically of counting the total number of stars between successive magnitude limits. These counts and the mathematical analyses of the counts enabled him to estimate (1) the flattening of the stellar system toward the plane of the Milky Way, (2) the relative extent of the Galaxy and (3) the general distribution of stars as a function of magnitude and galactic latitude. Further, for his 'Betrachtungen über die räumliche Vertheilung der Fixsterne' of 1898, Seeliger constructed an ellipsoidal model of the Galaxy which had a diameter of about 3000 pc along the galactic plane and stretched for about 1300 pc at right-angles to the plane. However, to secure detailed information on the actual spatial density an astronomer needed information on the variations in the intrinsic brightness of stars and, in particular, the luminosity function—that is, the number of stars per unit volume of space in successive intervals of absolute magnitude.

At the start of the 20th century so few trigonometric parallaxes of stars were known that an attempt to determine the luminosity law directly was out of the question. Kapteyn's response to the paucity of parallax data was to develop various mathematical techniques to exploit the more easily obtained observations of magnitude and proper motion; of these the most valuable involved an empirical expression for the average parallax of a group of stars as a function of their magnitudes and proper motions. With the aid of these techniques, Kapteyn approximated the luminosity law and then calibrated the dependence on distance of the space density of the stars.

An early product of Kapteyn's scrutiny of the proper motions of the stars was his discovery, announced in 1904, that the stars tended to move in two distinct directions. Kapteyn supposed this phenomenon to be the result of two intermingled streams of stars moving relative to one another. While an explanation of Kapteyn's find became one of the outstanding problems of galactic astronomy, the immediate and surprising message of the star streams was that the stars do not move randomly, as had been assumed, but that there is an order amidst the apparent jumble of stellar proper motions.

Kapteyn was also anxious to secure within a reasonable time representative samples of the immense amount of data that he believed necessary to a proper study of the Galaxy. He therefore proposed in 1906 that astronomers should obtain as much information as they

could about 206 selected stellar areas uniformly spread over the sky. This plan was soon taken up by a number of observatories.

Despite their hopes of achieving a greater understanding of the structure of the Galaxy, statistical astronomers labored under a major handicap: the lack of firm knowledge about interstellar absorption. The possibility of the absorption of star light made it difficult to decide whether the observed thinning out of the stars with increasing distance was genuine or whether it was the result of absorption. Statistical astronomers were particularly uneasy because the observed change in density seemed to place the Sun in a nearly central, and apparently privileged, position in the Galaxy.

In the late 19th century E E BARNARD (1857–1923), a renowned American observational astronomer, had noticed dark regions in his photographs of the Milky Way. Such regions had been known since the time of William Herschel and astronomers had pondered whether they were areas genuinely devoid of stars or whether dark obscuring clouds were blocking the light of the stars that lay beyond. Until the 1910s many astronomers accepted that the dark regions were indeed holes or rifts, but Barnard's later photographs of the Milky Way were largely instrumental in convincing his colleagues that they were really clouds of obscuring material situated among the stars.

By about 1916, however, astronomical opinion had moved toward the view that while localized obscuring clouds did exist, the general absorption of star light in space is insignificant. This shift was largely due to the examination by HARLOW SHAPLEY, then a young astronomer at Mount Wilson Observatory in California, of the color of the stars in globular clusters. Shapley had examined in detail the globular cluster M13 in Hercules. In 1915, he had estimated this cluster to be about 30 000 pc away, a much larger distance than the contemporary estimates of the diameter of the Galaxy. If absorbing material had been present it would, Shapley asserted, have manifested itself by reddening the light from the stars of the Hercules cluster: the color indices of the stars would then have been more positive than for a sample of similar stars in the solar neighborhood. Yet this was not the case, and so Shapley claimed that the extinction and reddening of star light could effectively be ignored in researches of the Galaxy. These studies freed Kapteyn of any reservations he had over assigning a nearly central position to the Sun in the Galaxy.

Shapley's model of the Galaxy

In his celebrated *Stellar Movements and the Structure of the Universe* of 1914, A S EDDINGTON (1882–1944) summarized the picture that modern researches had painted of the stellar system: 'It is believed that the great mass of the stars. . .are arranged in the form of a lens- or bun-shaped system. That is to say, the system is considerably flattened towards one plane. . .. In this aggregation the Sun occupies a fairly central position. . .. The median plane of the lens is the same as the plane marked out in the sky by the Milky Way, so that when we look in any direction along the galactic plane (as the plane of the Milky Way is called), we are looking towards the perimeter of the lens where the boundary in most remote. . . . The thickness of the system, though enormous compared with ordinary units, is not immeasurably great. No definite distance can be specified, because it is unlikely that there is a sharp boundary; there is only a gradual thinning out of stars. The facts would perhaps be best expressed by saying that the surfaces of equal density resemble oblate spheroids. To give a general idea of the scale of the system, it may be stated that in directions towards the galactic poles the density continues practically uniform up to a distance of about 100 parsecs; after that the falling off becomes noticeable so that at 300 parsecs it is only a fraction (perhaps a fifth) of the density near the Sun. The extension in the galactic plane is at least three times greater. These figures are subject to large uncertainties'.

Just a few years later, Shapley claimed that the Galaxy has a diameter of about 100 000 pc, a staggering increase on the commonly accepted size. Shapley, moreover, placed the Sun in an eccentric position thousands of parsecs from the Galactic center.

All of the main components involved in Shapley's invention of the big Galaxy were present by late 1917: his concern for the peculiar distribution of the globular clusters (they seemed to be almost all located in one part of the sky), a conviction that the Galaxy was much larger than his contemporaries conceded and a knowledge of the distances of the globular clusters. By early 1918, Shapley had decided that the globular clusters outlined the stellar system, and from their distances he had calculated that the Galaxy is about 100 000 pc in diameter and that the Sun is 20 000 pc from its center. Further, the globular clusters are symmetrically distributed throughout space on either side of the Galactic plane, and the center of the system of globular clusters defines the center of the Galactic system itself. The local group, which contains all of the stars ordinarily studied, is a few times larger than a globular cluster.

Not all of the elements of this radical model were new, however. Shapley's idea of the eccentric positioning of the Sun within the Galaxy was not the novelty he liked to suppose. The idea has an ancestry going back to the 18th century and only 9 yr earlier, in 1909, Karl Bohlin, a noted Swedish astronomer, had even tied it to the proposal that the globular clusters are symmetrically placed about the center of the Galactic system. Bohlin's hypothesis provoked little discussion, perhaps because of the strange version of the island universe theory that he had linked to his Galactic theory. In fact, in 1915 Shapley had explicitly rejected Bohlin's scheme because the distances Shapley had derived to the globular clusters, together with his estimates of the dimensions of the Galaxy, at that time clearly ruled out a model in which the clusters surrounded the center of the Galaxy.

Shapley's model was nevertheless unexpected. Astronomers had no inclination to demolish the contemporary notions of the structure and size of the Galaxy. Shapley was also arriving at his surprising conclusions on the basis of a new methodology. Instead of advancing meticulously outwards from the region of the solar neighborhood, as the statistical astronomers did, Shapley went to the other extreme of exploiting the remote globular clusters to advance into the Galaxy. Also, the two approaches did not seem to link up, and to many astronomers it seemed inherently unreasonable that the refined and familiar tools of statistical astronomy would give so bad a value for the dimensions of the Galaxy and such a poor answer for the location of the Sun.

In the early 1920s, Kapteyn wrote two papers that capped his life's work in Galactic astronomy and offered a vision of the Galaxy again very different from Shapley's. The first was composed in 1920 in collaboration with P J van Rhijn. The authors argued that the Sun is close to the center of the Galaxy, and that the limits of the Galactic system, which they represented as a flattened ellipsoid, were reached at a distance of about 1250 pc at right-angles to the Galactic plane and at 9000 pc along the plane. Two years later Kapteyn wrote what he called a 'First attempt at a theory of the arrangement and motion of the sidereal system'. He reckoned that the limits of the Galactic system, which he took to be where the star density sank to 1/100th of the density in the solar neighborhood, were found at roughly 1700 pc at right-angles to the plane and 8500 pc along the Galactic plane. Kapteyn thereby proposed dimensions for the Galaxy that, although small compared with Shapley's, were far larger than the estimates of the mid-1910s, and so the 'Kapteyn universe', as this model became known, was itself a notable departure from the previously prevailing orthodoxy.

Many astronomers reckoned there were weaknesses and flaws in Shapley's model, especially in his scheme of distances. These he obtained with the aid of three interlocking methods. Some of the larger, and apparently closer, clusters contained stars that Shapley identified as Cepheid variables. Yet Shapley's calibration of the period–luminosity relationship relied on a statistical analysis of the proper motions of only 11 stars. Furthermore, despite the advance in accuracy achieved in L Boss's catalogue of proper motions, the proper motions of these eleven Cepheids were still very uncertain.

To reach a cluster that contained no visible Cepheids, Shapley examined its 30 most luminous stars. He then discarded the five brightest in case they were field stars and not physically associated with the cluster. For the remaining 25 he calculated their mean luminosity. Shapley now derived the absolute mean magnitude for these 25 stars by following the same procedure for the clusters of known distance (that is, those containing visible Cepheids). He could now find the distances not only to those clusters in which he could detect Cepheids but to any in which he could distinguish the 30 brightest stars. For the very distant globular clusters that would not yield to either of these approaches, he employed their apparent angular diameters as distance indicators. To calibrate this final link in his chain of distance determinations he drew an 'apparent diameter versus distance' curve for the globular clusters calibrated by clusters that had submitted to the previous techniques.

It was to the initial Cepheid calibration that astronomers objected most strongly. If Shapley had erred at this point, then the claimed distances for the globular clusters, on which rested his theory of the Galaxy, would be undermined. To many astronomers it seemed imprudent to base a revolutionary conception of the Galaxy on a statistical analysis of a mere 11 stars. One of these astronomers was H D CURTIS of Lick Observatory in California.

In 1920 Curtis and Shapley discussed 'The scale of the Universe' at a meeting of the National Academy of Sciences in Washington. This encounter—the so-called 'Great Debate'—led in the following year to the publication of papers in a *Bulletin of the National Research Council* by Shapley and Curtis under the same title as their Washington addresses. The papers, however, were pitched at a much higher level than the Washington talks (Shapley, in fact, was most anxious in the 'debate' to impress those members of the audience concerned with selecting the next director of the Harvard College Observatory, a position he coveted), and a lengthy section of Curtis's 1921 paper offered a critique of Shapley's use of the Cepheids as distance indicators. In Curtis's opinion the proper motion data on the Cepheids were meager, and he was far from convinced that a period–luminosity relationship existed for the Cepheids.

Shapley appreciated that his calibration of the period–luminosity relationship was open to criticism and so, to counter Curtis's attack on the Cepheids, he employed in his own paper the B stars as the principal distance indicators to the globular clusters. But Curtis, like many other astronomers, rejected Shapley's claim that the B stars were reliable 'standard candles'.

It would, however, be a mistake to believe that around 1920 astronomers were faced with a stark choice between the Galactic models of Kapteyn and Shapley. By no means every astronomer was prepared to side with either Shapley or Kapteyn. Certainly the spiral model had numerous adherents. One result, then, was that despite Shapley's vigorous attempts to defend his model of the Galaxy, in the early 1920s it probably had more opponents than advocates.

Support for Shapley's models: Cepheids and Galactic rotation

In 1923, R E Wilson, an established American astronomer, re-calibrated the period–luminosity relationship for the Cepheids. Although Wilson concluded that Shapley's calibration probably needed altering by an amount that would decrease the distances derived from the Cepheids by a factor of around 1.3, his answer was sufficiently close to Shapley's that Shapley's model now gained in credibility.

In the next year, EDWIN HUBBLE, using the 100 in telescope at Mount Wilson, detected Cepheid variables in a number of spiral nebulae and soon demonstrated to the satisfaction of nearly all astronomers the extragalactic nature of the spirals (see EXTRAGALACTIC ASTRONOMY *c.* 1900–1950). In so doing, Hubble further underlined the reliability of the Cepheids as distance indicators and thereby made Shapley's model of the Galaxy still more plausible.

In 1927, more evidence came from an unexpected source for the two central features of Shapley's model of the Galaxy, the role of the globular clusters in outlining the Galaxy and the eccentric position of the Sun. This source was the rotation of the Galaxy. That the Galactic system rotated had long been suspected; indeed, its flattened form seemed to be the natural consequence of rotation. The spectroscopic measures in the 1910s and 1920s of the rotation of spiral nebulae had further strengthened the belief among astronomers that the Galaxy rotates.

In 1926, J H OORT (1900–92), a young Dutch astronomer based at Leiden Observatory, contended that our local system of stars is rotating around the center of the Galaxy. By so doing, he hoped to explain the well-known, but enigmatic, asymmetry of the motions of the high-velocity stars and globular clusters. The local system of stars, Oort argued, is moving more quickly than the high-velocity stars which are really a subsystem of stars rotating relatively slowly. In consequence, as the local system moves 'through' the high-velocity stars, these appear to drift asymmetrically with respect to the local system.

The following year Oort announced that, as a result of his attempt to verify directly Lindblad's theory of Galactic dynamics by an analysis of the motions of the globular clusters and high-velocity stars, he had secured firm evidence of a differential rotation of the Galaxy. In 1924 BERTIL LINDBLAD (1895–1965), through his attempts to interpret the phenomenon of star streaming, had considered a possible rotation of the Galaxy. By 1925 he had decided that the motions of the constituents of the Galaxy were explicable on the hypothesis that the Galaxy is divided into a series of subsystems, each of which has rotational symmetry about a common rotational axis. Each subsystem possesses a different speed of rotation, and hence a different degree of flattening, and he stressed that, while the high-velocity stars do not belong to the same dynamical system as those of low velocity, they must be related to the rest of the Galaxy since their motions are symmetrical with respect to the Galactic plane. Lindblad, as Oort was soon to do, calculated the dynamical center of the Galaxy to be very close in Galactic longitude to the center of the globular cluster system as defined by Shapley. However, there was at first a basic difference between Oort's theory and that of Lindblad. As Oort recalled in 1971: 'Lindblad had tentatively supposed that the principal part of the greater galactic system is formed by an ellipsoid of constant density, and that as a consequence its rotation is approximately the same as that of a solid body. The systematic effects I found in 1927 indicated that the actual motions were quite different, and that the angular velocity increased strongly toward the center of the galaxy, indicating a large concentration of mass in the central area'. The detection of Galactic rotation had been very much 'in the air' and Oort had presented what most astronomers saw as its observational verification. Support for Oort's arguments, moreover, soon came from other investigators.

The 'discovery' of Galactic rotation, astronomers quickly agreed, gave support to Shapley's claims that the center of the Galaxy is defined by the system of globular clusters and that the Sun is eccentrically placed. There was, nonetheless, one point where the conclusions of Oort and Lindblad conflicted with Shapley's model. Oort had reckoned that the distance to the dynamical center of the Galaxy was about 6000 pc, roughly one-third of Shapley's estimate. Lindblad also thought that Shapley's distance to the Galactic center needed revision, and he suggested that it be reduced by a factor of 0.6. These estimates were, nevertheless, soon to be modified and brought into close agreement.

Trumpler's investigations of open clusters

The impression that the effects of a general interstellar absorption within the Galaxy were insignificant was rudely disturbed in 1930 by the publication of the results of R J TRUMPLER'S study of the open Galactic clusters. Trumpler (1886–1956), an astronomer at the Lick Observatory, had assumed that the clusters of similar form have the same dimensions; by comparing the observed angular diameter of a cluster with the assumed average linear diameter of the subclass to which the cluster belonged, he derived a value for the cluster's distance. Trumpler had also examined the magnitude and spectral types of the stars within the clusters. Then, by constructing a Hertzsprung–Russell diagram for each cluster and comparing the observed diagram with a standard diagram, Trumpler secured another value for the cluster's distance. He thereby calculated that the two distance indicators to the clusters gave systematically different answers: the more distant the cluster, the more the two distance values differed.

The reason for this deviation, astronomers soon agreed, was that interstellar absorption diminished the brightness of the cluster stars but did not affect appreciably the measured diameters of the clusters. The effect of absorption, therefore, was to make the distance to a cluster obtained from its Hertzsprung–Russell diagram appear greater than it actually was. Although a number of earlier investigations can, with the benefit of hindsight, be seen to have pointed towards the existence of a general interstellar absorption, it was Trumpler's analysis of the Galactic clusters—probably because it was more extensive and complete than previous researches—that convinced astronomers that absorbing matter is present throughout the Galaxy, not just in isolated clumps.

The difference between Oort's distance to the dynamical center of the Galaxy and Shapley's estimate of the distance to the center of the system of globular clusters could now be simply explained: in his calculation of the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

size of the Galactic system Shapley had not allowed for the dimming effect of a general interstellar absorption, and as a result he had overestimated the distance to the Galaxy's center.

The vindication of the spiral hypothesis

By the mid-1930s, then, it was widely believed that the Sun is about 10 000 pc from the galactic center, but there was still no consensus on the overall size or structure of the Galaxy. J S PLASKETT, director of the Dominion Astrophysical Observatory in Canada, argued in 1935 that all astronomers would probably agree that the Galaxy's diameter is no greater than 40 000 pc, although some would limit it to 30 000 pc. In 1937 B J BOK, of Harvard Observatory and one of the leading students of the Galaxy, warned astronomers that the only well-established fact about the Galaxy's structure was the eccentric location of the Sun. Bok did, however, propose a detailed working model of the Galaxy in which the Galactic center lay in the direction of Sagittarius and in which a spiral arm passes from Carina through the Sun towards Cygnus. Shapley's model of the late 1910s, Bok asserted, had proved valuable for two decades, but now it needed replacing.

The suggestion that the Galaxy has a spiral structure was, as Bok acknowledged, hardly novel. However, in the late 1920s it had gained in plausibility after Hubble had demonstrated the spiral nebulae to be external galaxies. It was not, however, until the mid-1950s that astronomers judged there was conclusive evidence of the Galaxy's spiral structure. The new, and decisive, evidence did not come from the traditional statistical astronomy. Rather, it followed a shift in the way astronomers probed the Galaxy's structure with the emphasis now on the scrutiny of particular sorts of Galactic objects, as well as comparisons with external galaxies. Because of the Sun's eccentric position within the plane of the Milky Way, astronomers accepted they were surrounded by a confusing complexity of star and dust clouds, but by investigating the galaxies—star systems which seemed to contain the same kinds of objects as the Galaxy—astronomers judged they were better able to gain insights into the design of the Galaxy itself.

In his studies in the 1940s with the 100 in telescope at Mount Wilson, WALTER BAADE (1893–1960) had noticed that the bright blue stars lay along the spiral arms of the Andromeda galaxy. Shortly afterwards, in 1951, a group of astronomers led by W W Morgan investigated the distances of the bright blue stars in our Galaxy and found that they too seemed to trace out spiral arms. In 1952 Bok listed nine 'tracers' for discerning the spiral arms. One of these tracers exploited a new tool for the examination of the remote regions of the Galaxy: the 21 cm radiation.

For much of the Second World War the Netherlands had been under German occupation, but copies of the *Astrophysical Journal* still reached the Observatory at Leiden. Two papers by GROTE REBER, one of the pioneers of radio astronomy, appeared in the *Journal* in 1940 and 1944, and the second paper included a crude radio map of the Galaxy. Oort, the Director at Leiden, was prompted to suggest that if spectral lines could be observed in the radio region it would enable the kinematics and dynamics of the whole Galactic system to be analyzed since the radio region is unaffected by obscuring dust.

In 1944 a celebrated seminar was held at Leiden to discuss Reber's papers. At this seminar H C VAN DE HULST, following Oort's proposals, predicted that atomic hydrogen in interstellar space might emit an observable radio line at a wavelength of 21 cm. It was, however, to be 6 yr before the line was detected and strong evidence secured for what had been a theoretical possibility.

Although some astronomers were slow to appreciate the opportunities offered by the 21 cm radiation, its advocates claimed that it would help them investigate some fundamental problems concerning the Galaxy: the Galaxy's spiral structure, the distribution of mass and velocity in the Galaxy, the distribution of neutral hydrogen in the plan of the Galaxy and the presence of neutral hydrogen associated with the large complexes of obscuring dust and gas clouds. For its proponents, the great advantage of the 21 cm radiation was that it could penetrate clouds of obscuring matter without being diminished in intensity. Indeed, the elucidation of the Galaxy's fine structure would lie mainly with the infant science of radio astronomy.

Stellar populations

In 1921 Shapley and Curtis had spoken for most astronomers when they agreed that stars 'in clusters and in distant parts of the Milky Way are not peculiar—that is, uniformity of conditions and of stellar phenomena naturally prevails throughout the galactic system'. The view that each region of the Galaxy contained the same sorts of stars as all other regions was finally to be undermined in the 1940s by Baade.

Until 1943 all attempts to resolve the nucleus of the Andromeda galaxy into stars had, by general consent, failed. However, in 1943 Walter Baade equipped the 100 in Mount Wilson telescope with photographic plates especially sensitive in the red region of the spectrum. He thereby succeeded in resolving the nucleus into a swarm of faint red stars. Baade further concluded that the brightest stars in the nucleus were about 100 times fainter than the blue stars in the spiral arms of the Andromeda galaxy. These red stars, moreover, were similar in type and luminosity to the brightest stars found in globular clusters.

Astronomers had accepted since the 1910s that the outer regions of a number of spiral nebulae were much bluer than their nuclei. After his resolution of the nucleus of the Andromeda galaxy, Baade introduced the concept of 'stellar populations' to explain this apparent anomaly and to help interpret the structure of galaxies. Different populations of objects, he argued, have different spatial distributions. What he termed 'population I' objects were associated with the spiral arms of galaxies and included blue supergiant stars and galactic clusters. Baade linked

'population II' with elliptical galaxies, globular clusters and the nucleus of spiral galaxies.

The concept of populations also led to a reinterpretation of the motions of the Galaxy's stars. Even before the term 'stellar population' had been coined, astronomers had noted a correlation between the astrophysical characteristics of stars and their kinematical behavior. When plotted on a Hertzsprung–Russell diagram the high-velocity stars produced an array similar to that of a globular cluster, but the equivalent diagram for the low-velocity stars resembled that for a galactic cluster. Now astronomers argued that the different diagrams could be explained in terms of populations: the low-velocity stars are population I objects while the high-velocity stars belong to population II.

In 1952 Baade announced another surprising discovery. There was, he asserted, an error in the calibration of the period–luminosity relationship. The estimated distances to the external galaxies, which were based on this relationship, had therefore to be revised. Indeed, the distances had to be approximately doubled (see also EXTRAGALACTIC ASTRONOMY *c.* 1900–1950). The re-calibration of the period–luminosity relationship and the resulting doubling of the distances to the galaxies also meant that the estimates of the diameters of the galaxies had to be doubled: at last the lingering unease that the Galaxy might be truly exceptional, a continent amidst the islands of external galaxies, was dispelled.

Galactic Bulge

Bulges are the central visible spheroidal systems in DISK GALAXIES. The prominent bulges of early-type galaxies are exemplified by that of the SOMBRERO GALAXY, NGC 4594, shown in figure 1. The bulge of our own galaxy, which is of later type, is dominated by the disk, as is seen in figure 2.

A bulge is essentially a STELLAR POPULATIONS concept, the key properties being the age, kinematics and chemical composition of the stars of the bulge. The kinematics of the stars yield a certain structure, which is the nominal defining property of a galactic bulge. The general properties of bulges are well reviewed by Wyse *et al* (1997). The history of the study of the galactic bulge is recounted by Frogel (1988). Here we deal in turn with the age, kinematics, structure and chemistry of the bulge of the MILKY WAY.

Age

Our preconceptions about the stellar population of the galactic bulge are that it is old, like the halo, and that, like elliptical galaxies, it has high density and must have formed early in the galaxy's life, and perhaps in terms of cosmic time as well. But it is important to look at the *data* on the age of the bulge population.

Holtzman *et al* (1993, 1998) used the wide field planetary cameras of the Hubble Space Telescope to image main sequence stars in Baade's window (a relatively unobscured line of sight into the bulge at impact parameter 500 pc). They found a population of mixed age characteristics with stars younger than the Sun relatively deficient compared with the solar neighbourhood. Ortolani *et al* (1995) studied the same field and concluded that the age and other characteristics were similar to that of metal-rich globular clusters. Frogel *et al* (1999) have mapped the inner bulge in the infrared, and conclude that there is a young component of the stellar population observed near the galactic centre, but that it declines in density much more quickly than the overall bulge population, and is undetectable beyond 1° from the galactic centre.

While the main sequence provides a democratic census of stellar ages, VARIABLE STARS offer good tracers of stellar populations of certain ages. Oort and Plaut (1975) identified the RR LYRAE STARS in a number of similar windows. These are clearly old stars as a rule, the youngest simple stellar population with RR Lyrae stars being NGC 121 in the Small Magellanic Cloud, whose age is 11.5 Gyr according to Stryker *et al* (1985). Menzies and Whitelock (1985) found that the long-period variables in the bulge are of relatively short period ($\sim$200 days) by the standards of the galactic disk with bolometric luminosity approximately -4 mag. A similar luminosity was obtained for OH/IR stars (the terminal phase of asymptotic giant branch evolution) by Wood *et al* (1998). This also suggests a population from the age interval represented by NGC 121 to 47 Tucanae, a metal-rich Galactic globular cluster.

We conclude that the stellar population of the bulge of the galaxy is indeed predominantly old. We may be witnessing bulge formation in real (or at least 'lookback') time in the very high star formation rates ($10M_\odot$/year) at redshifts greater than 3 in Lyman dropout galaxies (Steidel *et al* 1996).

Kinematics

Our preconception of bulges from the stellar populations paradigm of Baade is that they are scaled down elliptical galaxies. The data, however, are more specific. Davies *et al* (1983) found that at every luminosity both ellipticals and bulges follow the isotropic rotator model. This model, described succinctly by Binney and Tremaine (1987), assumes an axisymmetric system that rotates about its symmetry axis. The model is flattened by rotation to an ellipticity ε, which is uniquely (in a model in which the orbits of the stars are fully isotropic) a function of the ratio of the rotation velocity and the central velocity dispersion.

Structurally, the bulge was traditionally difficult to get a quantitative fix on, although de Vaucouleurs and Pence (1978) were able to determine an effective radius, $r_e = 2.5$ kpc. The effective radius is the radius which contains half the light. Morrison *et al* (1990) found that this *over*predicted the halo density in the solar neighbourhood. Terndrup (1988) found that standard spheroid models (the Bahcall and Soneira (1980) model, in particular) *under*predicted the number of giant stars in the bulge. The K and M giants in the bulge fit a de Vaucouleurs law with $r_e = 0.25$ kpc, a full order of magnitude less than de Vaucouleurs and Pence found. Similar compactness was found for OH/IR stars by Habing (1986). It really seems that the bulge is a separate component from POPULATION II near the Sun. This would not be surprising if the bulge and halo were formed in different ways, for example the bulge by dissipative collapse at an early epoch and the halo by accretion subsequently (see HALO, GALACTIC).

The infrared has proved the answer to determining structural parameters of the bulge. Binney *et al* (1997) find axis ratios of (1:0.6:0.4). Zhao *et al* (1994) show that the bulge is really structurally a bar. This is not consistent with the isotropic rotator model, and one is left wondering what fraction of bulges are bars (as the Milky Way's apparently is), and what fraction resemble ELLIPTICAL GALAXIES.

Chemistry

Our preconception from spectroscopy is that the bulge is a super metal-rich stellar population (Whitford 1978), i.e. the metallicity is higher than the Sun's. The data, however, show a broad distribution (Minniti *et al* 1995), from -1 to 0.5 in [Fe/H] in Baade's window (McWilliam and Rich 1994), i.e. from a tenth to three times solar abundance. Rich (1990) showed that this distribution fits the simple model of chemical enrichment (Pagel and Patchett 1975), where the bulge behaves like a closed system, in which gas steadily, without our specifying the timescale, and eventually completely, turns into stars, never being replenished at any time.

Wood *et al* (1998) found that young stars in the bulge are between two and four times SOLAR ABUNDANCE. Jablonka *et al* (1996) studied a sample of bulges, finding a direct relationship between metallicity and luminosity and noting an enhancement of the element ratio Mg/Fe relative to the solar ratio. In principle, this means rapid initial enrichment in the bulge, relative to a more leisurely enrichment history in the disk's interstellar medium, dominated by iron producing type Ia supernovae (Wheeler *et al* 1989, Gilmore *et al* 1989).

Star clusters

A separate population of bulge GLOBULAR CLUSTERS has been identified by Barbuy *et al* (1998). There is a prevalence of core collapsed clusters among them. Core collapsed clusters have power-law radial density distributions, as opposed to the classical (King model) flattened cores. Rich *et al* (1999) note the tendency of these clusters to blue horizontal branches and depletion of red giants, a phenomenon which may result from the high frequency of stellar collisions in the dense environments of the cluster centres.

Formation

A very plausible model of the formation of the galactic bulge has the majority of the stars form through the dissipative and violent collapse of protogalactic gas clouds in the first billion years of cosmic history. There is clear evidence, however, that the bulge has added to its stock of stars since that time. A number of processes, such as mergers of dwarf galaxies and disk instabilities, could be responsible for that extended population.

Galactic Latitude

The angular distance between the galactic equator and celestial body, measured perpendicular to the galactic equator, and taking values between 0 and 90°. It is denoted by b^{II} to signify that the value of galactic latitude relates to the galactic equator defined in 1959 by the International Astronomical Union by reference to the centerline of the Milky Way defined by radio observations of neutral hydrogen. The previous system is denoted b^{I}.

Galactic Longitude

The angular distance between the direction of the galactic center and the point on the galactic equator perpendicularly below (or above) a celestial body; it is measured in an anticlockwise direction, and takes values between 0 and 360°. Galactic longitude is denoted by l^{II} to signify that it is referred to the position of zero longitude agreed in 1959 by the International Astronomical Union (and coinciding with the radio source Sagittarius A which is presumed to be the galactic center). The old system (denoted l^{I}) was referred to the point of intersection of the galactic equator and the celestial equator, and was offset from the galactic center by some 30°.

Galactic Metal-Poor Halo

Most of the gas, stars and clusters in our Milky Way Galaxy are distributed in its rotating, metal-rich, gas-rich and flattened disk and in the more slowly rotating, metal-rich and gas-poor bulge. The Galaxy's halo is roughly spheroidal in shape, and extends, with decreasing density, out to distances comparable with those of the Magellanic Clouds and the dwarf spheroidal galaxies that have been collected around the Galaxy. Aside from its roughly spheroidal distribution, the most salient general properties of the halo are its low metallicity relative to the bulk of the Galaxy's stars, its lack of a gaseous counterpart, unlike the Galactic disk, and its great age. The kinematics of the stellar halo is closely coupled to the spheroidal distribution. Solar neighborhood disk stars move at a speed of about 220 km s^{-1} toward a point in the plane and 90° from the Galactic center. Stars belonging to the spheroidal halo do not share such ordered motion, and thus appear to have 'high velocities' relative to the Sun. Their orbital energies are often comparable with those of the disk stars but they are directed differently, often on orbits that have a smaller component of rotation or angular momentum. Following the original description by Baade in 1944, the disk stars are often called POPULATION I while the metal-poor halo stars belong to POPULATION II.

GLOBULAR CLUSTERS are the most readily identifiable component of the Galactic halo. Roughly 150 are known and most, but not all, occupy a spheroidal distribution, have radial velocities that are much larger than expected for disk-like rotation, and are metal poor. Figure 1 shows the distributions of the metal abundances, [Fe/H] ($\equiv \log[n(\mathrm{Fe})/n(\mathrm{H})]_\star - \log[n(\mathrm{Fe})/n(\mathrm{H})]_\odot$). Figure 2 shows the distribution of clusters' distances from the Galactic plane as a function of [Fe/H]. Two 'populations' of globular clusters exist: one belonging to the metal-weak halo, and a more metal-rich one that is a disk, possibly a 'thick disk' population (see GALACTIC THICK DISK). Field stars show very similar behaviors in metallicity and kinematics.

Globular cluster masses range from a few hundred $M_\odot$ (AM-4) to several million $M_\odot$ (ω Centauri = NGC 5139). Despite their large masses, globular clusters contribute only a small fraction (≈2%) to the total mass of the metal-poor stellar halo. Field stars dominate the mass. The total mass of the metal-poor stellar halo may be estimated using the density of such field stars in the solar neighborhood (≈0.2–0.5% of the disk stars) and the cumulative distribution of the mass in globular clusters as a function of Galactocentric distance. In field star and cluster stellar mass, the metal-poor halo amounts to only about 10^9 $M_\odot$, about 1% of the Galaxy's total stellar mass.

Despite its minor contribution to the Galaxy's stellar mass budget, the halo has been studied extensively to answer a wide variety of questions. In 1918, Shapley exploited the positions and approximate distances to globular clusters to identify the direction of and distance to the Galactic center, R_{GC}. Globular clusters and the halo population 'standard candle' RR LYRAE VARIABLES are still used to measure R_{GC}. The recognizability of globular clusters and RR Lyraes and their large range in R_{GC} provide good 'test particles' to map out the Galaxy's gravitational potential and discern the distribution of both the stars and the DARK MATTER. Most work on the halo population, however, arises from our desire to understand the Galaxy's formation process and its early history, and, in fact, to discern the chemical abundances produced by the BIG BANG since it appears that the first stars to be formed in our Galaxy lie in the Galactic halo. What were the abundances of those earliest stars? How did they change and how rapidly? How did the Galaxy form and evolve?

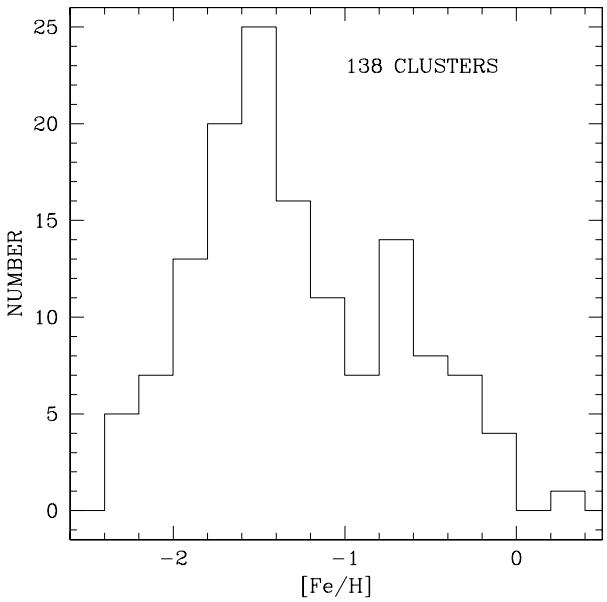

Figure 1. The distribution of [Fe/H] values for globular clusters.

Chemical abundances

Figure 1 employs [Fe/H] as the measure of 'metallicity'. For brighter field stars and the brightest stars in globular clusters, this may be determined by employing high-resolution, high-signal-to-noise spectroscopy to measure line strengths. In conjunction with atomic line parameters and an appropriate model stellar atmosphere, one may derive element-to-hydrogen abundance ratios such as [Fe/H]. The process is often iterative, involving tests to make certain that the derived abundances do not depend on the lower energy levels of the atomic transitions (to check the model's effective temperature), on the line strengths (to assess the effects of turbulent line broadening) and on gravity-sensitive and gravity-insensitive lines. The technique is often referred to as a 'fine analysis' or a 'curve of growth' analysis.

Because of long exposure times, such analyses of field and cluster stars are not always employed to estimate [Fe/H] values. Instead, metallicity 'indicators' are calibrated using results available from such analyses

and then exploited to study larger and/or fainter samples of stars or clusters. Lower-dispersion spectra are easier and faster to obtain than high-dispersion spectra, and one technique that exploits this method is called ΔS since it employs a measured apparent difference in spectral type. In RR Lyrae variables, one measures the spectral type using the hydrogen lines and compares that with that defined from the 3933 Å line of Ca II. The difference is an indicator of the calcium abundance. A similar method, called W', exploits the three strong lines of Ca II at 8498, 8542 and 8662 Å and is used to estimate [Fe/H] (assuming a constant or at least monotonic relation between [Ca/H] and [Fe/H]) for red giant stars in globular clusters. One may also employ photometric methods. As [Fe/H] increases, both the predicted and the observed colors of stars along the red giant branch become redder, and thus the red giant branch color is a good metallicity indicator. Quantitatively, one measures the dereddened $B - V$ or $V - I$ color indices at the magnitude level of a cluster's horizontal branch. The resultant values, $(B-V)_{0,g}$ and $(V-I)_{0,g}$, are calibrated using [Fe/H] values available for a well-studied subsample of clusters.

High-resolution spectroscopy of metal-poor halo stars is valuable for measuring the abundances of elements other than iron to study the chemical evolution in the early Galaxy and, in fact, those produced by the Big Bang. Five results are especially noteworthy.

(1) Figure 1 shows two roughly Gaussian distributions of [Fe/H]. Simple models may explain such behavior. In brief, a gaseous system with an initial metallicity, $[Fe/H]_{init}$, produces stars, some of which explode as supernovae, and the metallicity of the gas rises. Low-mass, long-lived stars then preserve the record of this enrichment process. The fraction of stars with higher metallicities rises until roughly 50% of the gas has been converted into stars or expelled from the system. At that point, the metallicity continues to rise, but the fraction of stars with higher metallicities diminishes owing to the decreasing gas supply, eventually reaching $[Fe/H]_{final}$ when all the gas is gone. The low mean metallicity of the halo is thought to arise because most of the gas was expelled from the halo before significant supernova-induced enrichment could occur. This gas may have formed much of the Galaxy's bulge. Figure 1 also suggests that two separate chemical evolution histories have been involved in the production of the metal-poor halo and the moderately metal-poor thick disk.

(2) Globular clusters are fairly massive systems, yet only one, ω Centauri, shows clear signs of metallicity variations that might be due to self-enrichment during the formation of the cluster. Since the colors of red giant branch stars depend on [Fe/H], the failure to detect *spreads* in colors of clusters' red giant branch stars implies a lack of significant self-enrichment. Given the small total mass in any one globular cluster, this may not be surprising. Some primordial variations in selected elements have been claimed, however.

(3) The abundances of the 'α' elements, oxygen, magnesium, silicon, calcium and titanium appear to be enhanced relative to iron by a factor of between 2 and 3 in metal-poor stars and clusters. Figure 3 shows the behavior of elements other than oxygen in field and in clusters, from which it is clear that ['α'/Fe] $\approx$ +0.4 for [Fe/H] <-1.0. The cause is thought to be the dominance of type II SUPERNOVAE, which are the explosive deaths of

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

massive, and short-lived, stars. Models predict that such stars will produce all the elements, from helium to carbon and oxygen through the iron peak and beyond into the neutron capture domain. The decline in ['α'/Fe] is thought to arise from the later appearance of type IA supernovae, thought to be due to the deflagration–detonation of white dwarfs that exceed the Chrandrasekher mass limit owing to mass transfer. Their ejecta should be very rich in iron-peak elements and relatively deficient in lighter elements. Thus figure 3 may be the signature of the initial type II events, followed later ($\approx 10^9$ yr) by a mixture of type Ia and type II supernovae. Oxygen is the most abundant heavy element, but, unfortunately, disputes continue about the trend of [O/Fe] versus [Fe/H]. Analyses of OH lines in the ultraviolet suggest that [O/Fe] increases linearly as [Fe/H] declines, but analyses of O I in main sequence stars and of [O I] in red giants show the same behavior as in figure 3.

(4) Neutron capture elements, including those manufactured in the S-process and the R-process, can reveal the relative importance of these processes and, hence, the relative contributions to nucleosynthesis in the young Galaxy by the stars responsible for these processes. The s-process may arise largely in the late evolutionary stages of intermediate-mass stars, while the r-process is thought to occur within type II supernovae. As in the case of the 'α' elements, changing ratios of s-process and r-process abundances indicate changing relative contributions by asymptotic giant branch stars and supernovae. If the models are correct, r-process production should dominate the first several hundred million years of chemical evolution. Further, some of the r-process elements, such as thorium, are radioactive and, in principle, may have their abundances measured in stars, enabling their ages to be determined.

(5) The most metal-poor stars formed out of material enriched only slightly from stellar evolution and supernovae and a more easily detectable contribution from the big bang. Lithium, beryllium and boron are especially interesting since their production ratios are determined by the baryon density, its smoothness and the effects of cosmic rays. In almost all metal-poor stars that do not have deep convection zones that could carry lithium to deeper layers where it can be destroyed by proton capture, the lithium abundances appear to be constant, about a factor of 10 below the current interstellar medium value, and indicative of a low baryon density universe. There are, however, some puzzling exceptions, including a few metal-poor stars with little or no detectable lithium and a few others with enhanced lithium abundances.

Distances and motions

Radial velocities of stars in the field and in clusters may be measured directly using stellar spectroscopy and the Doppler effect. Tangential velocities may be determined only if a star's PROPER MOTION and distance are both measured since $v_{\rm tan} = 4.74\ \mu d$, where μ is the proper motion in arcsec per year and d is the distance in parsecs. If all these are known, one may determine velocities in the Galactic frame. In the solar neighborhood, these are called U, V and W, and are directed toward ($\ell = 180^\circ$; $b = 0^\circ$), ($\ell = 90^\circ$; $b = 0^\circ$) and ($b = 90^\circ$), respectively. With a model Galactic gravitational potential, Galactic orbits may be estimated, including apogalacticon, $R_{\rm apo}$, perigalacticon, $R_{\rm peri}$, and maximum distance from the Galactic plane, $Z_{\rm max}$. Stars and clusters at different $R_{\rm GC}$ may be handled similarly, but Π, Θ and Z replace U, V and W, retaining the same (local) vector orientations. Three-dimensional motions have been measured for over 30 globular clusters and over 1000 metal-poor field stars.

The distance scale for metal-poor stars remains a controversial but crucial topic. Distances to stars help to determine their velocities as well as their absolute magnitudes. The former are necessary in studies of relations between kinematics versus chemistry that provide insight into the Galaxy's dynamical history. The latter are vital because it is the luminosity of the main sequence turn-off that is used to estimate the relative and absolute ages of globular clusters.

Trigonometric PARALLAXES have been measured for a significant number of metal-poor main sequence stars, and such data may be used to calibrate relations between absolute magnitude, color and metallicity. These may in turn be used to estimate distances to those globular clusters with high-precision photometry of their faint main sequence stars. Another 'standard candle' is the RR Lyrae variable. It appears that $M_V({\rm RR}) = 0.20[{\rm Fe/H}] + 0.8$, although the zero point is uncertain by about 0.2 mag. Measurement of horizontal branch magnitudes, corrected for reddening, thus enables measurement of cluster distances. In fact, using the relation for M_V(RR) and measuring the apparent V magnitude of the main sequence turn-off yields the M_V value for the turn-off, *independent* of reddening.

Ages

Two lines of evidence suggest that the most metal-poor stars and clusters with [Fe/H] < -2.0 have the same age to the limit of our abilities to measure them. First, spectroscopic evidence indicates that the r-process dominates over the s-process in such systems, suggesting that intermediate-mass stars had not yet polluted the interstellar medium, and implying that the age differences probably do not exceed 10^9 yr. Figure 3 also suggests a similar timescale in that supernovae of type II dominated the production of iron. Second, evidence favoring common ages comes from color–magnitude diagrams. Recent ground-based and space-based observations have extended the comparisons to large distances, including NGC 2419 with $R_{\rm GC} = 90$ kpc. Figure 4 shows that this cluster is indistinguishable in age from M92, which lies only 9 kpc from the Galactic center, and is similar in age to several other low-metallicity ([Fe/H] < -2.0) clusters with $R_{\rm GC}$ values ranging from 6 to 9 kpc. Again, the maximum age spreads are roughly a billion years or less. Analyses of field star ages using Strömgren photometry also show no sign of age differences among the most metal-poor stars.

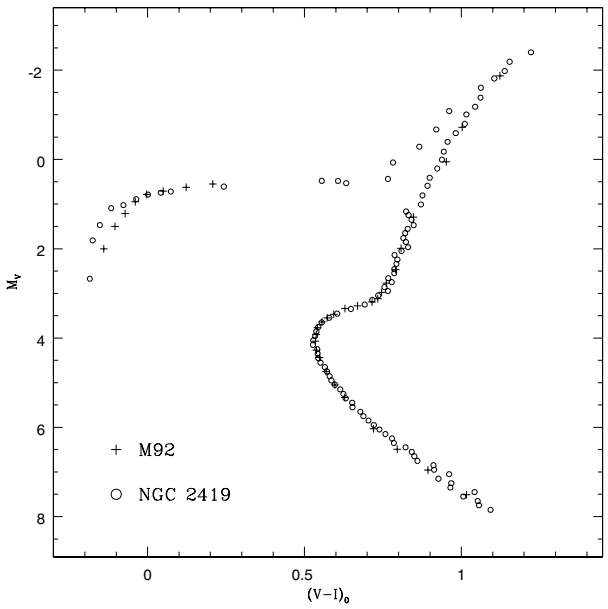

Figure 4. Superposed color–magnitude diagrams of the middle halo globular cluster M92 and the distant cluster NGC 2419, taken from Harris *et al* (1997).

The next important chronological questions are whether the metal-poor and metal-rich field stars and clusters differ in age and whether this difference is a function of their location in the Galaxy. The age differences imply the speed at which the metal-poor halo was chemically enriched, and differences in initial densities of the young Galaxy's central, middle and outer halo may have produced differences in the rate at which stars and clusters formed and the rate at which the metallicity enrichment proceeded. At large R_{GC}(>80 kpc), it appears that intermediate-metallicity clusters, with [Fe/H] ≈ -1.5, are of order 2×10^9 yr younger than comparable metallicity clusters with R_{GC} values of 6–12 kpc. The implication is that the metallicity enrichment proceeded more slowly in the outer halo. Thus the differences in gas density between the outer and middle halo may have been an important factor in the Galaxy's evolutionary rates. We do not yet know whether these trends of equal ages at the lowest metallicities and smaller age spreads continue into the innermost halo ($R_{GC} < 3$ kpc).

The age spread among the intermediate-metallicity and relatively metal-rich ([Fe/H] ≈ -1) clusters in the middle halo remains a matter of debate. Field stars appear to show age spread at such intermediate metallicities. There are clear examples of significant age differences among clusters, the pair NGC 288 and NGC 362 being one of the best examples. Another pair of unusually young clusters is Ruprecht 106 and Palomar 12, which appear to be several billion years younger than average. In fact, the ['α'/Fe] ratios for these clusters are close to solar and, hence, very low for their [Fe/H] values, as shown in figure 3. Their behavior may be explained by very young ages (but then the question is why are they so metal poor?) or by an origin perhaps quite different from that of the bulk of the metal-poor globular clusters. In any case, there seems little doubt that *some* globular clusters are younger than average, but how many and by how much? To attempt to detect smaller age differences than possible from the main sequence regime, shown in figure 4, attention has turned to the HORIZONTAL BRANCH STARS, identified in the figure as those stars with $M_V \approx +0.5$ mag. Theory predicts that, for intermediate-metallicity clusters, younger clusters might be distinguished from older clusters by the distribution of stars along the horizontal branch: redder indicates younger ages. NGC 362, with a red horizontal branch, is indeed younger than NGC 288, which has a very blue horizontal branch. The problem is actually quite complex, and this 'second parameter', the color of the horizontal branch compared with those of other clusters with similar [Fe/H] values (the 'first parameter'), may also be affected by stellar interactions in dense environments. Indeed, some clusters, such as NGC 2808 and NGC 6229, show bimodal horizontal branches yet no signs of two epochs of star formation. What can be said is that *some* clusters with intermediate metallicities in the middle halo are younger than average.

The absolute ages of the Galaxy's oldest globular clusters are of great interest but two key problems remain. First, if star formation began first in the Galaxy's central regions, the oldest clusters, those with low [Fe/H] values but lying close to the Galactic center, have not yet been studied. Of greater concern, however, is the dichotomy in results for M_V(RR) that has arisen from the Hipparcos satellite's trigonometric parallaxes. Absolute magnitudes for field metal–metal main sequence stars have been used to estimate distances and main sequence turn-off luminosities for comparably metal-poor globular clusters. Ages range between 12 and 14 billion yr. However, the M_V(RR) values derived are brighter than those of field RR Lyrae variables obtained with Hipparcos. On the other hand, the detection of thorium (and other r-process elements) in the spectra of some metal-poor field stars, most notably CS22892-052, has enabled estimates of stellar ages from radioactive decay. Values near 14 billion yr appear favored.

Formation and evolution of the halo

Early work on the chemical abundances, velocities and ages of what we now call the metal-poor halo field stars and clusters culminated in a classic paper by Eggen *et al* (1962). They derived U, V and W velocities for 221 field dwarf stars selected from two catalogs: one of nearby stars and one of stars with large proper motions (hence a good source of high-velocity stars). They estimated metallicities from the 'ultraviolet excess', $\delta(U-B)_{0.6}$, which in essence is an indicator of the degree of heavy element line blanketing in the near ultraviolet. The velocities were combined with a model Galactic gravitational potential to estimate the stars' orbital eccentricities, and the most important result

Copyright © Nature Publishing Group 2001

Dirac House, Temple Back, Bristol, BS1 6BE, UK

was that the orbital eccentricity correlated well with the metallicity. The orbital eccentricities of the most metal-poor stars were found to be uniformly high, indicating that the stars were formed on plunging orbits. Assuming metallicity is a proxy for time, the conclusion was that the Galaxy began to form stars while it was still in a state of collapse. The large spherical halo could then be explained as the earliest stage of the Galaxy, following which it rapidly collapsed and settled into a disk configuration. The process was rapid because the plunging orbits implied a nearly free-fall timescale, of order 2×10^8 yr, and it was a coherent process since the study did not reveal stars with low metallicities (the oldest stars) with disk-like orbits or stars with high metallicities (the more recently formed stars) with high-velocity halo-like orbits.

The first major challenge for the rapid–coherent collapse model was the study of Galactic globular clusters by Searle and Zinn (1978). One key point of the collapse model is that globular clusters should all have the same age, at least to within our abilities to measure them. Searle and Zinn noted that clusters with large R_{GC} tend to have redder than average horizontal branch colors. If the 'second parameter' is age (which appears to be true for the most distant clusters), then the process was not as rapid as originally believed. A slower, coherent contraction would still be a reasonable interpretation of the data, except that in such a case enough time would have passed to permit the remaining gas to be enriched by supernovae. As the gas contracted to form the disk, one would then expect the innermost stars and clusters to have higher metallicities since star formation should have continued longer. A radial gradient in metallicity would have been established, but Searle and Zinn failed to find any evidence of such a gradient for R_{GC} values larger than about 8 kpc. Based on their cluster data, they proposed that the halo was formed out of 'protogalactic fragments', each with an individual metallicity enrichment history. The assemblage of these fragments would then have resulted in a dynamically hot halo whose field stars and globular clusters have a range in ages yet no metallicity gradient owing to the random, 'incoherent' nature of the process. Additional support for the 'incoherent' model came from studies of field stars. Kinematically biased studies of stars selected only from proper motion catalogs (the 'Carney–Latham' sample) and stars selected without kinematical bias by Norris revealed a lack of correlation between metallicity and kinematics, as shown in figures 5 and 6.

An obvious argument favoring an accretion origin for some, perhaps most, of the halo was the discovery of the SAGITTARIUS DWARF GALAXY by Ibata *et al* (1994). This is a large dwarf galaxy on close approach to our Galaxy. In an astronomically short time, it will shed many stars, including its four globular clusters (M54, Terzan 7, Terzan 8 and Arp 2), into the Galaxy's halo. Several other signs point to the importance of accretion as a source of some of the halo's stars and clusters.

First, if the evolution of the halo into the disk was a coherent process, the halo should possess modest net prograde rotation. Figures 5 and 6 show that if the local Galactic rotational velocity, Θ_0, is 220 km s^{-1}, then the net halo rotation is very small. Further, Majewski (and others) have found that stars 5 kpc or more from the plane may possess net retrograde rotation. This suggests that at least some fraction of the halo's stars did not participate in the

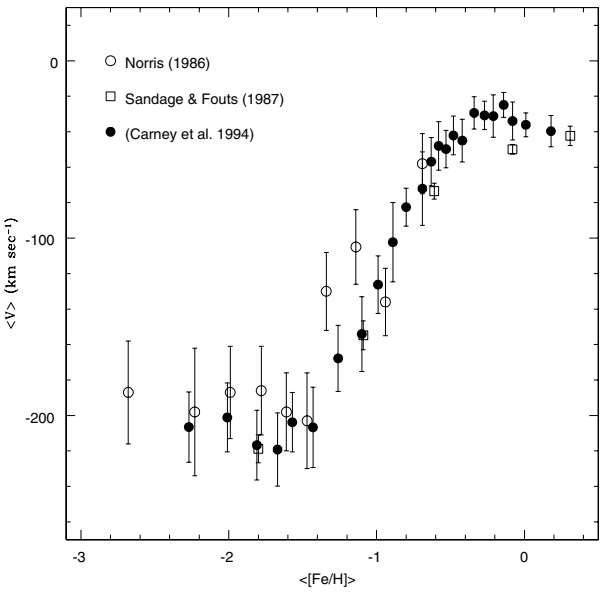

Figure 5. Average velocities V as a function of [Fe/H] using equal bin sizes from kinematically biased (Sandage and Fouts 1987; Carney *et al* 1994) and unbiased (Norris 1986) samples of field stars.

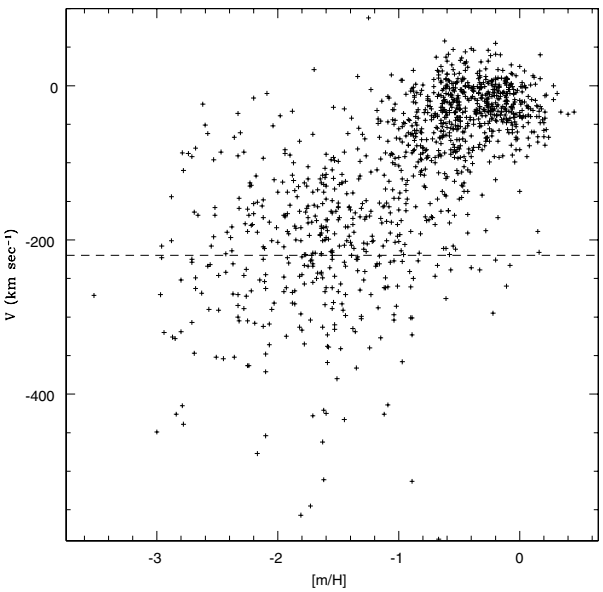

Figure 6. The velocity V versus [m/H] from Carney *et al* (1994). The dashed line divides prograde and retrograde Galactic orbital motion.

coherent Galaxy formation process. Other studies have suggested that globular clusters with horizontal branch colors implying younger-than-average ages also show signs for retrograde rotation. The evidence is weak given the one-dimensional velocity information and the small sample sizes, however.

Another possible signature of independent origin and evolution is chemistry. If two gas clouds produce stars at similar rates and with similar mass functions, the supernova enrichment history should be the same, and in consequence identical trends of [α/Fe] versus [Fe/H] should result. However, if one cloud forms stars more slowly, the appearance of the effects from the type Ia supernovae should first appear when the mean metallicity is still 'stuck' at a lower value, perhaps much lower than seen in the Galaxy at [Fe/H] ≈ -1. Ruprecht 106 and Palomar 12, identified in figure 3, could be explained by delayed star formation in a small 'fragment' or dwarf galaxy that was accreted by the Galaxy. A small number of field stars have also been found with unusually low [α/Fe] ratios, the most extreme being BD+80 245. An interesting additional feature of these stars is that they are generally very high velocity, with orbits that carry them out to $R_{GC} = 20$–40 kpc. Ruprecht 106 and Palomar 12 also lie at fairly large distances, $R_{GC} = 17$ and 14 kpc, respectively. On the other hand, not all stars with such large apogalacticon values or clusters with such large distances have unusual abundance ratios. Studies of such systems appear to more frequently find the enhanced [α/Fe] values typical of middle halo stars and clusters.

Another avenue to explore for signs of accretion is the idea that disintegrating satellite galaxies would leave behind a stream of stars (and gas, if they possess any). The MAGELLANIC STREAM is an example of a spoor that is apparently induced by the Galaxy's tidal effects on the MAGELLANIC CLOUDS. (Note this also indicates that the Clouds are also doomed to merge with the Galaxy.) The Magellanic stream traces almost an entire great circle on the sky, and the stream also passes near the positions of the Draco and Ursa Minor dwarf spheroidal galaxies. Another such great circle includes the Fornax, Leo I, Leo II and Sculptor dwarf galaxies, as well as a number of Galactic globular clusters. Another search technique recognizes that each distant dwarf galaxy or globular cluster in orbit about the Galaxy has an orbital pole and that, in the absence of three-dimensional motions, the pole occupies a point along a great circle in the sky. Intersections of such great circles suggest common orbital poles and have been used to identify possible streams. However, until accurate proper motions become available for more globular clusters and the distant dwarf spheroidal galaxies, the reality of these common origins for some such systems must remain speculative. Finally, common origins for larger numbers of objects but with all three components of velocity known may show up in the form of velocity 'substructure'. A dynamically hot population such as the halo should have stars well dispersed in velocity space. Observed 'clumpings' of stars at high velocities indicate either that the halo is not well mixed kinematically or that these clumps arose because of tidal destruction of small stellar ensembles by the Galaxy's tidal forces.

Even if the evidence cited above supports accretion of proto-Galactic 'fragments' or dwarf galaxies, this does not necessarily rule out that many of the metal-poor, high-velocity stars were part of a coherent formation process, as outlined by Eggen *et al*. While some subsets of globular clusters may show net retrograde rotation, others show prograde rotation. While some globular clusters may be younger than average, many appear to be coeval with other clusters of similar metallicity. Some globular clusters and field stars, especially with large R_{GC} or R_{apo} values, have unusual [α/Fe] values, but most do not, even clusters like NGC 7006 ($R_{GC} \approx 35$ kpc) and numerous extreme-velocity field stars. Furthermore, metal-poor stars close to the Galactic plane show not only prograde rotation but signs of a radial metallicity gradient, as do subsets of globular clusters. Both processes, coherent evolution plus accretion, have almost certainly contributed to the formation of our Galaxy's metal-poor halo, but a much larger and more complete census will be required to determine the relative numbers of natives and immigrants.

Galactic Nucleus

The central core of a galaxy. In elliptical galaxies and in the central bulges of spiral galaxies, the nucleus corresponds to the location at which the optical brightness reaches a maximum, and to the region within which stars are most densely concentrated. Irregular galaxies do not contain well-defined nuclei. Active galaxies, which comprise a few percent of the total number of galaxies, contain intensely bright, compact nuclei, called active galactic nuclei (or AGNs), that radiate strongly over a wide range of wavelengths (from x-ray to radio) and in many cases display substantial variability.

The nucleus of our own Galaxy, the Milky Way, contains a compact source of radio emission, called Sagittarius A* (pronounced Sagittarius A-star), is less than 15 astronomical units in diameter and appears to coincide in position with a relatively weak source of x-radiation. Ionized gas clouds within a few light-years of the center are moving at speeds of up to several hundred kilometers per second under the gravitational influence of a central concentration of some 5 million solar masses, only about half of which appears to be contained in stars. These observations, taken together, are consistent with the hypothesis that the galactic nucleus contains a black hole of some 2.5 million solar masses surrounded by an accretion disk. The Milky Way Galaxy, therefore, appears to contain a miniature, and low-powered, version of an active galactic nucleus. Because the nuclei of some other 'normal' galaxies display similar characteristics, it has been suggested that many, perhaps all, galaxies contain massive black holes at their centers.

The Andromeda galaxy has a double nucleus, the brighter component of which may be the core of another galaxy that, following a galactic collision, has been absorbed by the larger system.

Galactic Open Clusters

Galactic open clusters are beautiful objects to view through telescopes, especially when blue and red supergiant stars are present in the cluster field. They are stellar systems containing from a few hundred to several thousand stars and are readily distinguished on sky photographs by a density of stars much larger than that in the surrounding field. About 1200 such objects have been catalogued so far and about half of them have been investigated at least once. Typical clusters are, by order of increasing age, the Orion nebula cluster, the Pleiades, Hyades and Messier 67. The brighter objects have been listed in the Messier catalogue, while most are recorded in the New General Catalogue (NGC) of Dreyer (1888). Open clusters are different from GLOBULAR CLUSTERS in many aspects. They are found mainly within or close to the Galactic plane and have ages ranging from a few million to ten billion years, while globular clusters populate the Galaxy halo and are as old as the universe. Consequently, open clusters may be used to describe the history and evolution of our Galaxy after the formation of the disk.

The strong interest for open clusters results from their unique and fundamental properties: the stars in a cluster are at the same distance from the Sun, (the depth effect is negligible for open clusters at distances larger than about 300 pc), they have the same chemical composition (the cosmic scatter on the chemical composition is much smaller than the precision of the determination of element abundances) and the same age (the age spread at cluster formation amounts only to a few million years and appears to be important only for very young open clusters with ages less than 10 million years). The stars, however, differ by their mass: the most massive stars in the youngest open clusters have masses of about 80 solar masses, and the lower mass limit is below 0.08 solar masses, reaching the domain of brown dwarfs.

Consequently, open clusters offer many opportunities of investigating the dependence of astrophysical phenomena on the stellar masses (by working in one cluster both the chemical composition and age are fixed) or on ages (by selecting stars of a given mass in several clusters of a given chemical composition). For example, the x-ray observations obtained by the ROSAT satellite for clusters of different ages have permitted the study of the decrease of the x-ray emissivity of solar-type stars with the increasing ages of the parent clusters.

Open clusters seem to be really ideal tools, but there are a number of problems to solve before one can fully benefit from their diagnostic power. Like other (distant) objects, open clusters suffer from the effects of absorption of light by interstellar matter, which has to be first estimated. The CLUSTER MEMBERSHIP of the stars is the second important problem to solve. On photographs or CCD frames, cluster members and field stars are all projected on the same plane and there is no direct way to separate them. Additional observations are needed to separate the cluster members from the field stars.

Fortunately, this can be achieved, at least for clusters not too far away, by using another property of open clusters: all member stars share the same spatial motion; if this were not the case, the group would rapidly dissolve. Therefore, by measuring their PROPER MOTIONS relative to the background stars or galaxies on photographic plates taken at a large epoch difference, which may now reach 100 yr, it is possible to compute the membership probability of each star and select the candidate members. The RADIAL VELOCITY provides also a powerful criterion to select the cluster members, but was a rather difficult and slow method to implement until recently, because the spectra used to be recorded on glass plates. New more efficient detectors and new specialized instruments have led to the increased use of this cluster-membership selection method.

Basic cluster parameters are the amount of interstellar absorption (reddening), the distance, chemical composition and age. The last of these is not a quantity directly obtained from the observations but through the comparisons with theoretical models. When enough clusters have been observed and their parameters determined, then astrophysical and Galactic applications can be undertaken. We are facing a case of extreme information concentration: on CCD frames thousands of stars have to be measured to obtain a few parameters describing the open clusters. Also, for example, when enough ages have been obtained, one parameter, the slope of the age distribution, will summarize the data resulting from large observing efforts.

The importance of open clusters

Different astrophysical problems are investigated with open clusters of different ages.

Very young open clusters, with ages less than a few million years, are the direct results of star formation processes and are still associated with the cloud from which they are born, which gives rise to spectacular bright nebulae, such as the Orion nebula. Some clusters are still embedded in clouds which are completely dark at visible wavelengths. They are only revealed by near-infrared imaging. An extensive description of very young open clusters is crucial to constrain the various scenarios of molecular-cloud fragmentation and STAR FORMATION. Ideally, one would wish to address the following topics:

- the number of stars of various mass formed,
- the percentage of binaries among stars of different mass,
- the distribution of their orbital parameters,
- the initial distribution of stellar rotation,

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

- the sequence of star formation and the importance of age spread,
- the radial structure and the importance of initial mass segregation.

Observations indicate that stars frequently form in clustered environments, either in rich clusters of many hundreds to many thousands of stars or in smaller groups and aggregates containing of order ten to a few tens of stars. It is only recently that properties of extremely young clusters are beginning to be well characterized.

Young open clusters, covering the range from 10's to 1000 million years, are especially interesting because of the variety of their stellar content. They contain several kinds of VARIABLE STARS and of 'abnormal' stars: emission-line stars and chemically peculiar stars. When the distance and age of the parent clusters are known, the intrinsic properties of these stars are determined more accurately than by any other means.

Intermediate-age and old open clusters, older than 1000 million years, have been mostly useful to understand the main trends and details of STELLAR EVOLUTION, because the evolutionary effects are more evident with a spectacular red giant branch. The best-observed old cluster, Messier 67 (NGC 2682), is a prototype for this kind of morphology and contains numerous RED GIANT STARS. Because cluster stars have the same age, each cluster defines an isochronous sequence in the photometric equivalents of the Hertzsprung–Russell (HR) diagram. Such sequences can be computed from grids of evolutionary models and compared with the observed data.

Properties of open clusters

The color–magnitude diagram

The main tool used to study open clusters is the HERTZSPRUNG–RUSSELL DIAGRAM in which the star's luminosity is plotted as a function of the temperature. In such a diagram each point represents the observations obtained for one star. The original form of the HR diagram, based on the absolute magnitude and the spectral types, has been replaced by a photometric equivalent form which displays the apparent magnitude as a function of a color index.

A color index represents the ratio of the fluxes measured through two filters: for example, the widely used *B*–*V* index results from the ratio of the fluxes emitted in the blue (*B*) and visible (*V*) parts of the stellar energy distribution. Several photometric color indices are closely related to the effective temperature.

The apparent *V* magnitude differs from the absolute magnitude by a constant which is called the distance modulus of the cluster. This quantity, denoted by $m - M$, is related to the distance r, expressed in parsecs (pc), by the simple relation $m - M = 5 \log r - 5 + A_V$, where A_V represents the correction for the interstellar absorption. The visual absorption A_V is itself proportional to the color excess: $A_V = RE\ (B - V)$, where $E\ (B - V) = (B - V) - (B - V)_0$ is the difference between the star's intrinsic color $(B - V)_0$ (not affected by interstellar absorption) and that observed. R is the ratio of total to selective absorption and must be determined observationally. Often a value of R of 3.2 (mag/mag) is assumed. These simple relations show that the determination of the amount of interstellar absorption is very important for the determination of the distance.

Examples of typical color–magnitude diagrams are shown in figures 1, 2 and 3, based on data extracted from the WEBDA database described in the final section. In very young open clusters, such as the Orion trapezium cluster (figure 1), only the most massive stars have completed their formation and have reached the ZAMS, while the less massive stars are still in the phase of contraction toward the ZAMS. Membership of these PRE-MAIN-SEQUENCE STARS is difficult to determine from photometric criteria only and spectroscopic observations are needed to search, for example, for the presence of emission in the Balmer Hα hydrogen line or of lithium absorption lines, which are both signs of youth. When possible, proper motions and radial velocities are of course also used to confirm the membership.

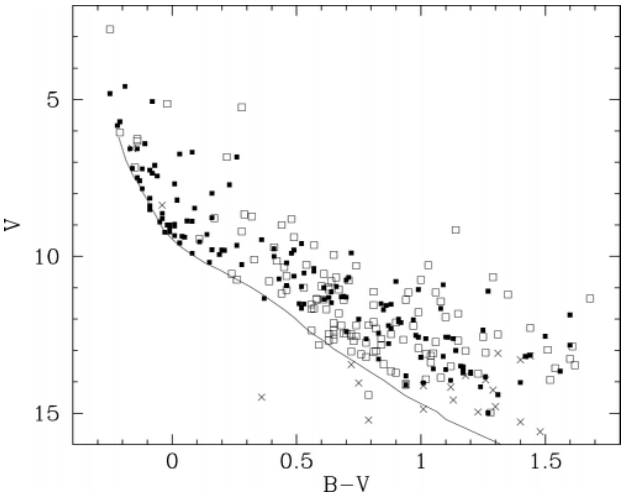

Figure 1. Color–magnitude diagram for the Orion nebula cluster. The star brighter than $V = 10$ have completed their formation, while the stars fainter than this limit are still contracting toward the zero age main sequence (ZAMS) (continuous line). Filled squares are for the stars with membership probability larger than 50%, open squares for stars with probability less than 50%, and crosses for stars without membership information. The nebulosity in the cluster region absorbs the light of some stars and alters their colors, making them redder. This is called differential reddening. Additional information is needed to separate the stars really belonging to the cluster from the field stars.

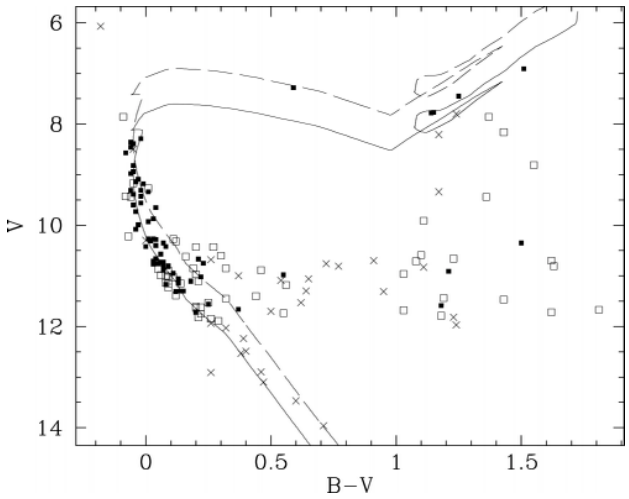

Figure 2. Color–magnitude diagram for NGC 2287 (M41). Symbols are related to the cluster membership of the stars (filled squares, more than 50% chance of being a member; open squares, less than 50%; crosses, no information). The continuous curve is a theoretical isochrone for 240 million years. The dashed curve is the same isochrone shifted by 0.75 mag to mimic the binary boundary. Both curves delineate the main sequence band and reproduce quite well the observed morphology.

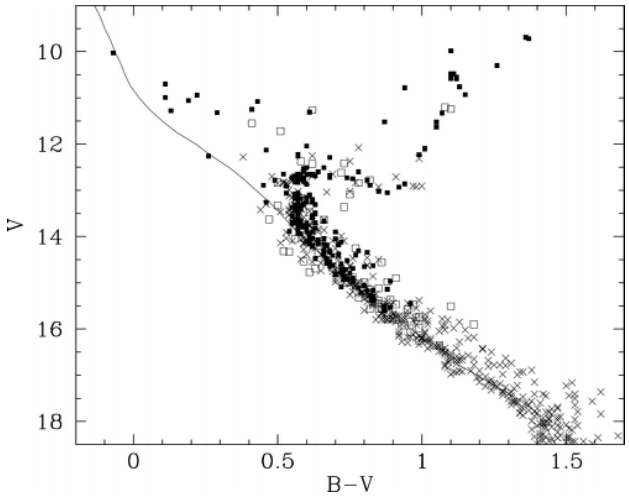

Figure 3. Color–magnitude diagram for NGC 2682 (M67). In this characteristic diagram, the main sequence is well populated. The upper main sequence is bending toward the right (redder color) under the effect of stellar evolution. After a small gap, resulting from a rapid phase of evolution at the end of the hydrogen burning phase, the structure of the stars changes and the stars move toward the right of the diagram. They become red giants and start ascending the red giant branch. The helium burning phase lasts for a longer time and produces a small clump of stars with similar magnitudes and colors, located at V ~10.5 and $B - V$ ~1.05. Blue stragglers are located to the left of the main sequence bending ($B - V < 0.50$), in a position where stars are not expected to remain according to the cluster age. The thickness of the main sequence is due to the presence of binary stars. Symbols are the same as those in figure 2.

If all stars were single, the sequence observed in the color–magnitude diagrams would be very thin. However, even with the high-precision photometric data obtained with the Hubble Space Telescope, the main sequence presents a finite thickness. The major part of the scatter is produced by BINARY STARS. Obviously, unresolved double stars are brighter than single stars of similar temperature. Because the magnitude is on a logarithmic scale, the addition of the fluxes of two identical stars makes the binary system brighter by 0.75 mag. The main sequence band, defined as the zone between the ZAMS and the upper binary ridge, is then populated by binary stars which have mass ratios less than 1 (the mass ratio $q = M_B M_A^{-1}$ is by definition always smaller than 1). The smaller the mass ratio, the closest the stars to the ZAMS. When the ratio of the luminosities (L_A/L_B) reaches the value of 100, the presence of the secondary is no longer distinguishable.

Stellar rotation and peculiarities also introduce scatter on the star position within the main sequence band by affecting the magnitude and/or the colors.

However, the main characteristic visible in color–magnitude diagrams is the effect of the stellar evolution. At any age, the more massive stars are more evolved than low-mass stars, because the speed of evolution depends on the initial mass. This explains why the upper part of the main sequence is evolved away from the ZAMS and presents a characteristic shape for each cluster and age. The comparison of the observations with theoretical isochrones permits at the same time the determination of the ages of open clusters and the testing of evolutionary models. For 10 yr, models with larger cores, including the effects of convective-core overshooting, have been preferred to the so-called canonical ones, because they better reproduce the observed diagrams.

Luminosity and mass functions

Young open clusters are the direct products of the processes of star formation and therefore provide fundamental clues to the understanding of cloud fragmentation. Ideally, if we were able to count the number of stars of different masses, we should be able to describe the end-product of the formation processes, i.e. the initial mass function. What is observed in fact is the luminosity function, defined as the number of stars in magnitude bins, and masses are deduced from a mass–luminosity relation. As a rule, most clusters conform to the Salpeter law, although the universal character of this law has not yet been fully demonstrated. It is not a trivial task to decide whether the differences observed between the luminosity or mass functions in different open clusters are real or produced by biases and incompleteness. The complete description of the stellar population, although of fundamental importance, is quite difficult to derive because we face the problems of membership determination, stellar multiplicity detection

and the completeness of the samples, because the radial extension and structure of the clusters are still poorly known. In addition, because of the possibilities for stars to escape from their parent clusters, the observed present-day mass function can be related to the cluster initial mass function only through a thorough knowledge of the dynamical evolution, which is difficult to achieve.

For these reasons, for none of the clusters do we have complete information, although meaningful progress has been made in several areas.

Radial and spatial structure

The structure of open clusters has been for a long time mainly a topic for theoreticians and numerical simulation. All we knew was derived from models, because relevant observations were not available. As more proper motions and photometric studies became available, it was realized that open clusters were not limited to the bright central area which is prominent on photographs, but that they extend to much larger distances. The problem is, however, to identify the stars in the surroundings. The statistical approach consisting in counting stars at larger and larger distances from the center until one reaches the level of the sky background obviously fails when the density of cluster stars is lower than the fluctuation of the number of stars in the sky background. Therefore, there is no other solution but to identify the stars one by one in the cluster corona with the help of proper motions and radial velocities, which ensures that the stars are moving together with the same spatial motion, and of photometric information, which proves that the stars are at the same distance.

The radial distributions of stars have confirmed the theoretical predictions: in most clusters the massive stars are found close to the cluster center, while less massive stars are more uniformly distributed over the cluster area. This mass segregation is caused by star interactions or collisions which redistribute the kinetic energy and make the massive stars fall toward the cluster center. The same phenomenon is also true for the binaries, for which the sum of the masses makes them heavier than single stars. However, recent observations show that the time evolution of mass segregation is not straightforward. As a cluster emerges from its parent cloud, it undergoes dynamical changes and the most massive stars are found at the cluster center. We are facing a dilemma: either the massive stars are formed at the cluster center and remain there or they are brought to the center by some forces, for example dynamical friction in the cloud. From this initial state, a fine mass segregation will develop by dynamical evolution of the cluster until the mass difference between the maximum and minimum masses becomes small and the star distribution becomes more uniform, when stars have more or less the same masses.

Another prediction of the models is that open clusters lose stars by an evaporation process. During encounters one star may acquire enough energy and speed and become able to leave the cluster, especially after the collision of a single star and a binary system, during which star exchange may happen, with the concomitant ejection of one component. This phenomenon has the consequence that open-cluster lifetimes are limited: if they are not massive enough to retain their stars, the cluster will dissolve within a few 100 millions years. As recent observations of star forming regions have shown that stars predominantly form in clusters, the field stars are explained as resulting from the disruption of many clusters. The verification of this hypothesis requires numerous comparisons of the properties of field and cluster stars. Tidal interactions of clusters with molecular clouds in the Galactic disk also contribute efficiently to the disruption of the clusters.

Rotation distribution

Since the beginning of the 20th century and until recently, high-resolution spectra could be recorded on glass plates only for relatively bright stars. Therefore information on stellar rotation in open clusters was limited to the brighter stars on the upper main sequence. Furthermore, the quantity determined was not exactly the rotation speed, but the product of the equatorial velocity and the inclination angle i of the rotation axis, i.e. the quantity $V \sin i$. Therefore it was not possible to easily know whether a star with a small $V \sin i$ measurement was rotating slowly or whether it was seen more or less pole on. The velocity is maximum if the star is observed equator on, i.e. if the angle is close to 90º ($\sin i = 1$). New instruments and larger telescopes have allowed the $V \sin i$ observations to be extended to solar-type stars and the distribution of projected rotation along the main sequence to be derived.

For O- to middle F-type stars the maximum rotation shows a moderate decrease, but, because of the presence of the factor $\sin i$, most values between 0º and the maximum possible rotation are observed. However, at about 7000 K, the onset of convection in the stellar atmosphere rapidly brakes the rotation. The initial phase of braking is rather rapid, reducing the projected rotation to values of $V \sin i$ less than 10 km s^{-1}. Subsequently the effect is not as marked and the rotation is more gradually reduced during the star main sequence lifetime.

The observations of main sequence solar-type stars in open clusters of various ages, between 1 million and 1 billion years, have permitted us to understand how rotational braking develops. There seems to be no uniform law: each star is braked depending on its initial velocity and mass. The initial spread is thought to be linked to the time at which decoupling of the accretion disk surrounding the pre-main-sequence stars occurs.

Binary frequency

Stars are usually formed in binary or multiple systems, although the true frequency, which may vary between 25% and 60%, is not exactly known, because we are not yet able to detect all possible binaries along the main sequence, down to the faintest stars. Frontier technology (SPECKLE IMAGING OF BINARY STARS, INTERFEROMETRY and ADAPTIVE OPTICS imaging) now allows the detection of binary systems with separations between 0″.05 and 1″.0. Further progress in spectroscopic observations will be possible with new multifiber spectrographs which will be able to obtain the spectra of some 100 stars simultaneously. Systematic observations of representative clusters have already been undertaken, which will produce, in the next few years, a great development of our knowledge of the duplicity of stars in various open-cluster environments, ages and richness.

The radial-velocity spectrometers, developed in the mid 1970s, have permitted the measurement of the radial velocities of solar-type stars in nearby clusters and the determination of the orbital parameters of most SPECTROSCOPIC BINARIES discovered. Main sequence binaries with periods smaller than 8 days have circular orbits, while all others have elliptical orbits, the mean eccentricity being around 0.3. This cut-off period results from the effects of tidal interaction between the two stars in binary systems, which are stronger during the pre-main-sequence phase because the stellar radii are larger and the atmospheric convection zone is more developed. The transition limit between circular and elliptical orbits is around 150 days for binaries with a red giant primary and 1500 days for supergiant stars.

Comparison of the binary frequencies and separation distributions in various environments, namely from loose star forming regions, such as the Taurus–Auriga complex, to the dense cluster cores, as in Orion where the mass density reaches 10 000 solar masses pc^{-3} in the 0.2 pc central region, have shown that these characteristics are not the same. Do these differences originate from the formation processes themselves or do some dynamical interactions modify the original state? The answer is not known yet.

Variable stars

Various kinds of variable stars have been found in open clusters, as seems normal because intrinsic variability depends on the position in the HR diagram, as is the case for the δ Cephei variables. However, their presence in open clusters permits us to establish or study the relations between their periods, luminosity and chemical composition. Comprehensive surveys have been performed to detect other types of variable stars, called β Cephei variables, among the B-type stars in the upper main sequence of young open clusters. Surveys have also been undertaken with bidimensional detectors (CCDs) to search for δ Scuti stars, another kind of pulsating variable which presents often a combination of several periods of pulsation simultaneously.

Apart from the intrinsic pulsating variables, there are additional kinds of variables in open clusters: the flare stars in very young clusters, ECLIPSING BINARY STARS and stars in which the variability is induced by rotational modulation. Continuous observations are required to perform an extensive detection of variable stars. However, at the time of photoelectric photometry, stars were observed one by one and therefore the number of observations obtained for each star was not sufficient to have a complete detection of variablity. The advent of CCD cameras now allows us to obtain large numbers of frames over various time intervals, which enables the determination of variability periods up to several tens of days.

One kind of variable star discovered in open clusters in the beginning of the 1980s is related to the variability induced by the presence of spots on the star's surface and the rotation of the stars. Because the spots are less luminous than the star surface, the presence of spots makes the stars a little less luminous, by a few 0.01 magnitudes. The rotation produces a cyclic variation which is often quite stable over time intervals of months or years, depending on the lifetime of the spots. Such observations are at present very active because the derived periods are the direct rotation periods. If the equatorial diameters of the stars can be determined, the equatorial speed can be computed.

Recent surveys in old open clusters have permitted the discovery of relatively large numbers of contact binaries (binary stars so close that they reach contact) all along the main sequence and even among the stars in position of blue stragglers.

Blue stragglers

BLUE STRAGGLERS form a population of stars which has been originally discovered in old open clusters. They remain in the color–magnitude diagrams beyond the observed turn-off, i.e. they are brighter and bluer than the normal end of the main sequence. According to the masses deduced from their luminosities, these stars should not be present at all in such a position, because they should have evolved away from the main sequence. Figure 3 (M67) illustrates the positions of these stars in a well-studied old open cluster. A variety of plausible explanations exist, from delayed star formation through binary mass transfer, or coalescence, to internal mixing. Probably, several mechanisms are needed to explain the variety of properties observed.

Space observations

The observation of open clusters with instruments on board satellites requires great sensitivity and high spatial resolution to resolve the sources and cross-identify them

with cluster stars. Not all major satellites were able to be efficient in this respect.

HIPPARCOS

The HIPPARCOS satellite was not designed to do imaging and could observe only four stars per square degree. Therefore the main results were obtained on nearby open clusters which cover large areas of the sky. Hipparcos provides fundamental estimates of the cluster distances because the observations are independent of any *a priori* astrophysical assumption on the star structure or chemical composition. This is very important because the cosmic-distance scale, through the determination of the zero point of the CEPHEID PERIOD–LUMINOSITY RELATION, is mostly based on the distance of open clusters.

The best observed cluster was the Hyades and Hipparcos' trigonometric parallaxes and absolute proper motions permitted the distance of the cluster center to be determined with an unprecedented accuracy: 46.34±0.27 pc, i.e. 151 ly. The precision of the individual parallaxes also allowed a three-dimensional view of the cluster to be built. Because of its proximity, the Hyades is the only cluster where the three-dimensional distribution of stars can be observed.

Good distances have also been determined for nine further open clusters closer to the Sun than 300 pc, including the Pleiades, Praesepe and Coma Berenices clusters. The mean cluster parallaxes have not been obtained from the individual parallaxes, but a global solution, based on all measurements of all member stars in the cluster field, has been computed from the great-circle intermediate data. Results are in agreement with what was expected, except for the Pleiades, for which the distance obtained from the Hipparcos satellite is 10% shorter than that determined from the ground by classical techniques. So far (March 2000), the reason for this discrepancy has not been identified: some authors incriminate the satellite itself (but why in the Pleiades only?), others question the properties of Pleiades stars, especially the adopted chemical composition. As many as 2158 transits for 54 stars in the Pleiades were used to compute the final solution.

IUE

The International Ultraviolet Explorer (IUE) satellite worked in a star by star mode and many observations were targeted at massive O-type stars in young open clusters, because they mostly emit ultraviolet radiation. The main goals were the study of the ultraviolet spectra of young stars of known ages but also the properties of the interstellar matter and especially the clouds from which the stars have been formed. The ultraviolet observations from the IUE satellite contributed to the determination of the absorption law in several clusters still associated with reflection nebulae, such as NGC 2244, NGC 2264 and NGC 6530.

ROSAT

Results from the Einstein x-ray satellite had shown that x-ray emission is a common property of solar-type stars and that most main sequence dwarf stars in the Hyades do emit x-rays. This result prompted the observation of several open clusters with the ROSAT x-ray observatory, covering an age range from a few million to more than a billion years. The resulting trend is very clear: the intensity of the x-ray emission is lower in older clusters. This can be understood because the x-ray emission depends on the star's activity, which is itself related to the rotation rate and age. Studies of stellar rotation have shown that the rotation decreases with increasing age. The angular-momentum loss results from the interaction of the stellar winds and magnetic field.

In clusters for which observations have been obtained over a long time, variability in x-rays has been observed. Flaring activity explains the large flux increase, but the data are not complete enough to provide information on the variations of x-ray activity during the whole stellar cycles.

One interesting by-product of the ROSAT x-ray imaging is the discovery of faint member stars in nearby clusters, through their x-ray fluxes, as for example in the young southern open clusters IC 2391 and IC 2602. These two clusters are spread over large areas and photometric and astrometric surveys did not really succeed in identifying faint members among the several ten of thousands of stars measured on Schmidt plates (over such areas, CCDs are completely useless). However, because of the youth of these clusters, faint members were easily detected thanks to their x-ray emission. Ground-based follow-up observations confirmed the membership of most candidate stars.

The Hubble Space Telescope

The HUBBLE SPACE TELESCOPE (HST) produced beautiful images of very young open clusters still associated with nebulosity and of dense clusters which cannot be completely resolved with ground-based instruments. Two objects were more intensely observed: NGC 3603 and the Orion nebula cluster.

NGC 3603 is a dense, rich and very young open cluster which is known as the densest concentration of early-type massive stars in our Galaxy, at a distance of about 7 kpc. It is in the core of the most massive visible giant H II region and is considered as a starburst and compared with the R136 cluster in the Tarantula nebula in the Large Magellanic Cloud. JHK photometry and spectral classification of the 14 brighter stars have revealed the presence of three Wolf–Rayet (WN) stars and a dozen very massive O-type stars.

The Orion nebula cluster, also known as the Trapezium cluster, is one of the most studied star-forming regions. The color–magnitude diagram based on the HST near-infrared photometry shows that the star formation appears to be remarkably coeval: 80% of the stars have an inferred age less than 1 million years (Myr) and 15% have an age between 1 and 4 Myr. The age spread is therefore only a few million years. Several new binary stars were found with separation below 1 arcsec, a domain which is not easily accessible from ground-based imaging. However, the most impressive result is the direct discovery of accretion disks around pre-main-sequence stars which showed up very clearly on HST images as dark DUSTY CIRCUMSTELLAR DISKS. The exceptional resolution of the HST images has also permitted the discovery of a phenomenon which has been called proplyds: when the low-mass stars are close enough to the cluster center and hence subjected to the strong winds emitted by the massive stars of the Trapezium, the material on the side of the disk facing the massive stars is heated by the hot radiation.

Prospects

The number of faint stars in open clusters has, so far, been the main difficulty in the systematic collection of spectroscopic information for the low-mass stars on the lower main sequence. The advent of CCD cameras solved this problem and photometry is now currently done to very faint magnitudes, although the measurement precision is degraded for the fainter objects. The development of large (8–10 m) telescopes (Keck, VLT, Gemini, Subaru) and of multi-object spectrographs opens completely new areas for the observations of open clusters. For example, better resolution at the center of dense or remote clusters will be possible. Infrared capabilities of bi-dimensional detectors on large telescopes will produce a wealth of new observations on embedded clusters and star-forming regions that should provide a much better understanding of the process of star formation. With multi-object spectrographs, astronomers will be able to obtain spectra of about 100 stars at the same time, greatly reducing the need for observing time, with an increased precision. These new facilities will greatly change our way of thinking and of working. We can therefore expect to have answers to the many basic questions, and among them the initial mass function, star multiplicity and chemical composition, simply because of the immense possibilities offered by the new telescopes and instruments, as well as future satellites.

One potentially interesting domain, not yet really explored, is the study of stellar cycles, analogous to the solar cycle, but for many stars along the main sequence of open clusters differing in ages and chemical compositions. The required precision lies within the capability of modern instruments. Such a program would be a long-term project best adapted for institutes which have their own telescope and are not subject to regular telescope-time request. The ouput of such long-term systematic observations will undoubtedly provide many astrophysically fundamental results.

Database

Published data for stars in open clusters have been collected in a database developed at the Institute of Astronomy of the University of Lausanne by the author. It contains, in spring 2000, information for more than 350 000 stars in about 600 open clusters covering the domains of astrometry, photometry, spectroscopy and bibliography. The database is publicly accessible on the world wide web, at the URL http://obswww.unige.ch/webda/. A powerful feature is the possibility of getting basic data for stars from scanned maps or plotted charts. It contains also a large archive of original data files.

Galactic Plane

The plane of the disc of our Galaxy. It follows a line running more or less through the center of the Milky Way, and is inclined to the celestial equator by an angle of about 62°. In the current system of galactic coordinates defined by the IAU in 1959, the galactic plane is defined by $b^{\mathrm{II}} = 0^{\circ}$ and is the central line of the distribution, as determined by radioastronomers, of neutral hydrogen in the Milky Way.

Galactic Thick Disk

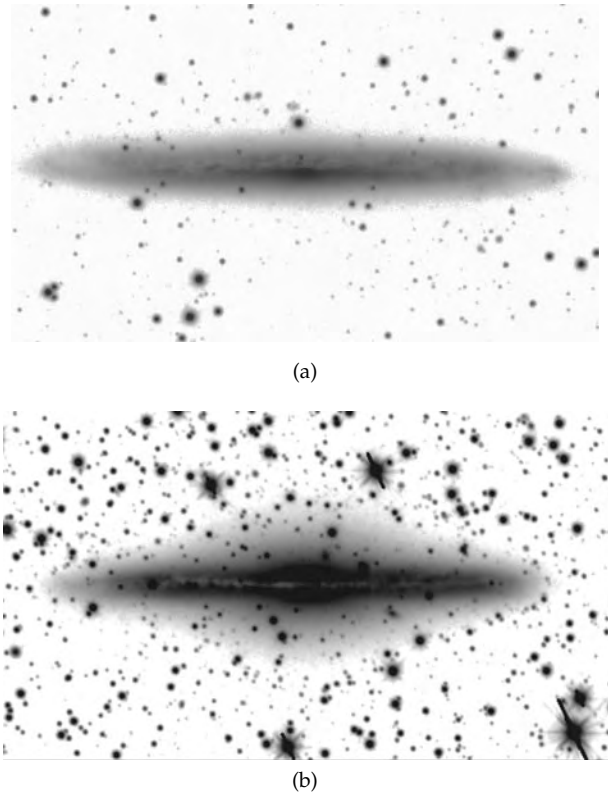
The MILKY WAY (the Galaxy) possesses a number of different stellar components—often referred to as populations, following the pioneering work of WALTER BAADE in the 1940s. Each of these components is described by a fairly well-defined set of observed distributions of kinematics, chemical abundance and age and has a distinctive spatial distribution. A comparison of these populations with the predictions of galactic formation theories and paradigms leads to insight into the manner in which the Galaxy formed and has evolved. Following Baade it was soon appreciated that there existed three critically important populations—the halo, the disk and the bulge, which have masses (1–3) $\times$ $10^9 M_\odot$, $6 \times 10^{10} M_\odot$ and $10^{10} M_\odot$, respectively[1]. (As the names suggest, the halo has a spheroidal distribution, the disk is a highly flattened rotating system, and the bulge comprises a well-defined central concentration. We note also that the disk and halo are often referred to as POPULATION I and II, respectively.) It also became evident that intermediate components exist, and the thick disk is one of these. It is intermediate in its properties between those of the halo and the disk (now renamed the thin disk; see GALACTIC THIN DISK). Insofar as the halo is old (age ~12–15 Gyr) and believed to pre-date the thin disk (age $\leq$10 Gyr), interest in the thick disk is driven by the working hypothesis that an understanding of it will lead to a clearer picture of the early evolution of the Galaxy, giving insight perhaps into the transition phase from halo to disk, or alternatively into phenomena which thickened an already existing thin disk.

The present discussion will proceed as follows. In the next section we shall trace the historical recognition of the Galaxy's thick disk, after which a description will be given of our current understanding of its properties. A discussion is then given of the main competing ideas which have been put forward to explain the various observations, followed by a brief confrontation of the observations with these concepts. It will be clear that at the time of writing (1999) our understanding is incomplete. We conclude with a discussion of prospects for resolving the problem.

Historical development

As noted above, the need for a component intermediate between the basic disk and halo populations soon became evident. Of particular interest in the present context was the designation, at an important Vatican Conference in 1958, of intermediate population II, although its implications for Galactic formation and evolution remained unclear. This component would later become recognized as the thick disk.

An important further clue came from studies of external DISK GALAXIES where it became clear that edge-on systems showed a variety of disk thicknesses. The upper panel of figure 1 shows the brightness distribution for the edge-on disk galaxy NGC 5907, from the recent work of Morrison and her colleagues, where the density distribution perpendicular to the disk can be well represented by an exponential, decreasing as $\exp(-z/z_0)$, where z is the vertical distance from the plane and z_0 is called the scale height, and in this object has the value 400 pc. Observations of other edge-on systems, however, revealed examples of a more complicated disk structure. Perhaps the most famous of these is NGC 891, which is shown in the lower panel of figure 1. This could be well explained in terms of *two* disk components having very different exponential scale heights—and astronomers were led to think, fairly naturally, in terms of 'thin' and 'thick' components. In NGC 891 the thinner component has a vertical exponential scale height of 400–650 pc and is not unlike the situation one finds in the Galaxy. The second, thicker, component has an exponential scale height of 1500–2500 pc. (For reference in figure 1 the disk of NGC



(a)

(b)

Figure 1. (Upper panel) The distribution of red light in the edge-on disk galaxy NGC 5907, which can be well represented in the vertical direction by a single exponential component. (Lower panel) The red light distribution in NGC 891. Here two exponential components ('thick' and 'thin') are required to explain the observations. The case has been made in the astronomical literature that the Milky Way seen edge on would look rather like NGC 891. (This diagram originates from the work of H L Morrison and her colleagues, and was kindly supplied by them.)

[1] The reader should distinguish the luminous halo, discussed here, from the 'dark' unseen halo, which is inferred from dynamical arguments, and contains ~50–90% of the Galaxy's mass.

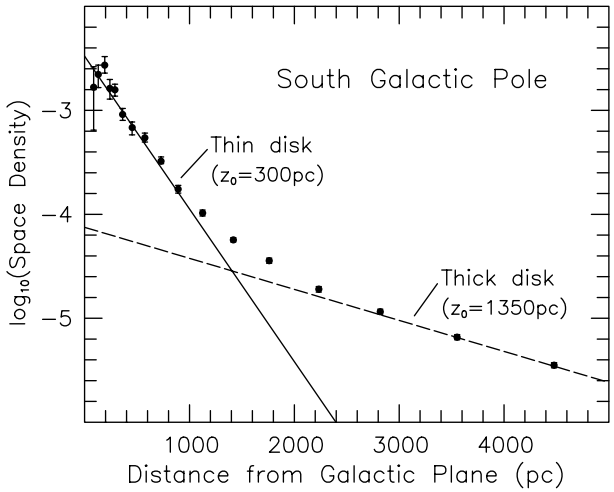

Figure 2. The logarithm of the space density of stars towards the south Galactic pole, as a function of distance from the Galactic plane, from the work of Gilmore and Reid. An exponential falloff of a single component would be represented by a straight line in this diagram and would clearly not be an adequate representation of the data. The authors fitted a two-component model, which they identify as the thin disk (scale height 300 pc) and thick disk (scale height 1350 pc).

891 extends some 35 kpc from end to end.) It is this second component, first given the name 'thick disk' in external systems, which is under discussion here for the Milky Way.

In the Galactic context, the term 'thick disk' was introduced by Gilmore and Reid in 1983 to explain their observation that star counts towards the south galactic pole were not well fitted by a single exponential, but rather could be nicely represented by two such components—one with scale height 300 pc and the other with scale height 1350 pc. The ratio of the density of the two components at the GALACTIC PLANE was 0.02. A representation of their seminal diagram is shown in figure 2. It is important to appreciate that the normalization of thick/thin $= 0.02$ at the Galactic plane is an order of magnitude larger than that of the halo population, which in the solar neighborhood is halo/thin ~ 0.001. That is, for every 1000 stars chosen at random in the solar neighborhood, one expects only one to be a member of the halo population, and 20 to belong to the thick disk. While the thick disk may be a minority component, in the solar neighborhood it far outweighs the halo.

For those who like to follow the impact of new instrumentation on the subject, it is interesting to note that this new development followed the implementation of large (wide-field) SCHMIDT TELESCOPES and powerful measuring machines necessary for the analysis of the large photographic plates on each of which huge numbers (hundreds of thousands) of stellar images were recorded. In a similar vein, historians of science will note that the 'thick disk' of Gilmore and Reid was also present in the reports of star counts towards the north Galactic pole by Yoshii in 1982.

Figure 2 deserves closer scrutiny. It is clear that two exponential components, 'thick' and 'thin' (shown by the straight lines), provide a sufficient explanation of the observations. However, are they a necessary requirement? It is trivial to demonstrate that a multicomponent or continuous distribution, based on existing observational data, can also be presented which very nicely fits the observations in figure 2. The reader should be aware that this is more than a semantic point. If, on the one hand, one accepts that the data are best represented by two components, 'thick' and 'thin', one will be led naturally to seek an explanation in terms of discrete phenomena. Indeed, it is probably fair to suggest that most workers have come to the view that the Galactic thick disk has resulted from the merger of a small satellite with the Milky Way. If, on the other hand, one accepts that the observed behavior in figure 2 represents a continuous, extended disk configuration, one will seek alternative explanations, involving perhaps dissipative collapse scenarios, multiple mergers or clumpy galactic collapse formation. What needs to be done, and which has not been systematically done to this point, is to compare the extensive and growing observational material with the predictions of both types of models—discrete and continuous.

Properties of the thick disk

Initial estimates

Work by Gilmore and his coworkers in the early 1980s led to the suggestion that the thick disk had abundance and kinematic characteristics quite intermediate between those of the halo and thin disk populations. At that time the mean chemical abundances, [Fe/H][2], of the halo and thin disk were -1.6 and -0.2, respectively: that of the thick disk was -0.6. The stellar velocity dispersions in the direction perpendicular to the Galactic plane were $\sim$90 and $\sim$15 km s^{-1} for halo and thin disk: for the thick disk the value was 60 km s^{-1}. Also, for the asymmetric drift—the velocity by which material lags behind the solar neighborhood in its rotation about the Galaxy—the halo and thin disk had values $\sim$220 and $\sim$15 km s^{-1}, respectively: that of the thick disk was 100 km s^{-1}. This laid the ground for the suggestion that the thick disk was a discrete component, with origins quite different from those of the other populations. Later investigations would support the abundance result but lead to more moderate kinematics, closer to that of the thin disk, with vertical velocity dispersion 40 km s^{-1}, and asymmetric drift $\sim$40 km s^{-1}.

Recent determination of thick disk parameterization

Current estimates of the properties of the thick disk and the other Galactic disk and halo populations are presented in table 1. The situation has become much more complicated in the past two decades not only for the disk but also for the halo, leading to greater difficulty in understanding the manner in which the Galaxy formed and has evolved.

[2] $[\mathrm{Fe/H}] = \log_{10}[N(\mathrm{Fe})/N(\mathrm{H})] - \log_{10}[N(\mathrm{Fe})/N(\mathrm{H})]_{\odot}$, where N(Fe) and N(H) are the number densities of iron and hydrogen, respectively.

Table 1. Some population characteristics of disk and halo components in the solar neighborhood.

Component	Scale height (pc)	⟨[Fe/H]⟩	σ_U, σ_V, σ_W [a] (km s^{-1})	V_{lag} [a] (km s^{-1})	Age (Gyr)	ρ/ρ_{tot} [b]
Old thin disk	300	−0.3	30, 20, 15	15	≤10	0.95–0.98
Thick disk	800–1500	−0.6	65, 55, 40	40	12–15	0.02–0.05
Metal-weak thick disk	1400:	−1.2:	Unknown	40	(12–15):	(0.0005–0.002):
Flattened halo (also called old, low or collapsed halo)	1600–2000	−1.6: [c]	130:, 100:, 90: [c]	160	12:–15	0.0008:
Spherical halo (also called younger, high or accreted halo)	Spherical	−1.6: [c]	130:, 100:, 90: [c]	270	12:	0.0002:

[a] σ_U, σ_V and σ_W are velocity dispersions in the directions away from the Galactic center, toward Galactic rotation and toward the north Galactic pole, respectively. V_{lag} ($=V_{solar\ nbd.} - V$) measures the asymmetric drift, the velocity by which the component lags the solar neighborhood in its systemic rotation.

[b] Ratio of the density of the component to total density in the solar neighborhood. We assume $\rho_{halo}/\rho_{disk} = 0.001$.

[c] Decomposition of the two halo components has not yet been achieved. The tabulated values are those determined for their admixture in the solar neighborhood. The values of the individual components are thus uncertain.

Substructure in the halo

To understand the disk one must also appreciate the situation with the halo. Although it comprises only a minuscule fraction of the mass of the Galaxy, it contains the oldest material and yields crucial clues to the earliest phases of the system. Current indications suggest that the halo is a multiple population, with components which originated during both an initial dissipative collapse (as described in 1962 in the seminal work of Eggen, Lynden-Bell and Sandage) and the later accretion of smaller fragments which had evolved independently of the central concentration, and later came into dynamical equilibrium with it (as advocated in the equally important work of Searle and Zinn in 1978). The recent discovery of the SAGITTARIUS DWARF SPHEROIDAL GALAXY, currently in catastrophic collision with and being destroyed by the Milky Way, attests indisputably to the operation at some level of the merger scenario. In table 1, the halo is represented by two components, described by different workers by various descriptors. This is no doubt a gross oversimplification, and current efforts are being directed to ascertaining how much discreteness remains evident in the accreted component.

Substructure in the thick disk?

The situation with the thick disk has also become more complicated. In table 1 one sees what one might call the 'canonical' thick disk first appreciated by Gilmore and Reid, with ⟨[Fe/H]⟩ ∼ −0.6, and kinematics much closer to that of the old thin disk than originally claimed. Observational evidence now also exists to support the case for the existence of material with disklike kinematics and [Fe/H] <–1.0—called by some the 'metal-weak thick disk'. The meager data available for this component are also presented in table 1. The case for the population remains to some extent controversial, but evidence continues to grow that some ∼10–30% of material with −1.6 < [Fe/H] < −1.0 has disklike kinematics. There are even GLOBULAR CLUSTERS in this abundance range (old, populous, star clusters previously believed surely to be members of the halo) with recent well-determined space velocities which are characteristic of the disk rather than the halo.

The question which begs to be answered, if the metal-weak thick disk is real, is whether it is yet another discrete component of the disk created by merger or part of a more continuous structure, formed perhaps in a dissipative manner. Another tantalizing question provoked by table 1 is the significance of the similarity in many respects of the metal-weak thick disk and the flattened halo component.

Gradients in the thick disk?

A critical consideration for an understanding of the thick disk is the existence or otherwise of abundance and kinematic gradients within it. Since most of the available data exist for material not too far from the solar neighborhood, and the thin disk far outweighs the thick disk close to the Galactic plane, one must always be concerned that leakage of the thin disk, due to observational errors, into putative thick disk samples will simulate the effect of vertical gradients. That said, most workers advocate that no vertical abundance gradient exists, or if it does it is small and currently at the limit of detection. Future insight into this question may come from analysis of external edge-on systems. Indeed, van der Kruit and Searle, in an early analysis of NGC 891 (see figure 1, lower panel), report a gradient in the photometric properties of the thick disk component of that system which is most easily interpreted as one in abundance.

Concerning kinematics, and in particular the asymmetric drift, there are two schools of thought. The first contends that the drift is a function of height above the Galactic plane (and is given by $V_{lag} \sim 18z + 15$ km s^{-1}, where z is the vertical distance from the plane in kpc), while the second finds no such dependence and reports that the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

drift is constant with height, with $V_{\rm lag} = 40$ km s^{-1}, at least within ~3000 pc of the plane.

Little information exists on the question of the dependence of kinematics on abundance in the thick disk population(s) or on gradients as a function of distance from the Galactic center. These are questions for the future.

To a large extent, resolution of the nature of the thick disk and its implications for Galactic disk cosmogony will turn on the issue of these interdependences of position, abundance and kinematics.

Age of the thick disk

The thick disk is old. Indeed, it contains the relatively metal-rich, so-called disk globular clusters, such as the brilliant 47 Tucanae, the age of which lies in the vicinity of 12 Gyr. Studies of thick disk field stars suggest that they too have ages similar to that of 47 Tuc. It is important to appreciate, however, that these estimates are accurate only to ~2–3 Gyr. With this in mind then, one should operate with care in seeking to answer the important cosmogonical question of whether the thick disk has the *same* age as the Galactic halo, for which estimates lie in the range 12–15 Gyr. Some workers advocate that the thick disk is younger than the halo by ~2–4 Gyr. In the opinion of this reviewer, at least, the issue remains unresolved at the ~2–3 Gyr level.

Models of thick disk formation

Numerous mechanisms have been suggested for the thickening of galactic disks. Foremost among others, these include internal collisional heating of the thin disk, merger with external systems and dissipative collapse. The different mechanisms make different predictions concerning the abundance, kinematic and age profiles of the thick disk and, in principle, comparison between observation and theory should enable the relevant process(es) to be identified. For example, the dissipative models predict abundance and kinematic gradients, while the minor merger ones appear not to do so. One might also not be surprised to find discontinuities between those properties of the thick and thin disks if the merger scenario is relevant. A slow dissipative formation mechanism might lead to a range in ages in the thick disk, intermediate between that of the halo and the old thin disk, while the age profile in merger scenarios will be driven by the conditions which existed at the time of the merger. Collisional heating of the thin disk will produce a thick component with characteristics which are closely related to those of the thin disk, modulo the manner in which the heating occurred.

One should always bear in mind that not one, but rather a combination of mechanisms may have contributed to the disk thickening. We briefly discuss the three mechanisms.

Internal disk heating

The disk of a galaxy will be heated by the scattering of its constituents by giant molecular clouds and transient density waves associated with spiral arms, and this is believed to be the origin of an observed dependence of velocity dispersion on age in thin disk material and to be responsible for vertical velocity dispersions less than 20–30 km s^{-1}. Only if one is prepared to accept the existence of massive objects such as black holes or clusters of Jupiters, of mass $>10^6 M_\odot$, is one able to produce velocity dispersions similar to those found in the thick disk.

Mergers

Computer modeling of the mergers of minor satellites with disk galaxies show very nicely how disk thickening might occur, given favorable relative orbits (prograde approaches strongly preferred) and satellite density profiles (dense satellites preferred). Studies, such as those of Quinn, Hernquist and Fullagar, show how effectively this mechanism can operate. Some of their results are shown in figure 3, where the satellite has 0.1 times the mass of the disk. One sees that over a relatively short time of a few Gyr the satellite is shredded and becomes part of the disk which itself has been thickened. The model makes important predictions among which is the finding that there will be essentially no change in the asymmetric drift of the thickened disk from its initial value. No vertical abundance gradient is produced in this type of model, although an existing one would be preserved. A caveat of the mechanism is that its success hinges on the density profile of the incoming satellite, and it has been demonstrated by Huang and Carlberg that mergers with low-density satellites, of the kind one observes in the local neighborhood now, do not produce disk thickening, but rather lead to disk tilting as they are assimilated into the larger system.

Since the thick disk is old, indeed as old as the halo of the Galaxy to within the observational uncertainty of 2–3 Gyr, the model requires that the most recent merger of this kind occurred $\gtrsim 10$ Gyr ago.

It is important to recall that the Searle–Zinn formation scenario for the halo of the Galaxy invokes the need for the merger of fragments in the forming system. Given that the age of the thick disk is commensurate with that of the halo, one should not be surprised to find that assimilation of fragments (not necessarily as large as those discussed in the above simulations) played a role in determining the thickness of the disk.

Dissipative collapse formation

In 1976, Larson modeled the dissipative collapse of a rotating system and produced galaxies with thick disks having an abundance gradient. Note that his work actually pre-dates the identification of this component in the Milky Way. A more recent variation of the model, which gives insight into the manner in which the thickening may have occurred, comes from the work of Noguchi, who simulated the collapse of clumpy star-forming galaxies in an effort to explain the peculiar morphology of high-redshift systems. The evolution of a typical galaxy is shown in figure 4. Beginning with a rotating ensemble of gaseous and dark matter particles, a

Dirac House, Temple Back, Bristol, BS1 6BE, UK

disk system forms on a timescale of 1 Gyr. Its evolution is critically determined by the formation of distinctive clumps of mass $10^9 M_\odot$. Dynamical friction causes these to spiral towards the galactic center, creating a bulge, while during the process stars and gas scatter off the clumps, thickening the disk. The scale height of the old stellar component in the model was 1.9 kpc, a little larger than that observed in the Milky Way, but not unlike the value observed for the thick disk of other galaxies (see also GALAXY EVOLUTION).

It will not have escaped the reader that we may have just entered the region of semantics. Perhaps the clumps in this formalism and the small merger fragments discussed at the end of the previous section are not unrelated. Indeed, the relative importance of the accretion and dissipative collapse mechanisms may turn on the spectrum of structure sizes in the vicinity of a forming galaxy.

Comparing the observations with model scenarios

What then may one conclude concerning the nature of the thick disk and what it has to tell us about the manner in which the disk formed? It is probably not unreasonable to conclude that most workers are inclined to the view that it resulted from a minor merger some ∼10–12 Gyr ago. One can certainly reproduce most of the observations in this manner, modulo, for example, the final word on the existence or otherwise (and their interpretation) of gradients, which are not predicted in this model. One might also be concerned by the necessity of mergers of the disk with 'hard' as opposed to 'soft' satellites noted in the previous section.

Another challenge for this scenario is to explain the nature of the so-called 'metal-weak thick disk'. Is it also discrete, and also produced by a merger? The critic might also well ask: is discreteness of the thick disk population(s) necessarily required by the observations, or are they really part of a continuous disk configuration? One will find in the bibliography below the challenge of Nemec and Nemec to all who would make claims on this matter: 'In most models of the Galaxy the number of components is based on preconceived ideas or on a subjective assessment of the observational data ... More objective ... procedures for estimating the number of components and goodness-of-fits tests ... for comparing competing models are available.'

Problems also abound for those who would advocate the alternative world view of a dissipative origin of the thick disk. While models of dissipative Galactic collapse exist in the astronomical literature, too few details are available with which one may confront the observations, and no detailed comparison is possible at this time.

Future prospects

The most limiting factor in efforts to understand the population structure of the Galaxy has been our necessary reliance on solar neighborhood samples within a few hundred parsecs of the Sun, where the important halo and thick disk stars represent only very small fractions, ∼0.001 and ∼0.02–0.05, respectively, of field stars. Ideally, one would like to observe samples well away from the Galactic plane, at distances of a few kpc, where the contaminating influence of the thin disk will be minimized. Fortunately, with the current advent of large multifiber spectrographs on 4 m class (and larger) telescopes which will permit the simultaneous observation of several hundred objects at these distances, this is now becoming possible. In principle, one may now obtain samples of several thousand stars (near main sequence turnoff dwarfs) in various critical directions (towards, for example, the Galactic poles, center and anticenter, and in directions of Galactic rotation) with a view to separating out the populations discussed above and to more strongly constraining the reality or otherwise of gradients, dependences of kinematics on abundance and substructure within components.

Because of their different characteristics, the halo and disk will give different signatures in different directions in the Galaxy, and one will be able to disentangle thick disk and halo several kpc from the Galactic plane and to look for the distinctive features of dissipation and merger events. One will be able to determine whether there is any evidence for vertical and radial gradients in abundance and kinematics, together with the density and (systemic) rotational properties of the various subcomponents.

When these data are available one will be in a sound position to confront the results of the various models of the manner in which the thick disk formed.

Galactic Thin Disk

Of the components of our MILKY WAY GALAXY, the thin disk is the most prominent part to our eyes. It manifests itself as the band of faint light that we see encircling the whole sky. Except for the bulge in the direction of the center of our Galaxy, the stars that make up the Milky Way as we see it are part of the thin disk, just as our Sun is part of that same population of stars. A remarkable fact is that when we look at the Milky Way from the southern hemisphere in winter—when the center of the Galaxy is almost at the zenith at midnight—the appearance is strikingly similar to somewhat later Hubble class, edge-on galaxies such as NGC 891 (of Hubble type Sb).

The young disk

As we will see below, the thin disk is made up of stars of a large range of ages. The youngest have only just formed out of the interstellar medium; the gas and dust between the stars out of which stars are being formed is generally considered to be part of the young disk. The gas can be mapped easily using the 21 cm line of neutral hydrogen (H I) and this has been done extensively for our Galaxy since RADIOASTRONOMY started to be practised in a systematic manner in the 1950s. It took until the 1970s, with the advent of aperture synthesis radio telescopes, until it could be done with sufficient angular resolution in external galaxies. The neutral hydrogen extends usually much further than the stellar disk, often exhibiting a deviation from the plane of the inner galaxy. This can be seen in edge-on galaxies as a curving upward on one side and a symmetric curving downward at the opposite. In moderately inclined galaxies there are kinematic signatures of these so-called warps.

The measurements of the neutral gas have to be supplemented by observations of the distribution of the molecular gas, most abundant in molecular hydrogen H_2. This, however, cannot be observed directly and its distribution is inferred from radio measurements of spectral lines of carbon monoxide, CO. This is transferred into distributions of H_2 by a still rather dubious 'X factor' which descibes the ratio of H_2 versus CO. This X factor is predicted on theoretical grounds and the dubious assumption is made that it is the same from galaxy to galaxy and with galactocentric radius in spite of known variations in heavy-element abundance and radiation field (the latter being important for photodissociation (see PHOTODISSOCIATION REGIONS)). The molecular gas is found to be concentrated to a large extent in giant molecular clouds (GMCs) that contain masses up to $10^6 M_\odot$ (see INTERSTELLAR MOLECULAR CLOUDS). In these GMCs star formation appears to be occurring.

The interstellar gas then is distributed in a very thin layer—much thinner than the older disk stars—with a thickness of order 100 pc. The molecular gas is more concentrated toward the galaxy's center. The velocity distribution at any position in the disk is largely isotropic with (one-dimensional) velocity dispersions of order 7 km s^{-1}.

STAR FORMATION occurs in groups. This is because for the conditions in the interstellar medium a gas cloud can only be unstable with respect to its own gravity if its mass exceeds about 10^5 or so $M_\odot$. This so-called Jeans' mass can be derived crudely as follows. Consider a spherical region of radius R and density ρ, or mass $M = \frac{4}{3}\pi R^3 \rho$. The gravitational (potential) energy can be calculated to be

$$\Omega = -\frac{3GM^2}{5R}.$$

The kinetic energy due to the random motions with dispersion $\langle V^2 \rangle^{1/2}$ is roughly

$$T = \tfrac{1}{2} M \langle V^2 \rangle.$$

The virial theorem then tells us that this region will not contract under its own gravity as long as $\Omega + 2T$ is positive, or in other words as long as there is sufficient kinetic energy to overcome the gravitational force. This then translates into a maximum radius for stability that is called the Jeans' length,

$$R_{\rm Jeans} = \left(\frac{5\langle V^2 \rangle}{4\pi G \rho} \right)^{1/2}$$

and the mass contained within this radius is the Jeans' mass.

In the interstellar medium near the Sun the gas density is of order 1 H atom cm^3 and the velocity dispersion is about 7 km^{-1}. Then $R_{\rm Jeans} \sim 400$ pc. This is more than the thickness of the gas layer. A circular area of the disk with this radius contains about $10^6 M_\odot$ in the form of gas.

Clusters of newly formed stars are called associations. There are two types, depending on the kind of stars seen in them. The most prominent are the OB ASSOCIATIONS; their brightest stars are heavy O and B stars and they are usually accompanied by H II REGIONS, where the interstellar gas is ionized by the UV radiation from these hot stars. The second type is called T associations; these are made up of T TAURI STARS, which are stars of solar mass or somewhat less contracting on their way to the main sequence. The existence of these two types of associations is one basis for a proposed concept of bimodal star formation, in which massive and less massive stars are formed independently.

The distribution of OB associations can be studied in much detail. In agreement with the fact that associations are formed out of the interstellar medium recently, they are also found in our Galaxy in a thin layer, comparable in thickness with that of the gas. The local system of OB stars deviates from that of the plane of the Galaxy; it is confined to a narrow, tilted layer; this is called GOULD'S BELT, since it is reflected in the distribution of OB stars on the sky and this is also generally along a great circle inclined to that of the Milky Way. The velocity distribution of OB stars also deviates from being isotropic, although the velocity dispersion is comparable with that of the gas. The long

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

axis of the velocity distribution does not point toward the Galactic center (has a so-called vertex deviation); this is probably the result of local disturbances in the smooth density distribution in the disk due to the spiral structure of the Galaxy.

Open clusters

Stars are being born in groups or clusters, each representing of the order of $10^5 M_\odot$. Most clusters dissolve in the course of time as a result of the gravitational interactions with the surroundings. Irregularities, such as those associated with spiral structure, are believed to play a major role in this, but also condensations in the interstellar medium, such as the GMCs, are important. It is not known which stars belong to the same cluster in which the Sun was one of the stars being born. Finding out about this is almost certainly impossible. Yet, some clusters or at least their more solidly bound central parts survive, in some cases as long as the age of the disk.

So, we have a whole range of clusters of varying ages. Their ages can be derived from their HERTZSPRUNG–RUSSELL DIAGRAMS. The youngest are the associations discussed above, the oldest—such as the cluster NGC 188—have ages up to about 10^{10} yr. Local examples are the Hyades (consisting of relatively bright stars over a fairly large area of sky and having an age of almost 10^9 yr) and the Pleiades (the brightest stars being visible to the naked eye and having an age of about 10^8 yr).

Star clusters are entities that have been able to retain their structure and to form a relatively securely bound group of stars. Clusters that have dissolved by gravitational tidal effects still may survive as recognizable clusterings in phase space. Even if the prominent structure of clusters in coordinate space has disappeared, their signatures in velocity space may survive on a longer timescale. Structure in the distribution of space velocities of common stars in the neighborhood of the Sun does show clear records of the dynamical history of the disk in the form of the so-called moving groups: collections of stars that are isolated in phase space and appear to share other properties such as age and/or abundance of heavier chemical elements.

The old disk

The old disk contains most of the mass in stars in the disks of our and other galaxies. In spite of the prominence of spiral structure in pictures of DISK GALAXIES, the underlying smooth component contains most of the light (and mass). The fact that spiral structure is so evident in atlases of galaxies derives from the fact that photographic print emphasize the gradients (photography essentially being a logarithmic process). Digital surface photometry shows that even the bright H II regions in the SPIRAL ARMS and the dustlanes on the inside of the arms are only relatively minor disturbances on the underlying brightness distribution. In a vertical column through the disk of our Galaxy in the solar neighborhood, the OB stars contribute only a third or so to the integrated surface brightness. For what follows we can take in external galaxies the surface brightness of the disk to be mainly representing the distribution of older disk stars, even at relatively blue optical wavelengths. The light from the older disk stars is of course dominated by their brightests members, i.e. the giant branch stars among them.

From studies of the surface brightness distributions in spiral galaxies—starting with those by de Vaucouleurs in the 1940s and 1950s—it was found that the radial fall-off from the center onwards is exponential. That is to say, the surface brightness can be fitted to a function of the form

$$L(R) = L_0 \exp\left(-\frac{R}{h}\right)$$

where h is called the scale length. The surface brightness $L(R)$ is expressed here in $L_\odot$ pc^{-2}, but in practice is measured in magnitudes per arcsec^2 and indicated by μ. For the majority of the bright spiral galaxies, Freeman in 1970 found that the central surface brightness was remarkably constant at 21.6 B magnitudes arcsec^{-2}. In the meantime, many galaxies with fainter central surface brightnesses have been found, but these are mostly small dwarf galaxies or a minority of so-called low-surface-brightness galaxies (constituting a small fraction of the mass in stars in the universe), but the result stands for the common disk galaxies such as our own.

The cause of this exponential nature of the distribution of stars appears to be the distribution of angular momentum in the gas from which galaxies form. The angular momentum probably results from tidal interactions between protogalaxies in the early universe, when they were much closer together. Irregularities in their mass distribution made them susceptible to gravitational tidal fields from their neighbors, resulting in a spinning-up of these gas clouds. It is commonly accepted that this, when the protogalactic gas clouds detached themselves from their surroundings in the expanding universe, resulted in entities closely resembling a uniform-density, uniformly rotating sphere. That is to say, the more or less spherical density distribution had a roughly uniform density and rotated everywhere with the same angular velocity. If this distribution of angular momentum is conserved during the collapse of the gas (after some of it was taken away as the stars that form population II in the halo) into a disk, then a roughly exponential distribution as observed will follow. This assumes that the gravitational field is mostly determined by that of a dark halo with a density distribution falling off as R^{-2} as implied by the rotation curves of spiral galaxies. The exponential nature of the light (and presumably mass distributions in galaxy disks) seems to reflect the effect of how galaxies acquired their angular momentum in the early universe.

The older disk stars form a system that is clearly thicker than that of the young population (see also GALACTIC THICK DISK). From the common stars in the solar neighborhood this follows both from counts that can be used to derive their spatial distribution as well as from

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

their kinematics. The velocity dispersion of stars such as our Sun locally is of the order of 20 km s^{-1} in the direction perpendicular to the Galactic plane. This is much higher than that of the young population and consequently the thickness of the thin disk of older stars must be much larger than that of the gas and very young stars. Since this system of old disk stars is almost certainly effectively self-gravitating (that is to say, these stars themselves provide essentially all of the gravitational force in the direction perpendicular to the plane; the z-direction) it can be expected that the spatial density distribution should approximate that of an isothermal sheet. This is a stratified layer in which the velocity dispersion is constant with distance from the plane.

It is well known that such an isothermal, stratified distribution, where stars move under the collective gravitational force of themselves, can be written as

$$\rho(z) = \rho(0)\,\mathrm{sech}^2\left(\frac{z}{z_0}\right)$$

where the vertical scale parameter z_0 is related to the velocity dispersion $\langle V_z^2\rangle^{1/2}$ by

$$z_0 = \frac{\langle V_z^2\rangle}{\pi G\sigma}$$

with σ the surface density (integrated over a vertical column):

$$\sigma = 2\rho(0)z_0.$$

Comparison with the distribution of stars in the solar neighborhood and their kinematics shows that this is a remarkably good approximation to the actual situation. The inferred vertical density distribution at larger distances from the plane approximates an exponential:

$$\mathrm{sech}^2\left(\frac{z}{z_0}\right) \approx 4\exp\left(-2\frac{z}{z_0}\right).$$

This has indeed been observed in the surface brightness distribution in external disk galaxies when seen edge on. What is more remarkable is that the scale parameter z_0 is to an excellent approximation independent of distance from the center. Using the exponential radial distribution mentioned above, it follows that the space distribution of old disk stars in a spiral galaxy can be described very well by

$$\rho(R,z) = \rho(0,0)\exp\left(-\frac{R}{h}\right)\mathrm{sech}^2\left(\frac{z}{z_0}\right).$$

Dynamical heating

When we look at more detail into the distribution of velocities of common stars in the solar neighborhood we find that their velocity dispersions increase with age. Apparently, stars are being born with the velocity distribution of the interstellar medium from which they form and subsequently gain velocity. Although the interstellar medium appears—as a result of collisions between gas clouds—to be essentially isotropic, the process by which stars on average gain in space motion quickly makes their velocity distribution anisotropic. The gain in velocity is at first rather rapid, but then seems to level off when the age is a few billion years. In the radial direction the gain in velocity is largest, leveling off at about 40 km s^{-1}, while in the vertical direction it reaches only about 20 km s^{-1}. This difference is possible because the motion in the vertical direction is independent of the motion in the Galactic plane. The increase of space motion of disk stars with age is usually referred to as dynamical heating or as secular evolution.

There are two processes that may be responsible for this dynamical heating. The first, proposed by Spitzer and Schwarzschild in the 1950s, is by scattering of stellar orbits by encounters with large mass concentrations in the interstellar medium in the disks; these were later identified with the GMCs mentioned above. This will statistically speed up the motions of the stars, but will quickly become less efficient and the space motions of the stars will level off as observed. This is so because, when the motions increase, stars will spend a larger fraction of the time out of the thin layer where the GMCs reside and the scattering will quickly become less effective.

The second mechanism was proposed in the 1960s by Barbanis and Woltjer and is the scattering of the stars by encounters with spiral arms. These also constitute variations in the gravitational field. This mechanism is less effective in the vertical direction, because the period of vertical motion of stars is very different from that from encountering the spiral structure. In the radial direction there is much more of a resonance between these encounters and radial oscillations and the effect is more efficient. Theoretical studies indicate that the first mechanism would predict the ratio of the vertical to radial velocity dispersions to be larger than observed, so it is likely that (at least in our Galaxy in the neighborhood of the Sun) the second mechanism has been more effective. Still, at various positions in different galaxies the actual dynamical heating is probably accomplished by both processes in varying relative importance.

Random motion of the old disk stars in galaxies is vital for matters of stability. If there were no relative motion of the stars, the disks of old stars would not be able to be as smooth as they are; any statistical density fluctuation would quickly result in gravitational collapse and the disks would break up in many dense concentrations. This is a dilemma that goes back to the days of Isaac Newton: if every star attracts every other one then why would they not have collapsed into a dense concentration? Newton's incorrect answer was that stars are distributed evenly in space, such that every star is pulled equally in all directions by the other stars. We now know that the correct answer is that stability derives from the relative motions of the stars, providing in essence a kind of pressure that prevents these gravitational instabilities from occurring.

Now return to galactic disks. We have seen that the random motions of the stars can stabilize any distribution

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

up to a certain radius. For flat disks we can rewrite this Jeans' criterion as follows. In an infinitesimally thin disk we have a surface density σ and a velocity dispersion $\langle V^2\rangle^{1/2}$. Then the kinetic energy in a region with radius R is

$$T = \tfrac{1}{2}\pi R^2 \sigma \langle V^2\rangle$$

and the potential energy is roughly

$$\Omega = \frac{2\pi^3}{3} G\sigma^2 R^3.$$

For this case of a very thin disk then the Jeans' length is

$$R_{\rm Jeans} = \frac{3\langle V^2\rangle}{2\pi^2 G\sigma}.$$

For the old stellar disk in our Galaxy in the neighborhood of the Sun, the surface density is about $80 M_\odot$ pc^{-2} and the velocity dispersion roughly 40 km s^{-1}. Then this radius comes out as about 5 kpc. So we find that random stellar motions can stabilize the old stellar disk only up to moderate scales.

So something else has to be responsible for stabilizing the disk over larger length scales. This stability can be provided by differential rotation, which means that the angular rotation velocity varies with galactocentric distance. Parts further out have a lower angular velocity and as a result of this, seen from any point in the disk, these parts lag behind in the motion around the center, while the parts further in go ahead. This appears for not too large distances as a rotation around this reference position, and the angular velocity at which this occurs is described by the so-called Oort constant B. If the rotation velocity around the center of the galaxy is $V_{\rm rot}$ then

$$B = -\frac{1}{2}\left(\frac{V_{\rm rot}}{R} + \frac{{\rm d}V_{\rm rot}}{{\rm d}R}\right).$$

This provides a centrifugal force that can counteract the gravity and in this manner can provide stability. Consider again a circular area in the disk with radius R and surface density σ. For a particle at the edge this centrifigul force is B^2R. On the other hand, the gravitational force from the matter within R is approximately that due to the mass M inside R, or $GM/R^2 = \pi G\sigma$. Now, contrary to the Jeans' stability mechanism there is a *minimum* radius for stability, because as R increases the centrifugal force due to differential rotation increases. This minimum radius occurs where this centrifugal force equals the attraction due to gravity and is

$$R_{\rm min} = \frac{\pi G\sigma}{B^2}.$$

In our Galaxy in the solar neighborhood the Oort constant $B \sim -13$ km s^{-1} kpc^{-1}. This then gives $R_{\rm min} \sim 5$ kpc.

As Alar Toomre first described in 1964, a galactic disk is thus stable at all length scales, if this minimum radius is equal to or smaller than the Jeans' length. From the numbers given, we see that the disk of our Galaxy is indeed stable, but only just. So, disks can be stabilized at small scales by random motions and at large scales by differential rotation. Putting the two together then gives for a disk with given surface density and differential rotation a minimum velocity dispersion required for stability:

$$\langle V^2\rangle^{1/2}_{\rm min} = \left(\frac{2\pi}{3}\right)^{1/2} \frac{G\sigma}{|B|}.$$

Stars that have a small velocity with respect to the the general rotation will, in a coordinate system that rotates along with this general rotation, descibe a small elliptical orbit (an epicycle) in which it goes around in a period $2\pi/\kappa$ and

$$\kappa^2 = -4B\frac{V_{\rm rot}}{R}.$$

κ is the so-called epicyclic frequency. In actual galaxies the rotation velocity $V_{\rm rot}$ is constant with radius over most of the disk and then $\kappa = -2\sqrt{2}B$.

Then we can rewrite the equation above as

$$\langle V^2\rangle^{1/2}_{\rm min} = 4.09\frac{G\sigma}{\kappa}.$$

In a more detailed analysis and for arbitrary rotation curves, Toomre derived this minimum velocity dispersion actually as

$$\langle V^2\rangle^{1/2}_{\rm min} = 3.36\frac{G\sigma}{\kappa}.$$

Disks of spiral galaxies, including our own, do not appear to be violently unstable. However, there is spiral structure and star formation, so some instability must occur. As it turns out, as best as we can measure the disks are close to the border between stability and instability. This presumably is the cause of the fact that star formation is regulated as a moderately slow process, whereby the conversion of the interstellar gas into stars proceeds at a reasonable rate, as observed from the distribution of stellar ages in the solar neigborhood. As we can derive from the Toomre minimum velocity dispersion criterion above, the minimum dispersion decreases with galactocentric radius, the epicycle frequency decreasing as R^{-1}, but the surface density σ exponentially. This is indeed roughly as observed. Furthermore, it implies also a decrease in the velocity dispersion in the direction perpendicular to the plane in such a way that it roughly produces the constant thickness of the thin disk (the radial constancy of the scale height parameter z_0).

Galaxies at High Redshift

Galaxies at high REDSHIFT are very distant galaxies and, since light propagates through space at a finite speed of approximately 300 000 km s^{-1}, they appear to an observer on the Earth as they were in a very remote past, when the light departed them, carrying information on their properties at that time. Observations of objects with very high redshifts play a central role in cosmology because they provide insight into the epochs and the mechanisms of GALAXY FORMATION, if one can reach redshifts that are high enough to correspond to the cosmic epochs when galaxies were forming their first populations of stars and began to shine light throughout space.

One fundamental prediction of the theory of the big bang, which has found empirical confirmation in the discovery of the cosmic background radiation, is that early in its evolution the universe consisted only of matter and radiation coupled in thermodynamical equilibrium and homogeneously distributed in space. No galaxies or stars or any other structure could exist in such physical conditions, except for minuscule primordial fluctuations of density, superimposed on the otherwise extraordinarily smooth distribution of matter and energy by quantum physical processes during the first instant of existence of the universe. Today, the universe is highly inhomogeneous, with the matter organized in a hierarchy of structures such as stars, galaxies, clusters and superclusters of galaxies. Understanding the mechanisms that led to the transition from the homogeneous early universe to the structured one observed at the present epoch is of central importance to cosmology and fundamental physics. Yet, they remain poorly understood and still defeat empirical investigation.

Our current ideas attribute the formation of the cosmic structures to the action of gravity, which amplified the primordial density fluctuations until they collapsed under their own self-gravity and became bounded structures. According to this paradigm, the epoch of galaxy formation and the properties of the nascent galaxies were decided by the properties and the relative abundances of the matter and the energy that permeated the universe shortly after the big bang. Galaxies are the building blocks of the distribution of matter in space, and an important step to decipher the history of the cosmic evolution is to identify the first galaxies that formed in the universe and study their properties at the time of their formation. The search for 'primeval galaxies' has traditionally played a central role in observational cosmology for more than three decades and, even after the spectacular accomplishments of the last 5 yr or so, is still driving much of extragalactic research.

The redshift and the expanding universe

One of the most important scientific discoveries of this century is the expansion of the universe. This makes the galaxies and the other larger structures that populate the cosmic space recede away from each other with a velocity that is progressively higher for objects that are separated in space by larger distances. If the recession velocity between two objects is small compared with the speed of light, its value is directly proportional to the distance between them, namely

$$v_r = H_0 d$$

where the constant of proportionality H_0 is called the 'HUBBLE CONSTANT'. For larger recession velocities this relation is replaced by a more general one calculated from the theory of general relativity. In each cases, the value of H_0 provides the recession velocity of a pair of galaxies separated by unitary distance, and hence sets the rate of the expansion. Since if the universe has been expanding at a higher rate it has taken a shorter time to go from the size at the big bang (close to a mathematical point) to the current size, a higher value of the Hubble constant also means a younger universe. Recent measurements of the Hubble constant place its value in the range between 60 and 70 km s^{-1} Mpc^{-1} (1 Mpc $= 3.1 \times 10^{22}$ m). This corresponds to an age of the universe between 10 and 15 Gyr (1 Gyr $= 10^9$ yr).

A result of the cosmic expansion and of the finite speed of light is that the light emitted from any given galaxy is observed by a remote observer (i.e. one located on a different galaxy, for example the Milky Way) as having a longer wavelength than it had at the emission. This is because the cosmic expansion has caused the space between the two galaxies to increase during the lapse of time between emission and detection, and while the light was traveling from one galaxy to the other. This causes a 'stretching' of the wavelength of the light, namely a shift towards longer (therefore redder) wavelengths. The fractional change in the wavelength with respect to the one at emission as measured by the observer is called the 'redshift'. It follows that, the higher the redshift, the longer the stretch in wavelength, and hence the more distant the two galaxies.

The redshift provides a measure of the distance to a galaxy as well as of the lapse of time between the instant of emission and that of observation. Thus, an observer can see the galaxy and study its properties as it was at the epoch of the emission. Galaxies located near ours have very small redshifts and are seen as they were a very short time ago compared with the age of the universe. In practice, local galaxies are contemporaries of our own, and hence the present cosmic time corresponds to redshift zero. The value of the redshift of objects seen at the time of the big bang is infinity. Figure 1 shows the relationship between redshift, distance and the corresponding age of the universe (i.e. the lapse of time from the big bang to that redshift) for two different assumptions for the cosmological parameters Ω and Ω_Λ, namely the total density of matter and the energy density due to the cosmological constant, respectively. In both cases the Hubble constant has been assumed to be 65 km s^{-1} Mpc^{-1}.

In practice, redshifts are measured from the spectra of the galaxies, namely diagrams that plot the intensity of

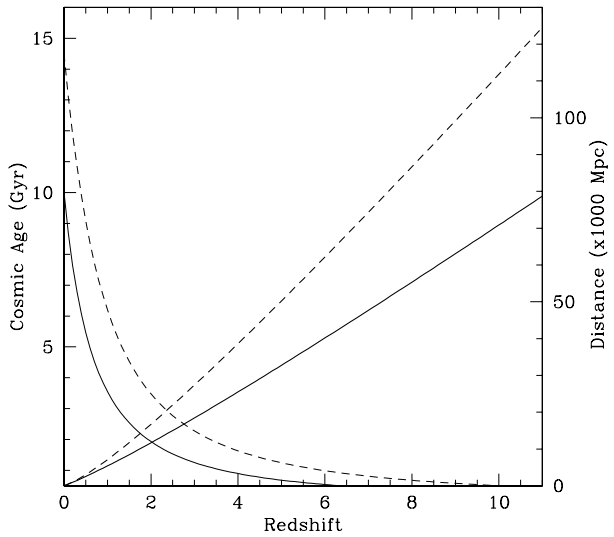

Figure 1. The relationship between redshift, cosmic age and distance for two different world models, both spatially flat (i.e. with Euclidean geometry). The Hubble constant is assumed to be $H_0 = 65$ km s^{-1} Mpc^{-1} in both cases. In one model only matter is present in space, namely $\Omega = 1.0$ (continuous curves); in the other model the space is filled with both matter and the cosmological constant, with $\Omega = 0.3$ and $\Omega_\Lambda = 0.7$ (dashed curves). The thin curves represent the cosmic age at the various redshifts. The cosmic age at the present epoch (redshift zero), is 10 and 14.5 billion years in the two models, respectively. At the time of the big bang (infinite redshift) the cosmic age was zero. Within the accuracy of the plot, redshift $z = 10$ can already be identified as infinite. The thick curves represent the distance of a source as a function of its redshift, expressed as $\times 1000$ Mpc. As a comparison, the Andromeda galaxy is at about 0.8 Mpc from the Milky Way and the Virgo cluster at about 18.5 Mpc. The most distant galaxies observed so far are located at a redshift $z \sim 5.5$.

a galaxy's light (also referred to as flux) as a function of its wavelength, by comparing the observed wavelengths of atomic and molecular features (either emission or absorption lines) with those of the same features observed in laboratories on Earth (i.e. at redshift zero). The top panel of figure 2 shows the model ultraviolet (UV) spectrum of a star-forming galaxy at redshift $z = 3$. Absorption lines can be observed as deep 'dents' in the spectrum. Another pronounced feature visible in the figure is the sudden dimming of the light at wavelengths shorter than the 'Lyman limit', as we shall discuss later.

The search for galaxies at high redshift

Because of their extreme distances, galaxies at high redshift necessarily appear to an observer as faint objects, even if their absolute luminosity is large. However, only a very small fraction of all the faint galaxies observed in a deep image of the sky are located at high redshifts. This is because galaxies have absolute luminosities that cover a wide range, extending over several orders of magnitude, and fainter galaxies are also much more abundant in space than brighter ones. As a result, deep images of the sky are crowded by a myriad of relatively close but intrinsically faint galaxies, while intrinsically luminous galaxies at high redshift are comparatively very rare. This 'contamination' by interlopers is in fact so severe that, without some criterion to cull them from the faint, nearby ones, it would be totally impractical to search for high-redshift galaxies by randomly measuring the redshifts of samples of faint galaxies until the very distant ones are found. Because of this elusiveness, high-redshift galaxies came to be regarded as the 'holy grail' of cosmological research.

Theoretical expectations of the mechanism of formation of the so-called spheroids, namely ELLIPTICAL GALAXIES and bulges of SPIRAL GALAXIES, provided a criterion to identify high-redshift galaxies. The stars that constitute the spheroids are among the oldest observed in the local universe, and currently there is no appreciable ongoing activity of STAR FORMATION in these systems. These facts indicate that the spheroids formed their stars during a very early cosmic epoch in a relatively short period of time. Since this epoch marked the first significant episodes of star formation during the cosmic evolution (note that about $\sim 1/2$ of all the stars of the present-day universe are found within spheroids), it has been traditionally identified with the epoch of galaxy formation, and the nascent spheroids themselves have been identified with the primeval galaxies.

The theoretical expectations predicted that the entire stellar content of a spheroid formed during the gravitational collapse of the proto-cloud of gas from which the structure originated. Simple physical arguments show that the duration of such a collapse is of the order of the time of free fall which, for a galaxy with the mass of the Milky Way, is about one hundred million years. If a whole galaxy's worth of stars is to be formed in such a relatively short time, the rate of formation of the stars must have reached very high values, a condition known as a starburst. For example, a galaxy like the Milky Way has a stellar mass of about $10^{11} M_\odot$[1], and if this assembled during a burst that lasted $\sim 10^8$ yr, the star formation rate must have been $\sim 10^3 M_\odot$ yr^{-1}. As a comparison, the star formation rate of the Milky way today is about $1 M_\odot$ yr^{-1}. A galaxy undergoing its first starburst is expected to emit intense UV radiation including, in particular, a very strong emission line at the wavelength $\lambda_\alpha = 1216$ Å called Lyman-α. This feature is produced by the recombination of hydrogen atoms, a gas which is very abundant in young, star-forming galaxies, photoionized by the intense UV light of young, massive stars.

Estimates of the age of the stellar populations of the spheroids place the epoch of the bursts in the redshift range $2 < z < 7$. The UV spectrum of such galaxies would then be observed redshifted to optical and near-infrared wavelengths and be detectable by ground-based telescopes and electronic detectors. For example, the

[1] The mass of the Sun is represented by the symbol $M_\odot$, and it has been measured to be $M_\odot = 1.98 \times 10^{30}$ kg.

Lyman-α of a nascent spheroid at redshift $z = 3.5$ today is observed at $\lambda_{\rm obs} = (1 + z)\lambda_\alpha \sim 5500$ Å, which is in the middle of the visible band. If at redshift $z \sim 7$ or larger the Lyman-α line is redshifted into the infrared portion of the spectrum.

Large observational campaigns to identify primeval galaxies by means of their Lyman-α emission line started in the early 1980s, when solid-state electronic imaging detectors replaced the traditional photographic plates. The electronic detectors, also known as CHARGED-COUPLED DEVICES, overcame the characteristic limited sensitivity and difficulty of calibration of the plates, which had so far limited the study of very faint objects. In the early 1990s, electronic detectors sensitive to infrared radiation also became available, which made it possible to extend the searches for Lyman-α emitters to higher redshifts than those probed by optical detectors. These observations were designed to be sensitive to sources characterized by the presence of a strong emission line. Some consisted of narrow-band imaging, namely of images taken through narrow filters that can isolate the line emission, if its redshift is such as to place it at the wavelength of the filter. The presence of the emission line is detected from galaxy's relatively brighter apparent luminosity in the narrow-band filter compared with that through a conventional filter. Other searches consisted of spectroscopy of regions of the sky and were designed to directly detect the emission line from the recorded spectra.

Interestingly, except for a handful of objects, Lyman-α emitters at high redshifts were not found, while numerous detections of relatively bright objects were expected if a whole population of galaxies (i.e. the spheroids) formed through the mechanism of gravitational collapse. The lack of detections provided support for competing models for the formation of the spheroids. These predict that spheroids were assembled through hierarchical merging of smaller subgalactic structures. These small systems themselves have formed through a gravitational collapse before they merged into larger galaxies. However, because they would be significantly smaller than the present-day bright spheroids, they are predicted to have been correspondingly fainter than massive spheroids at the time of their formation, in this way eluding detection.

Unfortunately, the lack of detections of bright Lyman-α emitters at high redshifts did not conclusively constrain the mechanism of formation of the spheroids. On the one hand it did not prove the merging scenario. On the other hand it did not disprove the monolithic collapse scenario, since other explanations can be put forward to explain the lack of Lyman-α emitters. The most important of these is the presence of dust, which can form in nascent galaxies in a relatively short time, of the order of the free-fall time, as a result of the high rate of supernova events that take place in these systems. Even relatively small amounts of dust can have large effects on the Lyman-α luminosity, because this emission line is resonant. This means that, contrary to non-resonant lines, whose photons can travel long distances within the interstellar gas before interacting with other atoms, the Lyman-α photons are constantly being emitted, absorbed and re-emitted again by virtually all the hydrogen atoms that they encounter in their path. This greatly increases the geometrical path of the photons within the gas cloud before they can leave it. This, in turn, greatly increases the chances for the photons of being absorbed and destroyed by dust grains present in the cloud, resulting in a selective dimming of the luminosity of the galaxies at the Lyman-α wavelength.

Very recently, thanks to the extraordinary sensitivity of telescopes of large aperture, such as the 10 m Keck, Lyman-α emitting galaxies at high redshift have been eventually identified (Hu *et al* 1998). Interestingly, when sufficient numbers of these galaxies were observed that their abundances in space as a function of the luminosity (the so-called 'LUMINOSITY FUNCTION OF GALAXIES') could be characterized with sufficient precision, it became clear that those luminous enough to be considered plausible proto-spheroids were too rare. By then, however, a massive population of star-forming galaxies at high redshift (with or without Lyman-α emission) had already been identified by means of another technique. While the properties of these galaxies provided an explanation for the paucity of Lyman-α emitters, they also provided plausible candidates for the present-day spheroids.

The Lyman-break technique

A completely different technique to search for star-forming galaxies at high redshift was proposed in the early 1990s. This technique exploits another major feature of the UV spectra of galaxies with ongoing star formation, namely the hydrogen ionization edge or Lyman limit.

Star-forming galaxies are very luminous at UV wavelengths and have a characteristic 'blue' spectrum, i.e. rich in radiation of short wavelengths, which is 'flat', namely the intensity of the light does not depend on the wavelength. In a diagram that plots the light intensity as a function of wavelength such a spectrum looks approximately horizontal, as the top panel of figure 2 shows. However, ionizing radiation, namely light with wavelength shorter than 912 Å, although copiously produced inside the galaxies, cannot escape them (and thus be observable), because it is entirely absorbed by the hydrogen gas, which is very abundant within and around star-forming galaxies. When a hydrogen atom is hit by a photon with wavelength shorter than 912 Å, it becomes ionized, that is its electron is stripped from the proton at the expense of the energy of the photon itself, which is destroyed.

As a result of this absorption of ionizing photons, the spectrum as recorded by an observer external to the galaxies has a very pronounced 'dimming' of more than an order of magnitude at wavelengths shorter than the Lyman limit. This is called the Lyman break (see figure 2, top panel). Additional absorption is also introduced by the intergalactic gas that the light from the galaxy travels through in its journey towards the observer. This increases the amplitude of the break even further (and also

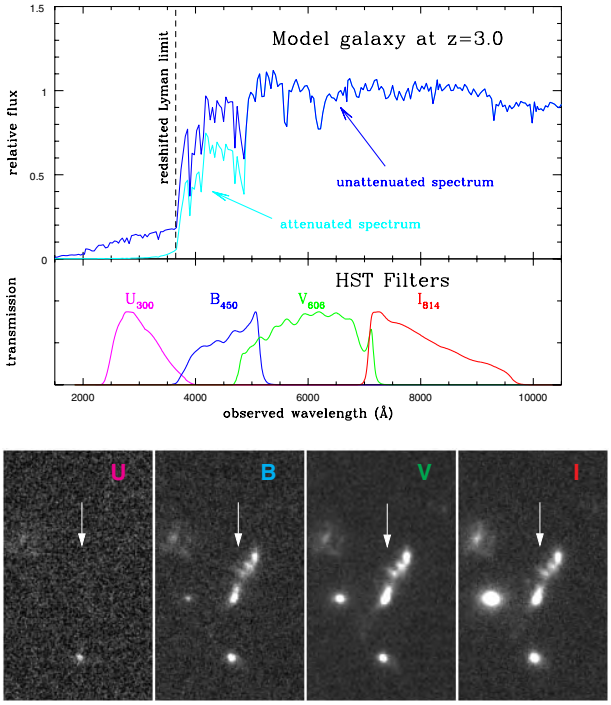

Figure 2. The UV spectrum of a star-forming galaxy observed at redshift $z = 3$, and the idea behind the Lyman-break technique. The top panel shows the spectrum redshifted at $z = 3$, namely with the intrinsic wavelengths increased by a factor $1 + z = 4$. Notice the sharp decrease of the intensity of the light at wavelengths shorter than the Lyman limit. The 'attenuated' spectrum illustrates the absorption of UV light by intervening neutral hydrogen. The middle panel shows the transmission curves of the four filters used to observe the Hubble Deep Field (HDF) with HST. When observing through a given filter, only radiation with wavelengths within the filter curve can reach the detectors. The bottom panels reproduce the images of a real Lyman-break galaxy at $z = 2.8$ (the multiple object with a sausage-like morphology indicated by the arrow) through each filter. Notice how the galaxy 'drops out' of the U filter, since this samples the spectrum to the left of the Lyman limit. Three other galaxies can be observed which do not drop out from the U filter (they are actually detected in the filter), but rather progressively dim, indicating that they are at relatively modest redshifts.

slightly attenuates the spectrum shortly before the break–see figure 2).

The Lyman break abruptly interrupts the 'flatness' of the spectra of star-forming galaxies, and provides the telltale clue to identify them. For example, at redshifts around $z \sim 3$ the Lyman break is shifted from 912 Å in the rest frame to ∼3700 Å in the observer's frame, well into the optical band, observable from the ground. When observed through a set of filters that straddle the Lyman break, star-forming galaxies at those redshifts appear relatively bright in those filters that probe the spectrum longward of the break (the I and V filters of figure 2), they dim a little just before the break (the B filter), and are extremely faint (or not visible at all) in those filters that probe shortward of the break (the U filter). Thus, by accurately measuring the light of galaxies in a carefully selected set of filters, it is possible to cull high-redshift galaxy candidates from the much more abundant galaxies of similar apparent luminosity placed at modest distances. This is illustrated in the middle and bottom panels of figure 2, which show the transmittance curves of filters used for this technique and one of the high-redshift galaxy candidates found in this way, respectively. These candidates are then followed up with spectroscopic measurements to confirm their redshifts. In practice, the selection of candidates is efficiently done with telescopes of middle size (e.g. 4–5 m), while the spectroscopic measurements to confirm the redshifts require telescopes of the 8 m class or larger. The candidate shown in figure 2 has been confirmed to be at redshift $z = 2.8$.

The wavelength of the filter bandpass is what determines the redshift range of the candidates. The filter suite shown in the figure is very sensitive in the redshift range $2 \lesssim z \lesssim 3.5$. However, by excluding the U band and using the B band in lieu to probe shortward of the Lyman limit, together with the V and I bands to probe longward of it, one can target higher redshift intervals, which in this case $3.5 \lesssim z \lesssim 4.5$. Other redder filters can be used for even higher redshift intervals.

The 'Lyman-break technique' turned out to be very sensitive and efficient. Although the exact numbers depend on the targeted redshift range, the fraction of the candidates that are confirmed at high redshifts by the spectroscopic measures is very high. For example, galaxies in the range $2 \lesssim z \lesssim 3.5$ are identified with essentially 100% efficiency. In the range $3.5 \lesssim z \lesssim 4.5$ the efficiency is still ∼50%. Two major surveys have been made using the Lyman-break technique. The largest one has been carried out by Steidel and collaborators (Steidel *et al* 1996, 1999) using ground-based telescopes for both the selection of the candidates and the spectroscopic confirmation. To date, this survey includes about 2000 candidates at $z \sim 3$, of which ∼1000 have spectroscopically measured redshifts, and another ∼300 candidates at $z \sim 4$ with ∼60 spectroscopic redshifts.

Another important survey has been made from space using the data collected by the Hubble Space Telescope during the observations of the HDF (HUBBLE DEEP FIELD) survey (Madau *et al* 1996). Although significantly smaller in size than the ground-based survey owing to the limited coverage of sky area, the HDF has allowed the identification of significantly fainter Lyman-break galaxies than possible from the ground, allowing researchers to study how the properties of these systems change with their luminosity. Because the archive is freely accessible to the world community, several groups have used the HDF data to identify high-redshift galaxies, and there have been reports of possible detection of galaxies with redshifts as high as $z \sim 5.5$ in the HDF.

The nature of high-redshift galaxies

The samples of high-redshift galaxies made available by the Lyman-break technique have eventually allowed

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

researchers to carry out empirical studies of their properties, opening the distant universe to the entire investigation. These studies include both statistical analysis of the large samples themselves as well as follow-up observations, including high-angular resolution imaging with the Hubble Space Telescope and imaging and spectroscopy at near-infrared wavelengths (to study the rest-frame optical ones) from large ground-based facilities and again from HST. This work has allowed us to test our fundamental ideas on galaxy and structure formation on an empirical basis.

One important thing must be kept in mind when interpreting the galaxies' properties. The UV luminosity of star-forming galaxies (i.e. the intensity of the UV spectrum) is powered by the emission of young, massive stars, those approximately 20 times more massive than our Sun, while less massive stars are responsible for the optical and infrared luminosity. Massive stars are produced during star formation together with less massive ones, but, in contrast to the latter, which can live up to several billion years (depending on their mass), they only live about a million year or so, and then they explode as SUPERNOVAE. If the star formation continues in a galaxy at a steady rate, new massive stars constantly replace the dead ones, and the UV luminosity of the galaxy remains constant. The higher the star formation rate, namely the higher the number of massive stars formed in a given time, the larger the UV luminosity of the galaxy. At the same time low-mass stars keep piling up, increasing the optical luminosity of the galaxies. If star formation ceases, massive stars die off within a few 10^6 yr, and the UV luminosity fades away. The galaxy, however, remains visible at optical and infrared wavelengths because of the long-lived less-massive stars. The longer the duration of the star formation phase, the larger the amount of small-mass stars formed and the higher the optical and infrared luminosity. Thus, the UV luminosity of star-forming galaxies is a direct measure of their star formation rate, while the optical luminosity is linked to the amount of small stars that have been formed.

The assembly of galaxy structures

High-resolution images at optical wavelengths obtained with HST have revealed a variety of morphologies and sizes (Giavalisco *et al* 1996). Since at these high redshifts optical images probe the UV light, they provide information on the regions with active star formation. The images show that some galaxies are compact systems, with relatively smooth and regular morphology that bears a pronounced resemblance to the spheroids observed in the present-day universe. One example of such galaxies is shown in figure 3. Other galaxies are also regular, but they have more diffuse light profiles (i.e. the variation of the brightness from the center to the outer regions) and look more similar to present-day spirals, although familiar features of these systems such as the spiral arms have not been identified at high redshift. Still other galaxies are irregular and fragmented, often showing multiple compact nuclei embedded in diffuse nebulosity, and overall morphology that cannot be classified in terms of the traditional galaxy types. One example of this category is the galaxy at $z = 2.81$ shown in the bottom panel of figure 2.

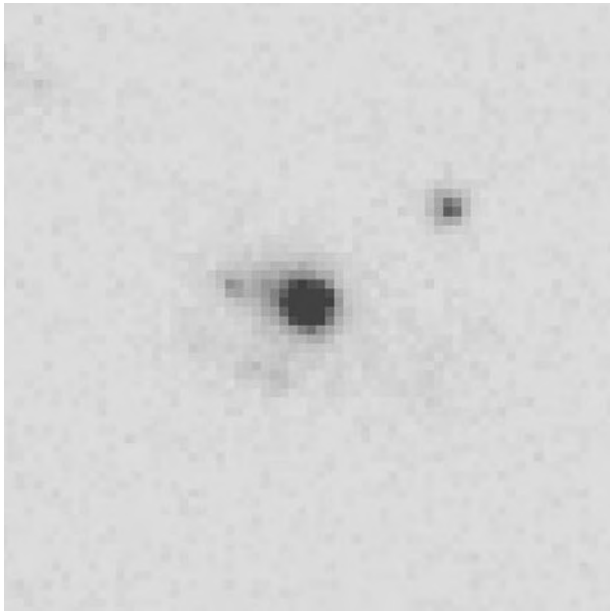

Figure 3. Picture of a Lyman-break galaxy at redshift $z = 2.96$ taken with the Hubble Space Telescope and the WFPC2 camera (the faint source to the upper left of the galaxy is unrelated). The image has been taken through the *V* filter F606W. The angular resolution is 0.05 arcsec, corresponding to a spatial scale of $\sim$0.5 kpc, and the size of the square image is 3.2 seconds of arc, or 27 kpc. The galaxy shows a regular morphology, and it is characterized by the same light profile commonly found in elliptical galaxies and bulges (the 'spheroids') of the present-day universe. The regular morphology of this galaxy contrasts with the fragmented structure found in the Lyman-break galaxy at $z = 2.81$ shown at the bottom of figure 2 (the third image from left of this galaxy has also been taken with the V filter F606W).

This diversity points to a variety of formation mechanisms. The compact, spheroidal galaxies can be explained if they formed as a result of a violent dynamical process, either a gravitational collapse of a proto-cloud or the merging of a number of discrete subunits, the more diffuse ones through the constant accretion of gas onto a rotationally supported disk, where it is converted into stars. In either case, the interesting fact is that the light profile of these galaxies strongly suggests that they are dynamically evolved and stable systems. At the observed rates of star formation and if left undisturbed in the course of evolution, they will have evolved into what are today elliptical and spiral galaxies of medium mass and luminosity, respectively. The fact that intense star formation seems to be occurring in these systems after the main dynamical event that gave origin to their structure (and most likely triggered the star formation activity) took place suggests that continued hierarchical merging after

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

redshift $z \sim 3$ is not necessary for the formation of some galaxies. One prediction in this case is that the mass of the regular Lyman-break galaxies is similar to that of present-day elliptical and spiral galaxies.

On the other hand, the irregular and fragmented morphology of other Lyman-break galaxies suggests that intense star formation occurs during interactions and merging events. In this case the expectation is that the mass of the forming galaxies progressively increases during the evolution (i.e. at smaller redshifts) and hence Lyman-break galaxies at $z \sim 3$ should also include small, submassive systems.

Direct measurements of the mass of distant galaxies are very difficult at the present, even with the most powerful of the current telescopes, whereas they will be routine with large-aperture space telescopes such as the proposed NASA 8 m Next Generation Space Telescope. Great progress in understanding the mechanisms of galaxy formation is expected with such a facility.

The cosmic evolution of star formation

One of the most important results that came out of the discovery of galaxies at high redshift is the possibility to reconstruct the evolution of the activity of star formation in the universe over a very large stretch of cosmic time. The temporal interval currently probed extends from the present epoch to when the universe was about 10% of its current age.

The amount of stars being produced in the universe at any given epoch can be estimated from the abundance and UV luminosity of star-forming galaxies at that epoch. The abundance is measured by their volume density, namely the number of galaxies in a given volume of space, for example 1 Mpc^3 (2.9×10^{67} m^3), while the luminosity is directly obtained by the photometry of the sources detected in the images. The counts of Lyman-break galaxies down to the faintest available UV luminosity, therefore, can be used to derive a measure of the UV luminosity density. Recalling that the UV luminosity is proportional to the star formation rate, this can then be expressed as star formation density, namely the amount of stellar mass formed in a given volume of the universe at a given redshift. A practical unit of measure for the cosmic star formation density is expressed as solar mass per year per cubic megaparsec, or $M_\odot\ \mathrm{yr}^{-1}\ \mathrm{Mpc}^{-1}$.

The diagram in figure 4 (top) shows the cosmic star formation density plotted (on a logarithmic scale) as a function of redshift. The different symbols indicate different surveys that have measured the cosmic star formation density in a variety of redshifts intervals, marked by the horizontal bars. Also shown are the uncertainties on the measurements, marked by the vertical bars.

Taken at face value, the diagram suggests that cosmic star formation activity started sometime just before redshift $z \sim 5$, gradually increased towards smaller redshifts, reaching a peak at redshifts $z \sim 1$ (about 1/3 of the cosmic age after the big bang) and then rapidly decreased towards the present epoch (i.e. $z = 0$) to the same levels as at $z \sim 5$. If confirmed, this would be a very interesting result, because it would empirically support the idea that during its early evolution the universe experienced a time when it contained no stars (dark age).

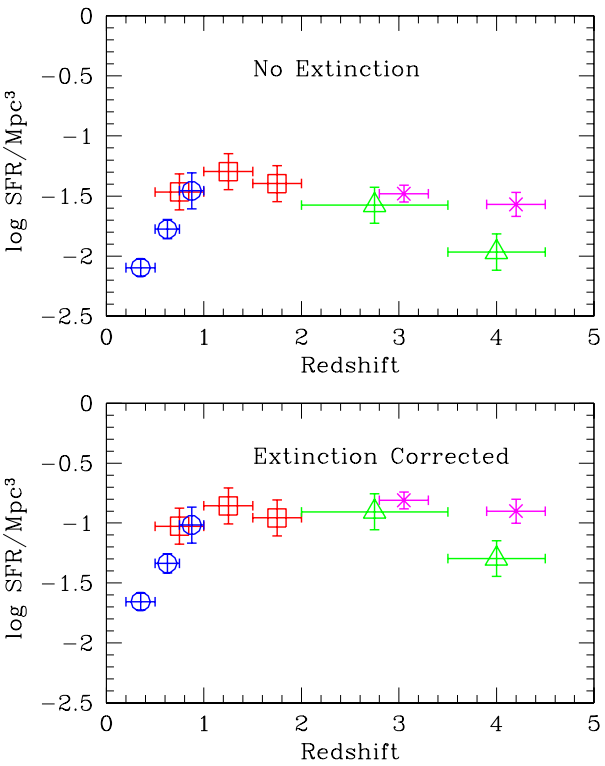

Figure 4. The history of cosmic star formation. Both plots show observations of the star formation density, namely the stellar mass produced every year in a cube of space 1 Mpc on a side, as a function of redshift. The y-axis is plotted on a logarithmic scale, and the mass is measured in units of the solar mass, i.e. 2×10^{33} g. The vertical bars for each data point represent the uncertainties on the measurements. The horizontal bars represent the redshift intervals covered by each data point. The top panel shows the data as observed; those in the bottom panel have been corrected for dust absorption, assuming that the properties of the dust do not change with redshift and are the same as observed in the local universe. Notice that the uncorrected data seem to suggest that the cosmic star formation began sometime prior to redshift $z \sim 5$, progressively increased until it reached a peak at $z \sim 1$ and then sharply decreased towards the present epoch, i.e. $z = 0$. The corrected data, however, do not support this interpretation, suggesting instead that the epoch of the onset of star formation in the universe has not yet been observed by the current data, and must be searched for at redshifts higher than $z \sim 5$.

However, these measurements must be taken with great caution, since they can be subject to systematic errors that can bias the results. As should be clear, the measures of abundance are of a statistical nature, since they are based on galaxy counts, and therefore they rely on the assumption that the observed samples at high redshift

Dirac House, Temple Back, Bristol, BS1 6BE, UK

are fair representations of the population of star forming galaxies at their epochs. This would not be the case, however, if the samples were too small, because in this case they could be subject to a statistical fluctuations (cosmic variance) and be either overpopulated or underpopulated in galaxies, depending whether an overdensity or underdensity region, respectively, has been (by statistical chance) targeted.

Another more serious and insidious source of systematic error is that measures of UV luminosity can be affected by unknown amounts of dust obscuration. The interstellar medium of nascent galaxies becomes polluted by dust in short time scales, as this is produced in the supernova explosions that end the short lives of massive stars. Dust affects the observed luminosity of these sources, because it absorbs UV and optical radiation and converts it into infrared radiation. Moreover, the absorption is more severe for radiation with shorter wavelengths than with longer ones. As a result, the observed UV spectra are fainter and redder than they would be if dust were not present, and an observer would conclude from them that the galaxies are less luminous and hence forming stars at a lower rates than they actually are.

Qualitatively, the presence of dust in the Lyman-break galaxies at $z \sim 3$ and $\sim$4 has been revealed by a number of indicators. These include the observed UV spectra, which are systematically somewhat redder (richer in radiation with longer wavelengths) than those of known dust-free galaxies with similar properties. Another indicator is the intensity of the rest-frame optical emission lines (observed at near-IR wavelengths, because of the redshift) which are comparatively too strong for the observed UV luminosity, consistently indicating the presence of dust reddening. Quantitatively, however, it is extremely difficult to estimate the amount of obscuration suffered by the galaxies and, therefore, attempt a correction to recover the intrinsic luminosity and star formation rates. This is because the correction depends on the properties of the dust (the so-called 'extinction curve') and on the shape of the 'unreddened' spectra (i.e. those that would be observed without dust obscuration). Since these are not precisely known, the correction can only be computed after making some assumptions, and thus it will depend on them.

The bottom panel of figure 4 shows the evolution of the cosmic star formation activity after corrections for dust obscuration have been made, assuming that the properties of the dust and the intrinsic spectra of the galaxies at high redshift are similar to those of starburst galaxies in the local universe. If these assumptions are realistic, the correction at $z \sim 3$ is about a factor of 5, implying that the amount of star formation at those cosmic epochs was actually 5 times higher than what one would naively derive using the observed data without any dust correction. Changing the assumptions to cover all the known cases of dust properties and spectra of star-forming galaxies would change the correction, making it as small as a factor of 2 or as large as a factor of 15.

Irrespective of the exact value of the correction, however, the important fact is that there is no obvious evidence for a decline of the cosmic star formation activity towards high redshifts (i.e. past $z \sim 1$) when some amount of dust correction is attempted. This means that, going toward the highest redshifts probed by the current galaxy surveys, namely $z \sim 4.5$ or $\sim$10% of the cosmic age, really there is no evidence that the cosmic star formation activity is decreasing from the level reached at $z \sim 1$. In other words, there is no evidence from the current data that, going from large redshifts toward small ones, we are seeing the end of the dark era and the beginning of the epoch of star formation, namely the transition from the epoch when the universe did not contain stars in appreciable quantities to when it started to efficiently form them. It seems now very likely that to detect and study this transition we will have to identify galaxies at even higher redshifts than we currently are capable of doing.

Are there more high-redshift galaxies?

One interesting question to ask is whether the Lyman-break technique, i.e. the selection of distant galaxies from their UV emission, returns all the galaxies that are physically present at the targeted redshifts. Star-forming galaxies with a large amount of dust or old galaxies, namely with previously formed stellar populations and no star formation activity, have very little UV luminosity, if any at all, and cannot be found with the Lyman-break technique. Discovering such galaxies at very high redshifts (say, $z > 3$), if they exist, would have enormous consequences. On the one hand, if UV-dark star-forming galaxies are present in large numbers, this means that we have severely underestimated the amount of stars formed early in the universe. This implies that today there are many more stars and heavy elements[2] than we currently observe in the universe. On the other hand, if old galaxies are already present at very high redshifts, this would imply either that we have underestimated the age of the universe or that we do not understand very well the physical conditions of the early universe or time scale of STELLAR EVOLUTION.

Recent imaging observations at sub-millimetric wavelengths (Lilly *et al* 1999) have unveiled a population of sources with properties consistent with star-forming galaxies at high redshift whose UV radiation is being either partially or completely absorbed by dust and re-emitted at far-infrared wavelengths (observed as submillimetric wavelengths because of the redshift). Interestingly, some of these sources have been identified as Lyman-break galaxies at $z \sim 3$ (Barger *et al* 1999) and, conversely, Lyman-break galaxies at $z \sim 3$ have been observed as submillimetric sources (Chapman *et al* 2000). Many others have eluded the efforts to identify them and assign them a redshift, and at present the redshift distribution

[2] Elements heavier that helium are produced in large quantities only in the interior of stars and released into space when these explode as supernovae. Before the beginning of star formation the universe essentially consisted only of hydrogen and helium.

of the submillimeter population is unknown. Of course, similarly unknown is the extent to which the Lyman-break galaxies and the submillimeter galaxies overlap, i.e. are the same objects. Assuming that the latter are placed at $z > 2$ and adding together all their luminosities yields a total energy output at infrared wavelengths that is a factor of several larger than that of the energy output at UV wavelengths by the Lyman-break galaxies. We have seen, however, that the UV luminosity of these sources is likely to be underestimated by a factor of several owing to dust obscuration, and, when a correction is included, the two contributions become comparable. This is consistent with the possibility that the two galaxy populations are the same one. In such a case the submillimetric emission would be powered by the UV light absorbed by dust and re-emitted at infrared wavelengths[3].

Unfortunately, with the current instrumentation it is not possible to identify the nature of the submillimetric sources with great confidence, and establish whether they have or do not have UV emission, which from high redshifts would be observed at optical wavelengths. This is largely because the angular resolution of the images is very coarse (about 15 seconds of arc) and many faint optical sources can be found within a circular region of the sky with such a large diameter, making the identification with optical galaxies very difficult. Future generations of submillimeter telescopes, such as the ALMA project that will be commissioned in Chile in 2007 as a joint collaborative project of the US, Europe and Japan, will have the sensitivity and resolving power to accurately image the sources and allow the identification with optical ones (or demonstrate that optical counterparts are very rare). It will be very interesting to see whether current UV survey have accounted for all the star formation activity in the young universe, whether most of it has actually been hidden by dust, or else if the universe was already populated by 'old' objects when it was only ∼10% or less of its current age.

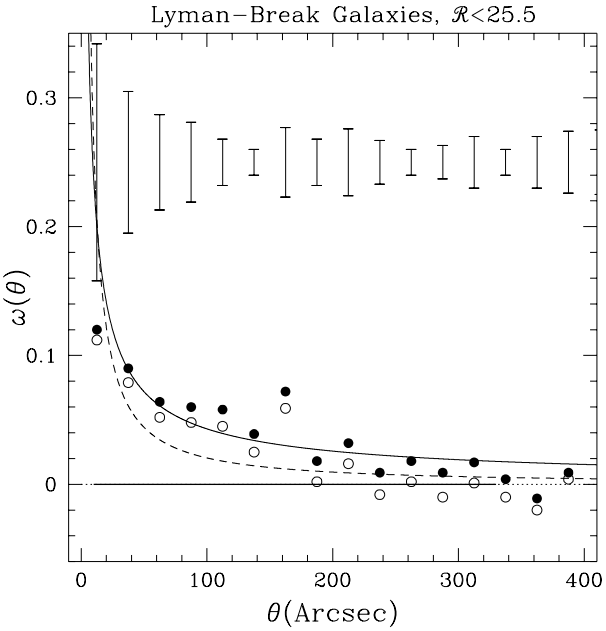

Figure 5. The angular correlation function of Lyman-break galaxies with apparent magnitude brighter than $\mathcal{R} = 25.5$. This quantity measures the probability of finding a pair of galaxies in the sky separated by an angle θ (measured in seconds of arc) as a function of the angle itself. The diagram shows that close galaxy pairs are much more likely to be found than loose ones, indicating the strong tendencies of Lyman-break galaxies to cluster in space. For clarity, the error bars have been plotted on the top of the figure. Filled and empty circles indicate two different estimators, used to test for the possible existence of systematic errors in the measurements. The continuous and dashed curves are the fits to the filled and empty circles (data points), respectively. The clustering and abundances of Lyman-break galaxies have been found to agree with the predictions of the theory of gravitational instability for dark matter halos, lending strong empirical support to the idea that galaxies have formed within halos that provided enough gravity to make gas condense and convert into stars.

Galaxy formation and dark matter

Another fundamental avenue of research opened by the identification of forming galaxies at high redshift is the possibility of testing the idea that gravity has been the force responsible for galaxy and structure formation.

If gravity has assembled the cosmic structures, then one prediction is that galaxies have formed in those regions of space where enough mass had condensed and produced the gravitational pull to confine the gas in a relatively small volume of space, promoting and facilitating its conversion into stars.

What are these mass condensations that seeded galaxy and star formation? There is compelling evidence that the majority of the mass present in the universe (about 90% of it) is not in the form of visible matter but is dark, either because it is cold or because it interacts very weakly with the electromagnetic radiation. Its presence, however, is detected through the gravitational effects, such as motion, that it induces in other, visible objects. The nature of the dark matter is unknown. It has been proposed that it might consist of ordinary matter such as objects similar to planets or unborn stars (brown dwarfs), or of more exotic types of matter, such as subatomic particles (e.g. massive neutrinos), other species of particles predicted by quantum theories (e.g. axions, photinos, gravitinos) or even of such systems as primordial mini BLACK HOLES. It is beyond the scope of this article to discuss dark matter in detail (but see DARK MATTER: ITS NATURE), and in the following we shall refer to it as a 'cosmological fluid' that, together with the regular visible matter, fills the space in the universe, and consider only its gravitational effects.

If gravity has assembled structures out of the cosmic fluid, then one specific prediction of the theory is that the spatial distribution of these structures (we shall refer to these structures as 'the halos') is not homogeneous,

[3] The equality of the two terms is expected in this case from the principle of conservation of energy.

but highly clustered. In other words, the halos are not expected to be distributed in space at random, but preferentially located next to each other, defining local concentrations that are also preferentially found next to other concentrations, and so on. Thus, if the visible part of galaxies (i.e. the stars) forms when gas condenses inside the dark matter halos, then the spatial distribution of forming galaxies must be the same as that expected for the halos themselves.

One of the most remarkable properties of the Lyman-break galaxies is that their spatial distribution is, within the uncertainties of the measurements, the same as that expected for the dark matter halos (Giavalisco *et al* 1998; Adelberger *et al* 1998). Figure 5 illustrates the strong spatial clustering of the galaxies. It shows the probability of finding a pair of galaxies separated by an angle θ in the sky as a function of the angle itself (measured in seconds of arc). This quantity is known as the angular correlation function and it is traditionally represented by the symbol $\omega(\theta)$. The data show that pairs of Lyman-break galaxies separated by small angles in the sky are much more likely to be found than pairs with large separations. This means that the galaxies have a strong tendency to cluster in space, namely to be physically closer to each other than in a homogeneous (random) distribution. If the galaxies were randomly distributed in space, the function $\omega(\theta)$ would have been flat, namely equal to a constant numerical value for any angular separation, indicating that pairs could have been found equally likely at all angular separations.

Because the distances to the galaxies are known, it is possible to transform the angular separations in the sky into physical separations in space and derive the spatial scales over which Lyman-break galaxies are clustered. These scales turn out to be of the order of 3–5 Mpc, the exact values depending on the Hubble constant H_0 and the cosmological parameters Ω and Ω_Λ, which are not yet precisely known. These observed scales have been found to be the same as those predicted by the theory of gravitational instability. The theory also predicts the abundances of the galaxies (i.e. the number of galaxies in a given volume of space), and, remarkably, the observed numbers of galaxies also agree very well with the predicted ones.

The predictions of the theory of gravitational instability concern structures that form out of the 'cosmic fluid' through the action of gravity. The simultaneous agreement of the observed clustering strength and spatial abundances of the Lyman-break galaxies with the analogous quantities predicted for the dark matter halos shows that the visible component of galaxies has the same properties predicted for the halos. This is consistent with the idea that visible galaxies and dark halos are physically associated and in fact are the same structures. This evidence provides strong empirical support for the notion that star formation takes place within the gravitational potential provided by the halos (recall that the dark matter accounts for ∼90% of the mass), which would act as 'condensation seeds', making it possible for the gas to condense and transform into stars. The observed clustering properties and abundances of Lyman-break galaxies represent a remarkable success for the theory and show that main ideas behind the paradigm of galaxy formation are generally robust.

Galaxies: Classification

Galaxies are majestically beautiful objects, and anyone who has seen a galaxy through a telescope, or even our own Milky Way Galaxy with the unaided eye, cannot help but wonder at the nature of these remote star systems and what they have to say about our universe and ourselves. Much of what is known about galaxies began with a simple classification of their appearance as seen on direct photographs taken with large observatory telescopes. Galaxies present a wide variety of forms, or morphologies, and can be naturally divided into categories in much the same way as living organisms can be divided into genera and species. However, galaxy morphology presents problems for classification that would not be encountered in biological taxonomy and that make it difficult to classify them with the precision that is normally associated with living species. Still, visual galaxy classification continues to be useful at a time when galaxies have never been better understood. Classification provides order to the daunting variety of forms even if we do not yet know how the different forms came about. Classification also provides a framework for further studies and suggests a logical approach to studying galaxies.

Factors influencing galaxy classification and morphology

The main problem with classifying galaxies is that no galaxy can be brought into a laboratory so that it can be viewed from any particular direction or distance. Most galaxies have preferred planes of symmetry, and ideally for classification we would like to view them all from directly above their preferred planes of symmetry. However, these planes are oriented randomly to the line of sight, making the appearance of many galaxies very dependent on viewing geometry. Also, galaxies are spread over a wide range of distances, such that the farther they are away from us, the harder it is to see details of their morphology.

The appearance of many galaxies also depends on the wavelength of light in which they are viewed. Photography and imaging of galaxies is usually done through filters which transmit a relatively small portion of their spectral energy distribution, which refers to the distribution of their light with wavelength. With some exceptions, spectral energy distributions of galaxies are dominated by starlight, with a small fraction of their light coming from glowing interstellar gas. Starlight tends to be mostly continuous thermal radiation (meaning all wavelengths are emitted) whose color is determined by the surface temperature of the star. Hot stars (surface temperatures of 20 000 K or more) emit most of their light as ultraviolet radiation and appear bluish in color, while cool stars (surface temperatures of 4000 K or less) emit most of their light as infrared radiation and appear reddish in color. When imaged in short-wavelength light, such as blue or ultraviolet, the appearance of galaxies tends to emphasize hot, blue and relatively young massive stars, but when viewed in long-wavelength light, such as red or infrared, the appearance of galaxies tends to emphasize cooler and generally older less massive stars. Young stars tend to be less smoothly distributed and much less frequently present than old stars, so many galaxies appear more patchy and uneven in blue filters than in red filters.

The presence of interstellar material known as dust also has a wavelength-dependent effect on the appearance of a galaxy. Dust consists of fine particles of heavy atoms and light elements that are thought to be produced by processes connected with the evolution of stars. In highly flattened galaxies, dust collects within a thin plane at the galaxy's mid-section; in other, less flattened galaxies dust may be distributed more randomly. Since interstellar dust scatters short-wavelength light more effectively than long-wavelength light (by virtue of the small size of the particles compared with the wavelength of visible light), the effects of dust on galaxy morphology and classification are more serious on blue light images than on red light images. Dust also impacts the appearance of galaxies at far-infrared wavelengths, where thermal emission from dust can actually dominate over the contribution of starlight. At longer (radio) wavelengths, starlight from galaxies can be very weak, and the appearance of a galaxy can be determined mainly by SYNCHROTRON RADIATION (nonthermal electromagnetic radiation produced by relativisitic electrons spiraling in strong magnetic fields) or by emission from cold neutral atomic hydrogen at 21 cm wavelength.

The expanding universe can affect the appearance of galaxies. The cosmological REDSHIFT both shifts and stretches the spectral energy distribution of galaxies which would impact their appearance in any set of fixed standard filters. For example, the blue light appearance of a galaxy may be seen only in a red filter because the redshift has shifted that part of the spectrum into the red. Thus, galaxies at high redshift can be difficult to classify and compare with those observed at low redshift.

The appearance of a galaxy is not expected to be perfectly fixed with time. Galaxies tend to rotate, new stars may be born and older stars may die, and interstellar gas may be consumed or replenished at rates dependent on both internal and external factors. Galaxies tend to be large compared with their typical separations, so that interactions may impact their structure over a long period of time. Because of the finite speed of light, very distant galaxies are seen as they were when the universe was much younger than it is now, and their appearance may have been influenced by the different conditions that existed at those times.

Finally, the morphology of a galaxy is also seriously influenced by its total mass and its environment. Massive galaxies tend to be much more structured and well ordered, more luminous and of higher average surface brightness than low-mass galaxies, such that catalogs over-represent high-mass galaxies and under-represent low-mass galaxies. Because of this selection effect, the galaxy classification systems in use today apply mainly

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

to massive galaxies. There do not necessarily exist low-mass counterparts of all of the known types of high-mass galaxies. For this reason, statistics of galaxy types must take into account the luminosity dependence of morphology in order to get an accurate picture of the entire population of galaxies. There is also a well-established correlation between a given galaxy's morphology and the density of surrounding galaxies (see GALAXY MORPHOLOGY–DENSITY RELATION). Certain types of galaxies are prevalent in high-density environments such as rich galaxy clusters, while others are prevalent in lower-density environments. This correlation is one of the primary observations that any theory of galaxy morphology and evolution would have to explain.

Classification of nearby galaxies at optical wavelengths

For historical reasons, the first classifications for galaxies were made at optical wavelengths and were entirely restricted to relatively nearby galaxies. From 1781 to 1847, Sir William Herschel and his son, John (see HERSCHEL FAMILY), searched the sky for 'white nebulae', objects which were later proved to be external galaxies. Through large telescopes, the Herschels were able to detect different degrees of central concentration, apparent flattening and mottling in these objects. More complex structure could be seen in a few of the brighter cases, but it was William Parsons, Third Earl of ROSSE, who, in 1845, added the attribute 'spiral' to some members of the Herschels' 'white nebulae'. This is when galaxy morphology began to get very interesting. Lord Rosse used a 72 in speculum metal reflector, the largest telescope in the world in his day.

The main classes of galaxies were identified not from visual observations but from photography with large telescopes using plates with emulsions sensitive to the blue region of the spectrum. Photography became important in astronomy towards the end of the 19th century, and by 1920 the main classes of bright galaxies were identified. After establishing the extragalactic nature of the 'white nebulae' in 1924, EDWIN HUBBLE developed a classification system for galaxies that, with some refinements, is still in use today.

The Hubble classification system

A schematic of the HUBBLE CLASSIFICATION system as it is used today is shown in figure 1, and examples of each type are shown in figures 2, 3 and 4. Initially, Hubble distinguished three main classes of galaxies: elliptical galaxies, which were smooth and largely featureless systems having a round or elliptical shape; spiral galaxies, which were highly flattened disk-shaped systems having spiral 'arms' in the disk; irregular galaxies, which showed a chaotic appearance. As with living species, subclasses can be distinguished within these main classes. For ELLIPTICAL GALAXIES, symbolized by the letter E, the only other criterion that Hubble was able to use for classification was the ellipticity of the isophotes. Hubble appended to the letter E a numerical index of ellipticity: $n = 10(1 - b/a)$, where b/a is the ratio of the minor axis dimension to the major axis dimension. E0 galaxies are round while E6 galaxies are highly elongated.

The uppermost panel of figure 2 shows two ellipticals, NGC 221 and Maffei 1. In many elliptical galaxies, the light declines smoothly with increasing distance r from the center as $r^{1/4}$. Some 40% of ellipticals are known to have dust which breaks the characteristic smoothness of the light distribution. The dust may be scattered in patches or collected in planes of symmetry. The intrinsic shapes of ellipticals are nontrivial to deduce, but it is generally believed that many are triaxial, meaning that the semi-axis radii of isophotes (or contours of equal brightness) along three perpendicular symmetry planes are unequal. The projected index n in the classification En does not connect directly to a preferred intrinsic shape, and indeed n may have little intrinsic significance to an actual galaxy. This has led some authors recently to propose replacing the index n with a subclassification based on the deviations of the isophotes of ellipticals from a perfect elliptical shape. The range of shapes, from boxy to pointy or disky, can be tied to more meaningful physics than the index n.

Among the nearest galaxies, the most common type is DWARF ELLIPTICAL or DWARF SPHEROIDAL GALAXIES. These galaxies tend to have much lower masses and surface brightnesses than the giant ellipticals. The nearest normal major elliptical to our Galaxy is Maffei 1, in the far northern sky. Although less than 10 million light-years distant, Maffei 1 is heavily obscured by foreground interstellar dust in our own Galaxy and is difficult to study at optical wavelengths.

The symbol for spiral galaxies in the Hubble classification system was S, but these systems offered four criteria for subclassification. SPIRAL GALAXIES tend to be composite systems consisting of a smooth, relatively spherical bulge of old stars superposed within a highly flattened disk consisting of spiral arms and often young massive stars lining the arms. Spirals differ according to the presence or absence of a bar-shaped feature, the relative prominence of the bulge, the degree to which the arms are open or tightly wrapped and the degree to which the arms are lined by discrete, resolved objects. The last three aspects seem to correlate in that galaxies having large bulges also have smooth, tightly wrapped arms while those having little or no bulge have patchy, open spiral arms. These characteristics led to the Sa–Sb–Sc and SBa–SBb–SBc 'tuning fork' classification of spirals shown in figure 1, where the B stands for bar. In BARRED SPIRAL GALAXIES, the arms break from the ends of the bar, while in nonbarred spirals the arms break directly from the bulge region. Galaxies of types Sa and SBa are frequently referred to as 'early-type' spirals in astronomical literature while those of types Sc and SBc are frequently referred to as 'late-type' spirals, nomenclature which draws from terms used in stellar astronomy to connote an evolutionary sequence. Studies by H Shapley and G de Vaucouleurs led to the extension of the spiral sequence to types considered to be 'later' than Sc. At types Sd and SBd, the bulge is very

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

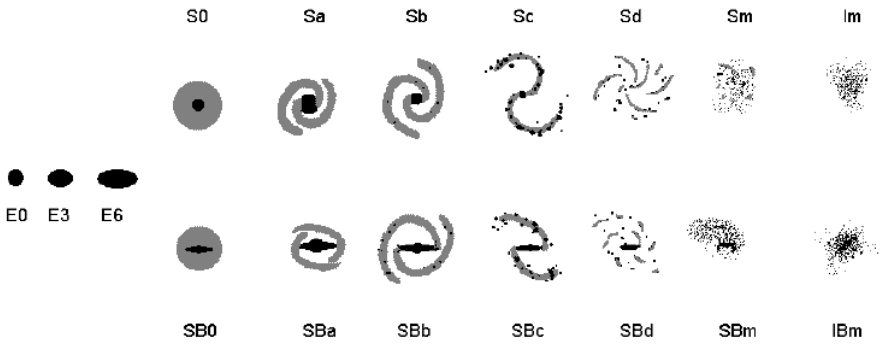

Figure 1. The Hubble sequence of galaxy types modified with additional types.

small or absent and the structure becomes increasingly open and highly resolved. The types Sm and SBm in figure 1 represent Magellanic-Cloud-type spirals. For a long time, the MAGELLANIC CLOUDS, two nearby galaxies seen in the far southern sky that are physical companions of our Galaxy, were regarded as IRREGULAR GALAXIES, but in the 1950s G de Vaucouleurs demonstrated that both have spiral structure with a characteristic asymmetry and no bulge component.

The majority of the galaxies that are listed in galaxy catalogs tend to be spirals of relatively high luminosity. In the Sa galaxy shown in the upper left panel of figure 3, the arms are smooth, tightly wrapped around the center, and the bulge is large compared with the disk. In the SBa galaxy in the upper right panel of figure 3, the bright bulge is crossed by a luminous bar. The bars of galaxies in general are composed of rather old stars compared with spiral arms.

The middle panels of figure 3 show typical examples of Sb and SBb galaxies, defined to be intermediate in bulge-to-disk strength, pitch of arms and resolution of arms compared with Sa,SBa and Sc,SBc galaxies. The Sb example, NGC 5985, shows a multi-armed spiral pattern. The SBb example, NGC 5850, shows a well-resolved spiral pattern of intermediate pitch angle.

The two lowest panels of figure 3 show typical examples of Sc and SBc galaxies. These tend to have the most well-developed and open spiral arms with a high degree of knottiness or resolution of the arms. The bulges tend to be very small compared with the extended disks. The objects that dot the arms tend not to be individual stars but unresolved clusters or loose associations of massive young stars. Such stars have spectral classes of O and B, and hence the clusters are usually referred to as OB ASSOCIATIONS. In the Sc example NGC 5457, these associations are several hundred light years in diameter and include hundreds of such stars.

The galaxies shown in the two upper panels of figure 4 are examples of Sd (NGC 45) and SBd (NGC 2500) types. In NGC 45, the spiral arms are weak and the bulge is very small; the bulge can only contribute a few per cent or less to the total luminosity of the system in this case. This is also true for NGC 2500, which has a clear bar. Note how both NGC 45 and NGC 2500 have many scattered 'knots', most of which are likely to be OB associations. The lower left panel of figure 4 shows a classic Magellanic barred spiral, NGC 4618, of type SBm. Although NGC 4618 has two clear arms, one arm is much brighter than the other and the center of the bar does not coincide with the center of symmetry of the outer disk light. These are characteristics of the SBm class.

Irregulars were originally characterized as 'nondescript' and lacking rotational symmetry. Although some are generally chaotic looking at relatively high surface brightness levels, at low light levels a faint, more symmetric disk can often be seen. It is now known that many irregulars do rotate and have bar-like structures in their disks. The properties of irregulars are so varied, and the range in their total luminosities is so great, that they have been the subject of much recent research. Irregular galaxies resembling the Magellanic Clouds but lacking any clear spiral structure are now referred to as Im or IBm types. The middle right panel of figure 4 shows a Magellanic irregular, NGC 2366, type IBm. This galaxy has numerous bright OB associations but no clear spiral structure. Its highly elongated shape suggests that it might be highly inclined.

In 1936, Hubble revised his classification system to include a fourth major galaxy class: S0 galaxies, which were armless DISK GALAXIES representing the transition from ellipticals to fully developed spirals. Some authors believe that the addition of this class destroyed the simple beauty of Hubble's original system. S0 galaxies are still an enigma because their relationship to spirals and ellipticals is still very unclear. Some authors believe that S0s represent spirals that were stripped of their residual gas by interactions in a cluster environment. Thus, rather than being transition types they form a separate sequence parallel to the spiral sequences. Other S0s may indeed be true transition forms between spirals and ellipticals. Note that elliptical and S0 galaxies are collectively referred to as 'early-type' galaxies, while irregulars are referred to as 'late-type' galaxies. These bracket the 'early-' and 'late-type' spirals. Some S0s have clear bars and are referred to as the SB0 type in figure 1.

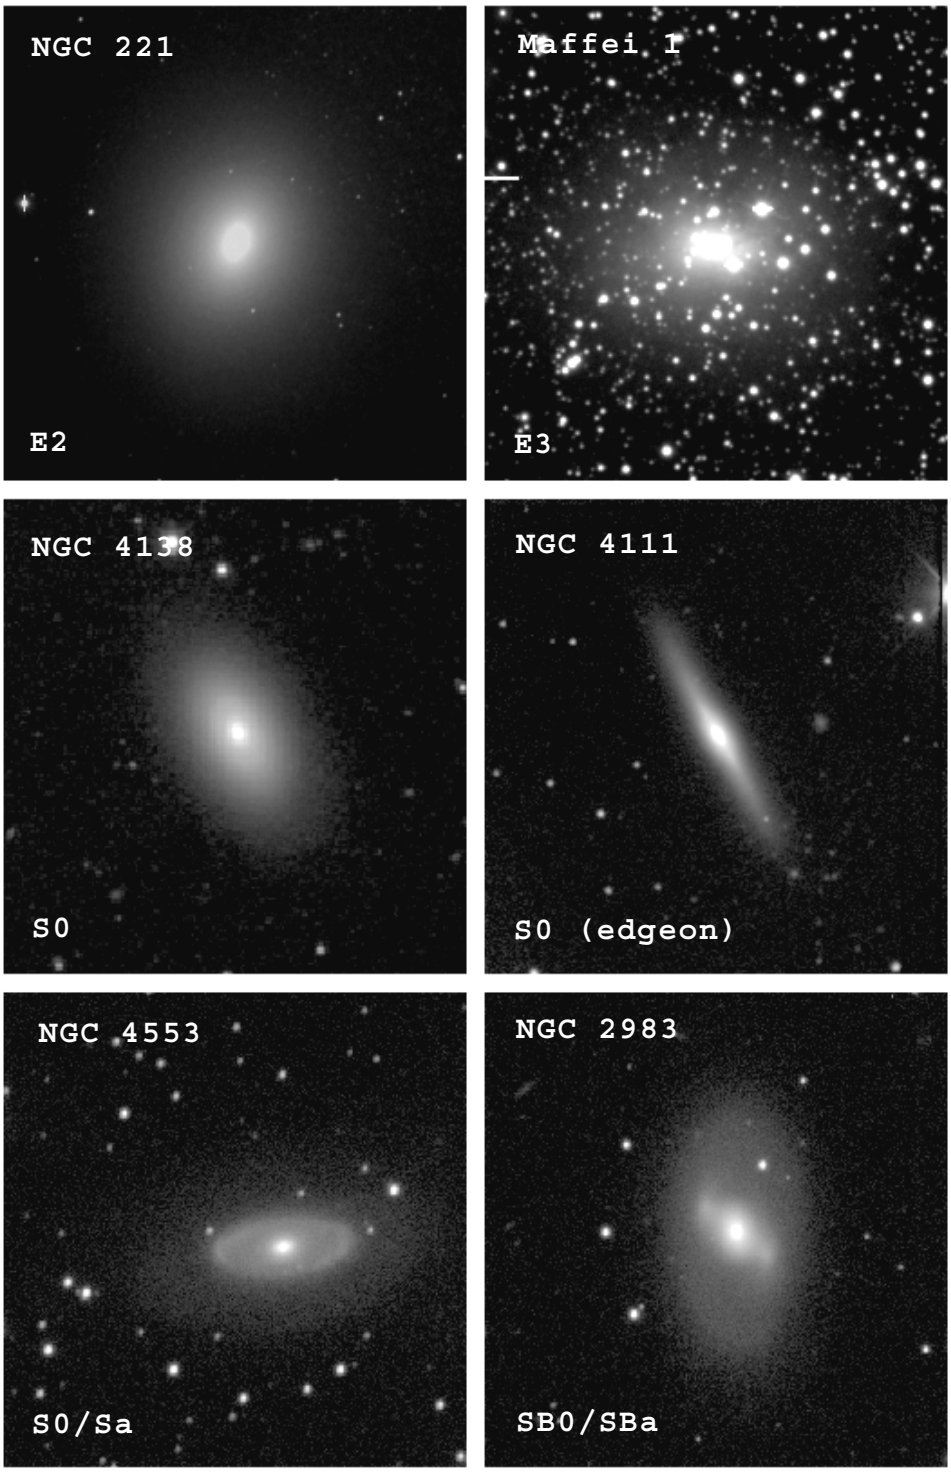

Figure 2. Examples of elliptical, early S0 and late S0 galaxies.

The morphology of S0 galaxies is best revealed by edge-on examples. When edge on, an S0 galaxy clearly shows its highly flattened, disk shape (see NGC 4111 in the middle right panel of figure 2). However, while edge-on spirals reveal dark lanes of dust in their midplanes, the best S0 galaxies show no such midplane of dust, implying

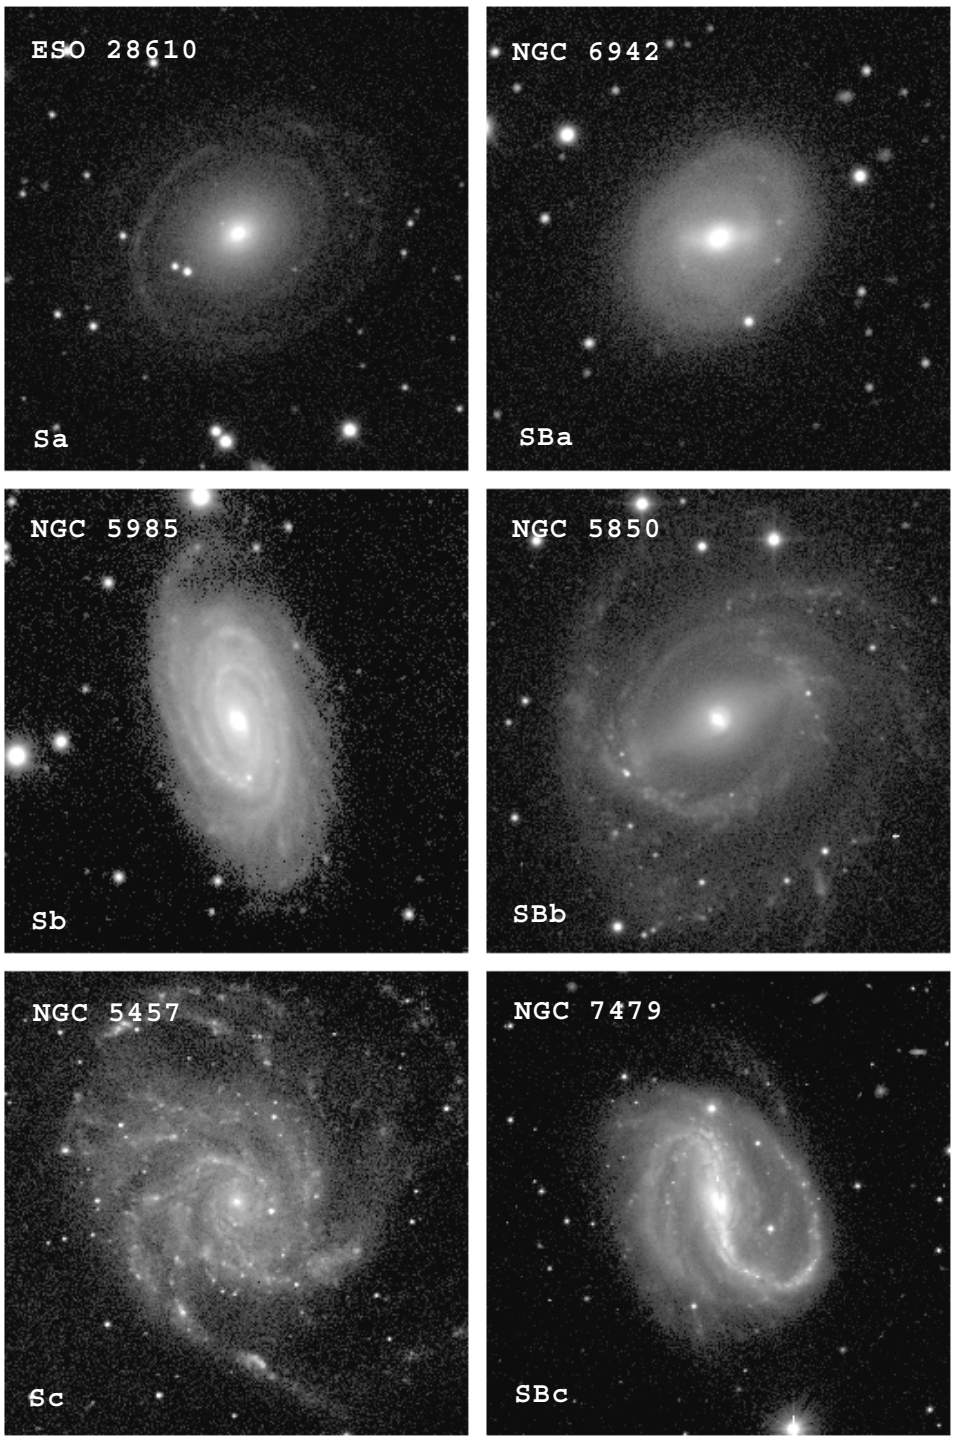

Figure 3. Examples of early- and late-type spiral galaxies.

the absence of much interstellar gas. This accounts for their smooth appearance and relatively red colors compared with spirals. Some 'late' edge-on S0s do show a midplane of dust.

At minimum, a true S0 galaxy should have no spiral arms, a clear bulge, and a clear disk or outer envelope of light. NGC 4138, shown in the middle left panel of figure 2, is a good example seen in an inclined but not

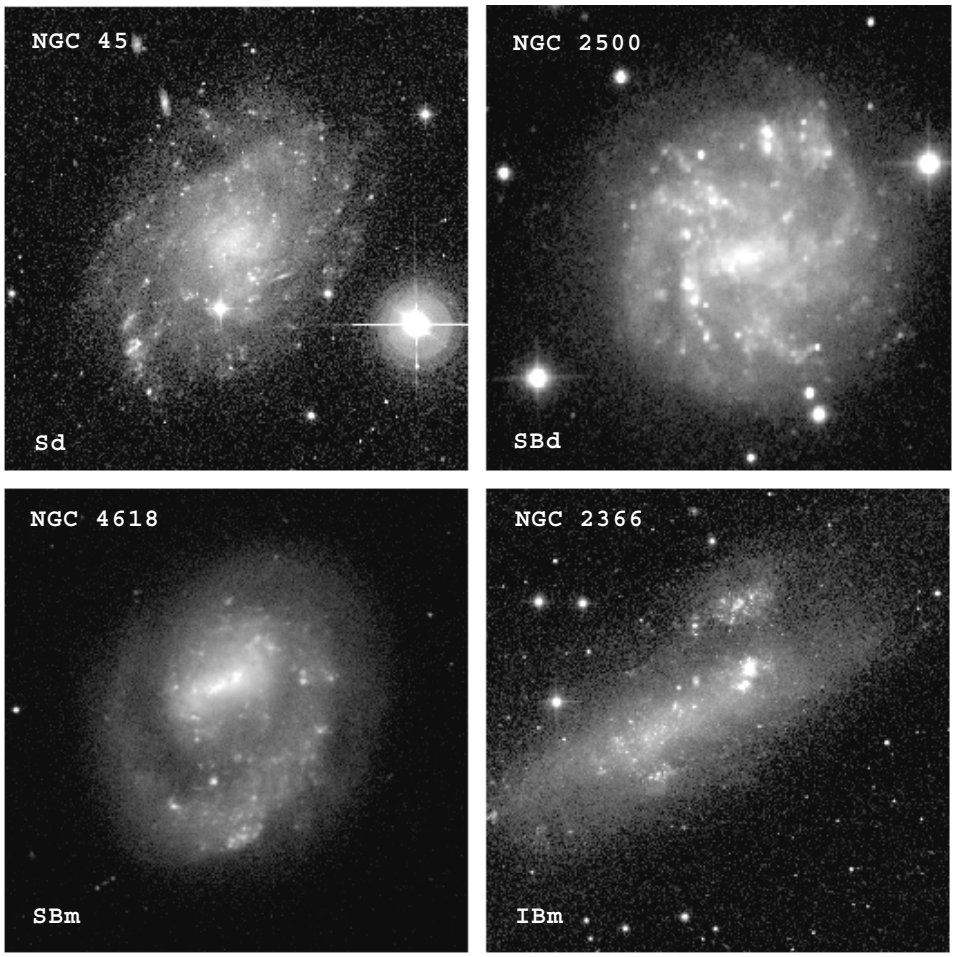

Figure 4. Examples of very-late-type and Magellanic spiral and irregular galaxies.

an edge-on view. This galaxy includes a weak ring of light just outside the bulge, which has led some authors to consider the galaxy to be a late S0. Seen face-on, the earliest S0s can be misclassified as ellipticals on inadequate image material. Late S0s have clearer differentiation of structure. Two examples are shown in the bottom panels of figure 2. NGC 4553 is a late S0 with a clear ring around the center. NGC 2983 is an SB0 with a well-differentiated bar and extended disk component. Both galaxies have also been classified as early-type spirals, although any spiral structure is very weak in both cases.

The relative luminosities of the bulges of S0 galaxies to their disks is a question connected to how we should interpret them. If they tend to have large bulge-to-disk luminosity ratios, then their placement in the Hubble sequence between ellipticals and spirals is likely to be correct. However, if some S0s have a relatively small bulge-to-disk ratio, then they could be 'stripped' spirals and should be placed on a sequence parallel to spirals.

The arrangement of ellipticals, S0s, spirals and irregulars along a sequence as shown in figure 1 is known as the Hubble sequence. The Hubble sequence is considered among the most important aspects of galaxies because certain properties of galaxies vary smoothly along the sequence. Interpreting what the sequence actually means is difficult because the mean luminosity of the galaxies is not the same at each type. The greatest spread in luminosity is found near the ends of the sequence, among the ellipticals and the late-type spirals and irregulars. An extremely important observation is how elliptical and S0 galaxies dominate the populations of rich and dense CLUSTERS OF GALAXIES, while spirals dominate looser clusters and the general field. This is the 'morphology–density' relation alluded to in the previous sections.

Other approaches to galaxy classification

Hubble's classification system is easy to use because it focuses on gross characteristics of galaxies. All of the original Hubble classes are rather broad in the galaxies they cover, but greater attention to detail is possible and other authors have proposed somewhat different points of view for classification, building on Hubble's idea.

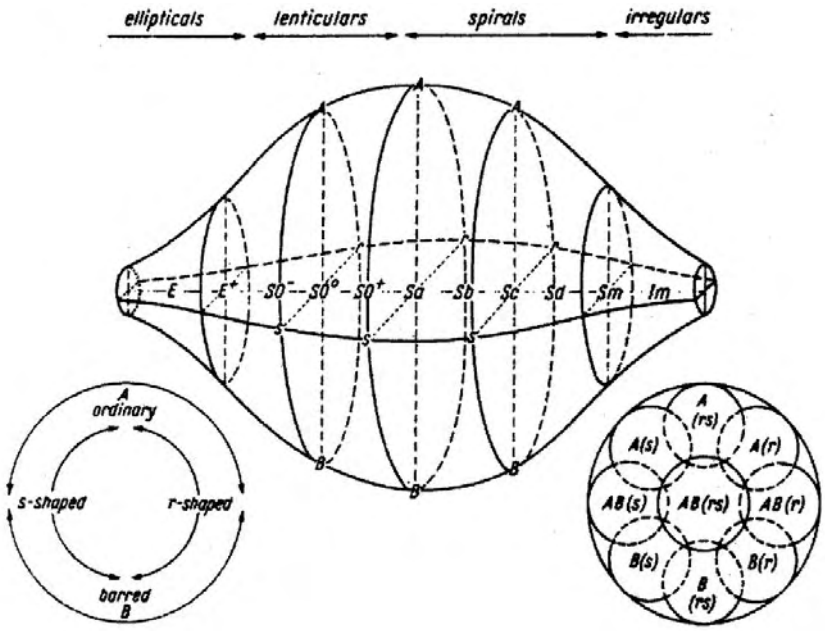

Figure 5. Illustration of the de Vaucouleurs revised Hubble classification system. In this system, S0 galaxies are referred to as 'lenticulars'. The lower left and right circles illustrate the arrangement of families and varieties within a cross-section through the system.

For example, rather than a two-pronged 'tuning fork' classification, G de Vaucouleurs proposed a classification volume whose main dimension is the basic Hubble type (i.e. E, S0, Sa, Sb, Sc, etc) and whose secondary dimensions are the family (presence or absence of a bar) and variety (presence or absence of a feature known as an inner ring; see figure 5). de Vaucouleurs' classifications provide a better description of what a galaxy looks like without being too complicated. Still, there are more than 100 'cells' in the de Vaucouleurs system compared with about 10 in Hubble's original system. The de Vaucouleurs system is recognized mainly for the addition of spiral types later than Sc, called Sd and Sm, and for the notation SA, SAB and SB to denote continuity of the bar characteristic. SA galaxies are true nonbarred (ordinary) galaxies, SB galaxies are true barred galaxies, while SAB galaxies are intermediate in apparent bar strength. Galaxies having a ring-shaped pattern in the inner regions are denoted as being of the (r) variety while those having no ring are said to be pure spirals, or the (s) variety. Galaxies having weak or partial, broken rings are assigned a variety of (rs), meaning a pseudoring is present. Examples of all nine possible combinations of families and varieties are illustrated in figure 6. The galaxies shown all have types of Sa or Sb. Inner rings are fairly common among these types, but are very much rarer among Sc types and later and nonexistent among ellipticals and early S0s.

In 1960, S van den Bergh demonstrated that galaxy morphology is influenced by the total luminosity or energy output of a galaxy. He assigned not only modified Hubble types to spiral and irregular galaxies, but also luminosity classes symbolized in a manner similar to stellar luminosity classes. The most luminous spirals or irregulars are luminosity class I while the least luminous are luminous class V. Categories II, III and IV have intermediate luminosities between these extremes. Most galaxies of luminosity classes IV and V are irregulars or very late-type spirals (Sd or Sm types). Of the spiral galaxies illustrated in this article, NGC 210, NGC 1300, NGC 1433, NGC 5457, NGC 5985 and NGC 7479 are luminosity class I or I–II, NGC 45 and NGC 2500 are luminosity class III, while NGC 2366 is luminosity class IV–V, as judged by A Sandage and G Tammann. Note how much more contrasted the spiral structure of the high luminosity class galaxies is compared with the intermediate or lower luminosity classes.

Spiral galaxies may also be classified strictly according to the appearance of their arms. Some spiral galaxies show a 'grand-design' spiral structure, consisting of two well-defined symmetric and long spiral arms. The first attempts to understand the nature of spiral structure in galaxies focused on grand-design spirals because they showed the best-defined spiral patterns. In other galaxies, however, the spiral arms are only chaotic or fragmentary and do not appear to be global in nature; such spiral patterns are often called 'flocculent'. The Hubble classification system and its revisions do not distinguish between these extremes in spiral arm morphology. D and B Elmegreen brought greater attention to these differences and proposed recognizing them with arm classes (ACs) ranging from 1 for the purely flocculent types to 12 for the best grand-design types. Intermediate-looking spirals

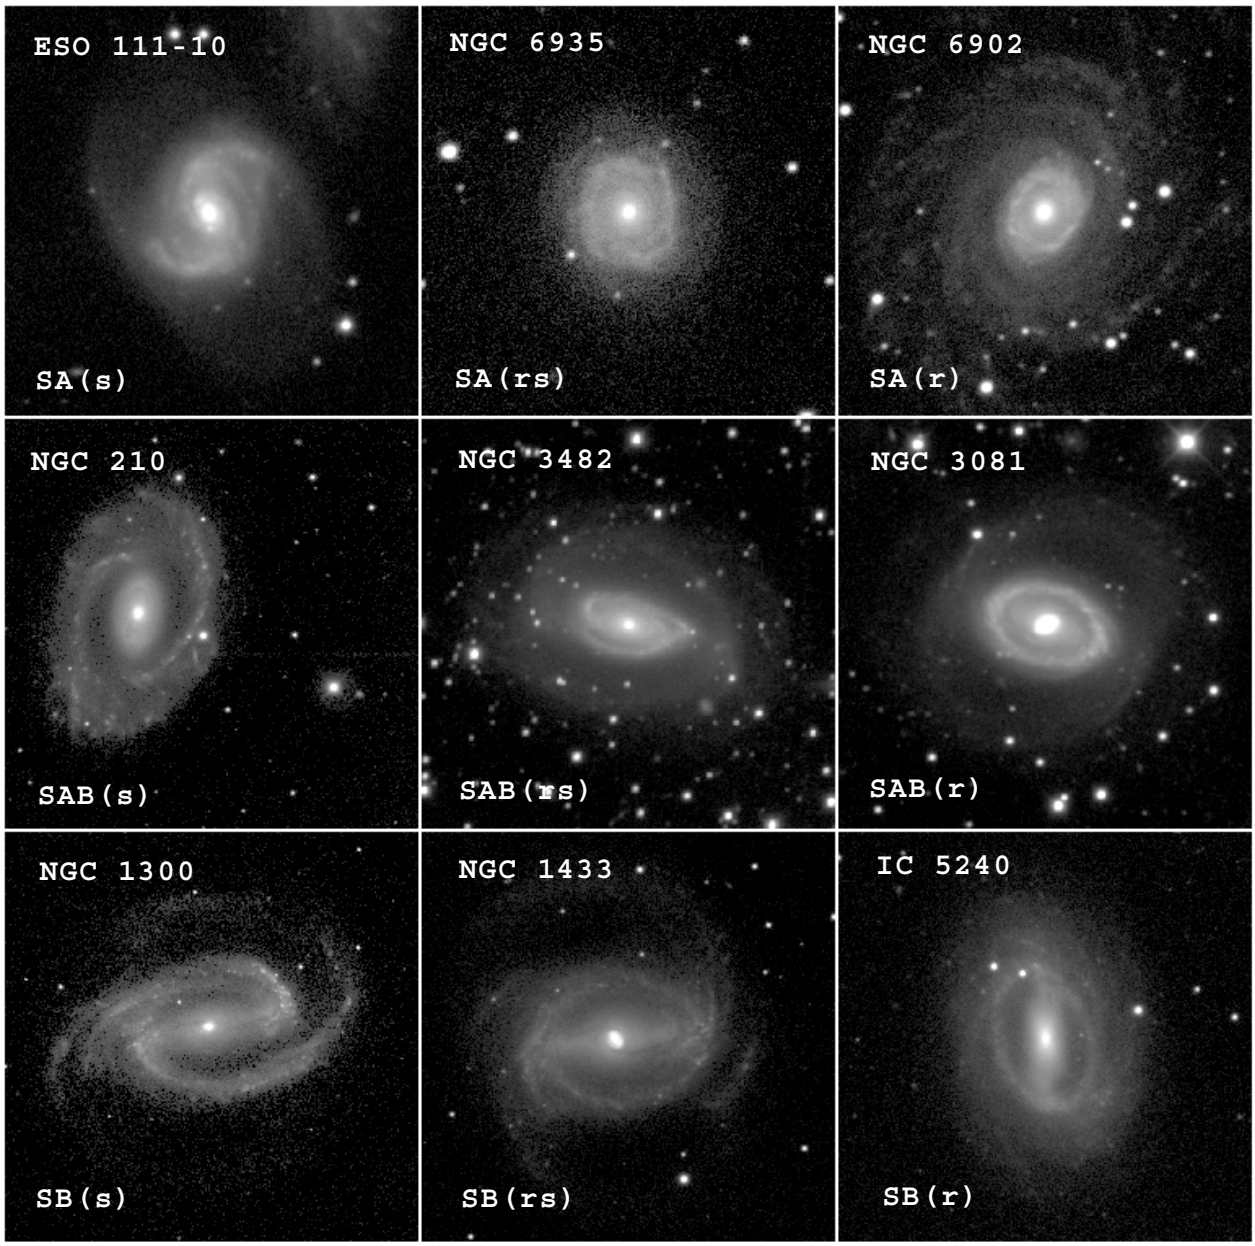

Figure 6. Examples of galaxies having different families and varieties in the de Vaucouleurs revised Hubble classification system.

have intermediate arm classes. In this article, NGC 1300 is an example of an AC 12 spiral while NGC 45 and NGC 2500 are examples of AC 1 systems. The distinction is worth recognizing because the origin of spiral patterns may differ among the different arm classes. Recognizing them allows one to do statistics to identify environmental factors that may be relevant.

W W Morgan proposed another classification system for galaxies in 1958 that tied galaxy morphology to the then-current ideas of STELLAR POPULATIONS in galaxies. The degree of central concentration of a galaxy was used to define a spectral classification system (population group) based on form alone. Galaxies with strong central concentration were known to be dominated by spectral class K giants (population group k) in their central areas, while those with little central concentration were dominated by spectral class A stars (population group a). The elliptical, S0 and early-type spirals illustrated in this article are all population group k systems, while the late-type spirals (Sd, Sm) and irregulars (Im) tend to be population group a. Morgan also identified an extremely important rare type of galaxy known as a cD galaxy. These

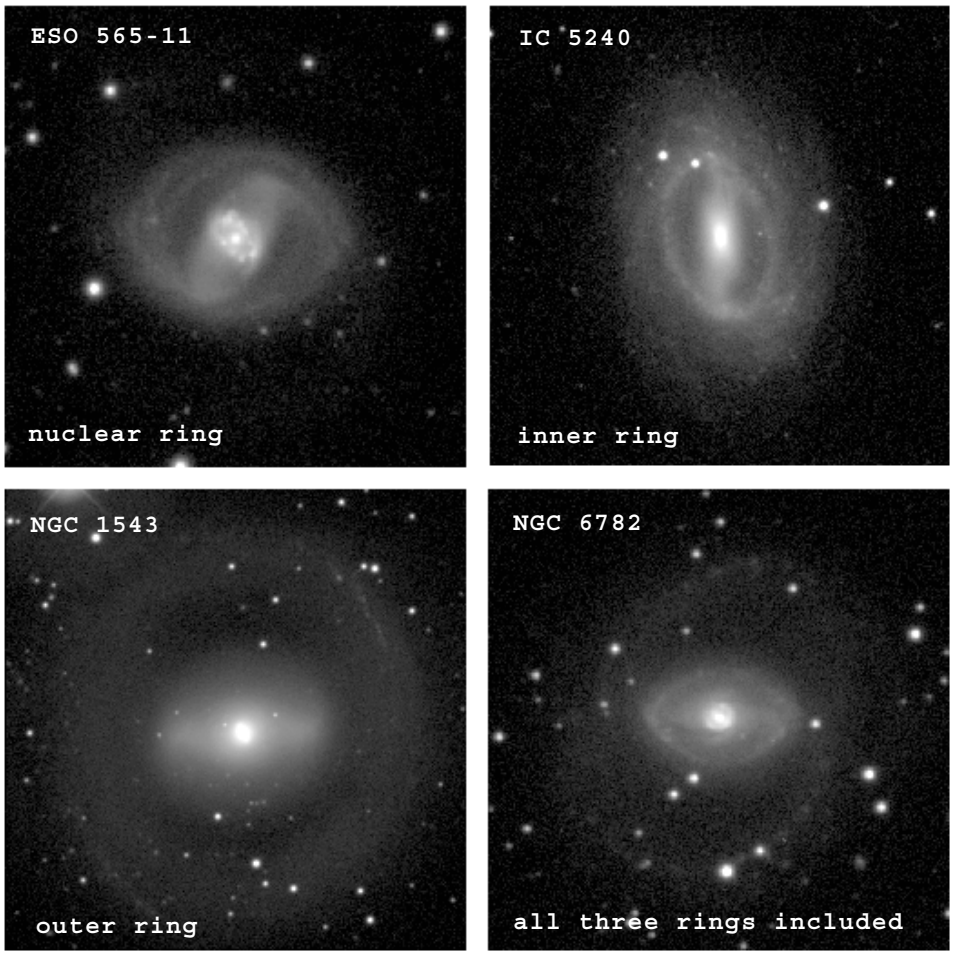

Figure 7. Examples of ringed galaxies.

are extremely large elliptical-like systems often found at the centers of rich galaxy clusters. They are characterized by a shallow light profile, low central concentration, and an extended envelope of light. The origin of such systems has been a topic of much research, and mergers of other galaxies is one possible interpretation.

Other classes or aspects of galaxy morphology

Ringed galaxies

A ringed galaxy is a normal spiral or S0 galaxy having a ring or ring-like pattern as part of the light distribution. In the jargon of normal galaxy morphology, there are three different types of rings: nuclear rings, which are small rings of active star formation often found in the centers of early-type barred galaxies, inner rings, which usually envelop the bars of barred spirals, and outer rings, which are large and faint structures having a diameter about twice that of the bar in barred galaxies. Of the three different types of rings, only inner rings are included as a major part of galaxy classification in the Hubble system, as noted in the previous section. The four panels of figure 7 show examples of all three ring types, one of which (IC 5240) is also included in figure 6. The classification symbols (nr), (r) and (R) are used for nuclear, inner and outer rings, respectively, and all three ring types may coexist in the same galaxy (see NGC 6782 in the lower right panel of figure 7). Inner rings and pseudorings can be identified in more than 50% of normal giant galaxies, and all three ring types are most frequent among early-type barred spirals.

Of the many morphological features of galaxies we have so far discussed, rings are among the best understood. They are features that seem to be generated by the way a bar can redistribute residual gas in a galactic disk, collecting the gas into ringed-shaped patterns that eventually condense into stars. The patterns are tied to locations known as orbital resonances, places where gas clouds move in step with the rotation rate of a bar pattern. Thus, rings and bars are features which are intimately connected.

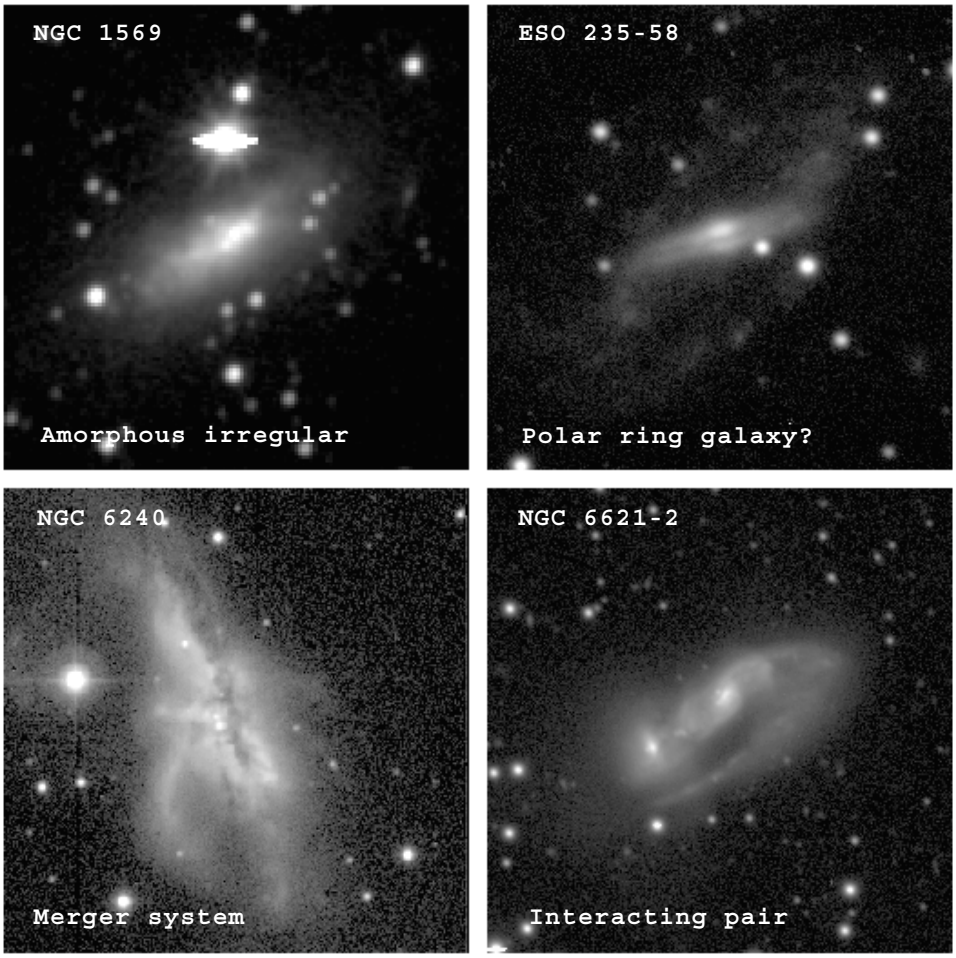

Figure 8. Examples of interacting galaxies and an amorphous irregular galaxy.

Amorphous irregular galaxies

Although classical irregular galaxies tend to be late-type systems with a considerable degree of patchiness and irregularity, another class of irregular galaxies has such amorphous characteristics that some astronomers considered them to belong near the transition between S0 and spiral galaxies. An example, NGC 1569, is shown in the upper left panel of figure 8. These objects tend to have much smoother distributions of luminosity than classical Magellanic irregulars. The distinction has been recognized since 1950, when E Holmberg suggested the term 'Irr I' be applied to normal late-type irregulars and 'Irr II' to these amorphous irregulars. de Vaucouleurs applied the term 'I0' to some of these objects, while Sandage prefers the general term 'amorphous' galaxies. The hallmark of the class is that the spectral character of the unresolved light is consistent with the presence of many young stars, unlike most other galaxies in the transition region between spirals and S0s. Interactions may play a role in the creation of these objects.

Interacting galaxies

Some of the most complex morphologies seen in the galactic population form directly as a result of gravitational interactions with neighboring galaxies (see GALAXIES: INTERACTIONS AND MERGERS). Interactions can be mild and may do no serious damage to the symmetry of a galaxy; however, such interactions may help to generate the formation of bars or even grand design spiral structure. Stronger interactions can lead to asymmetry and peculiar structure, and possibly even features known as 'tidal tails'. The strongest interactions can be so disruptive that the galaxies involved lose their individual identities and merge into a single, different type of object. It is currently thought that many giant elliptical galaxies formed as a result of the mergers of two spiral galaxies rather than naturally. Figure 8 shows a few cases of interacting systems. NGC 6240 in the lower left panel has been shown by numerous authors to be a remnant of a merger between two once separate galaxies; the system has not settled completely into a stable configuration and shows much peculiar structure. In the lower right panel, NGC 6621-2

is a pair of clearly interacting galaxies. Interactions of this nature are not rare and many galaxies may go through a phase of interaction throughout their evolution. Gravity has drawn out material into the form of an apparent bridge between the two systems.

Certain types of interactions can lead to very special and very rare galactic morphologies. For example, if a small galaxy plunges directly through the center of a larger disk-shaped galaxy, a collisional ring galaxy can result. These unusual systems can look like smoke rings in lacking a central nucleus. The ring in this case represents a shock wave moving outward, much like a water wave that results when a pebble is dropped in a pond. Another type of morphology can result when a small companion galaxy, usually a gas-rich irregular, passes close over the pole of a gas-poor S0 disk galaxy. In this circumstance, the interaction can disrupt the companion and capture it into a polar orbit. Eventually, the material that made up the companion spreads along the whole orbit, producing a POLAR RING GALAXY. The upper right panel of Figure 8 shows a likely example of a polar ring galaxy in formation. Known as ESO 235-58, this object actually shows a midplane dust lane dividing the central disk. Although the central section looks like a bar, bars do not normally have dividing dust lanes crossing them from end to end. The central section of ESO 235-58 must be an edge-on disk galaxy, and the other material is orbiting out of the plane of that disk.

Galaxy classification and morphology in the next decade

The era of the orbiting HUBBLE SPACE TELESCOPE (HST) has added a new dimension to galaxy morphology and classification that could not be tapped from previous ground-based observations. HST can provide images of galaxies at large cosmological redshifts of the same quality and resolution used to define the main morphological classes on ground-based images. GALAXIES AT HIGH REDSHIFT are being seen as they were when the universe was much younger than it is now. As noted at the beginning of this article, we do not expect that galaxy morphology is fixed and unchanging, but that change must have occurred. Thus, by studying high-quality images of galaxies at high redshift, we can see what typical changes must have occurred. Current results suggest that interactions between galaxies were more frequent in the past and that some galaxies had not yet settled into well-organized shapes. Thus, morphology contains clues as to how galaxies evolve, and galaxy classification will continue to be refined and adjusted to account for new findings.

The sheer numbers of galaxies available for classification will also have an impact on how astronomers will be classifying galaxies. A large survey can provide high-quality images of more than a million galaxies, and it is impractical to classify so many galaxies visually by one or more experts. Instead, the coming decade will see more and more the use of computers to objectively classify large numbers of galaxies for cosmological and other research.

Galaxies can also be classified in wavelength bands other than the blue-light band used to develop the Hubble classification system. The tendency for blue filters to emphasize hot, young, massive and relatively rare stars means that the classification system tends to overestimate the significance of these objects. In the next decade, galaxy classification will be revised in order to group galaxies according to their appearance in infrared light, which tends to emphasize the stars that dominate the mass distribution. This will be especially important for intermediate to late-type spirals.

Bibliography

Hubble's original paper on galaxy classification was summarized in

Hubble E 1926 Extra-galactic nebulae *Astrophys. J.* **64** 321–69

His revision to include S0 galaxies is described in

Hubble E 1936 *The Realm of the Nebulae* (New Haven, CT: Yale University Press) (reprinted 1958 New York: Dover)

The de Vaucouleurs revised Hubble classification system, including Magellanic spirals and irregulars, is outlined in

de Vaucouleurs G 1959 Classification and morphology of external galaxies *Handb. Phys.* **53** 275

Large atlases illustrating Hubble's final revised classification system are found in

Sandage A 1961 *The Hubble Atlas of Galaxies* Carnegie Institution of Washington Publ. no 618

Sandage A and Bedke J 1994 *The Carnegie Atlas of Galaxies* Carnegie Institution of Washington Publ. no 638

van den Bergh luminosity classes of galaxies were first described and later further outlined in

van den Bergh S 1960 A preliminary luminosity classification of late-type galaxies *Astrophys. J.* **131** 215–23

van den Bergh S 1960 A preliminary luminosity classification for galaxies of type Sb *Astrophys. J.* **131** 558–73

Sandage A and Tammann G 1987 *A Revised Shapley–Ames Catalog of Bright Galaxies* Carnegie Institution of Washington Publ. no 635

The Morgan system of spectral form classifications of galaxies is given in

Morgan W W 1958 A preliminary classification of the forms of galaxies according to their stellar population *Publ. Astron. Soc. Pac.* **70** 364–91

Arm classifications for galaxies are described in

Galaxies: Interactions and Mergers

For much of the 20th century—once the vast distances to galaxies were known—galaxies were thought to be 'island universes', forming and evolving in isolation with no contact between one another. In this picture, the processes which shape the galaxies we see today are uniquely determined by the initial conditions under which galaxies form and processes completely internal to the galaxies themselves.

As galaxy catalogs began to grow, however, more and more examples of paired galaxies were found, as well as many PECULIAR GALAXIES with long, luminous 'plumes' and 'tails' emanating from their bodies. These galaxies were found to have anomalously blue colors, arguing that their star-forming properties were quite different from normal galaxies. Examples were found of galaxy pairs so strongly perturbed that they were suggested as possible examples of actual merging encounters. Meanwhile, astronomers began to use computer simulation to study the effects of nearby companions on galaxies and found that many of the properties of these peculiar galaxies could be explained through gravitational interactions and mergers of galaxies.

From these studies, an alternative picture of GALAXY EVOLUTION began to grow. Rather than evolving in isolation, galaxies are found in clusters and groups and can interact quite strongly with their nearby companions (see GALAXY CLUSTERS). These interactions can have a profound impact on the properties of galaxies, resulting in intense bursts of STAR FORMATION, the onset of QUASAR-like activity in galactic nuclei and perhaps even the complete transformation of SPIRAL GALAXIES into ELLIPTICAL GALAXIES. Studies of galaxies in the early universe show a significant fraction of interacting and merging systems, and theories of cosmological structure formation indicate that most galaxies have had some form of strong interaction during their lifetime. Rather than being rare events, galaxy interactions may be the dominant process shaping the evolution of the galaxy population in general.

Dynamics of Interacting Galaxies

The evolution of interacting galaxies is governed largely by gravitational effects. That these interactions can have a profound effect on the participating galaxies is clear from the observational record. Morphologically, interacting galaxies are found to sport long bridges and tails, stellar bars and/or enhanced spiral structure and often severely distorted main bodies (see figure 1). At first, many astronomers believed the long streamers of stars and gas seen emanating from some interacting galaxies to be shaped by magnetic fields or nuclear jets—the thinness and linearity of these features made a gravitational origin seem unlikely. However, computer models of interacting galaxies in the early 1970s by Alar and Juri Toomre showed convincingly that these streamers were the simple consequence of gravitational tides acting on rotating disk galaxies, and these streamers were dubbed 'tidal tails'.

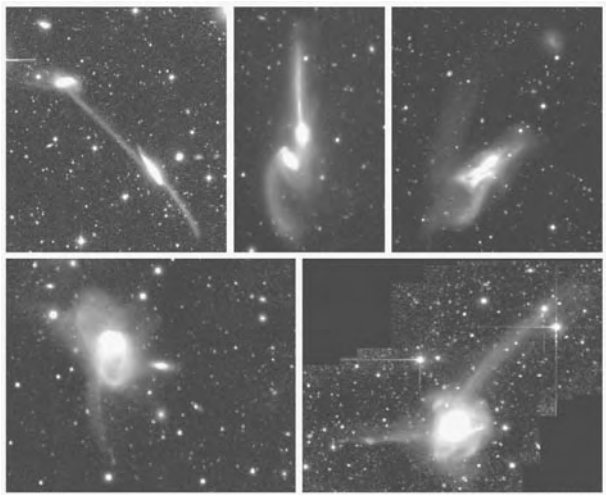

Figure 1. A montage of interacting and merging systems. Clockwise from upper left: Arp 295; NGC 4676 (The Mice); NGC 520; NGC 7252; NGC 3921. Image from Hibbard and van Gorkom 1996 *Astron. J.* **111** 655.

To understand the development of tidal tails, recall that tidal forces—the differential gravitational forces from a nearby mass—act to stretch an object radially. In this manner, our own Moon raises bulges on the surface of the Earth which give rise to our oceanic TIDES. Similarly, when two galaxies experience a close encounter, their tidal fields stretch one another radially. This stretching, combined with the galaxies' rotation, causes the stars and gas in the outskirts of each galaxy to 'shear off' from their parent galaxies. Material on the far side of each disk—away from the companion galaxy—is ejected into long, thin tidal tails, while material on the near side is drawn towards the companion. Depending on the encounter geometry, the nearside material may actually form a physical 'bridge' between the galaxies, along which material may flow from one galaxy to another. Because of the coupled effects of gravitational tides and galactic rotation, the development of tidal features depends strongly on resonances between the rotational and orbital motions of the galaxies. Prograde encounters, in which the galaxies' sense of rotation and orbital motion are matched, are most effective at tail-building. The lack of spin–orbit resonances in retrograde encounters, on the other hand, acts to suppress the formation of tidal tails.

The early computer models of Toomre and Toomre demonstrated these basics of building tidal tails and opened the door to the use of computer simulation to study the evolution of interacting galaxies. Because of the long timescales involved in galaxy interactions—hundreds of millions or billions of years—observations of interacting systems show only individual 'snapshots' of a complex evolutionary process. Piecing together these varying snapshots into a coherent sequence is a task made difficult by the unknown initial conditions of the different interactions. However, computer simulations

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

can be used to study a wide variety of well-defined galaxy interactions, and by studying the evolution of these models the *observational* snapshots can be more easily placed into a evolutionary context.

Computer simulations employ a Lagrangian technique known as N-body modeling, wherein galaxies are represented by N discrete particles whose initial positions and velocities sample the phase space distribution of a normal disk galaxy. Current simulations employ 10^6–10^7 particles, so that each particle represents 10^4–10^5 stars (simulating galaxies star by star is still well beyond current computational abilities). The N-body model is then advanced forward in discrete time steps by calculating the net gravitational acceleration acting on each particle from the other particles and then advancing each particle forward in time given its position, velocity and acceleration (for the interstellar gas, hydrodynamic forces must also be considered; these are discussed in a later section).

One example of such a computer model of colliding galaxies is shown in figure 2. In this model, two equal-mass spiral galaxies are placed on an initially parabolic orbit with a closest approach of $2.5h$, where h is the exponential scale length of the disk stars. One disk is perfectly prograde while the second is inclined by 71° to the orbital plane. As the galaxies first collide, the tidal forces act to distort each disk, launching the tidal tails. Moving at parabolic velocity, the galaxies quickly pass one another and move apart, reaching maximum separation at $T \sim 40$ (unit time is roughly 10 million years). After this point, the galaxies reverse their motions and fall back on one another, merging together to form a ellipsoidal merger remnant around $T \sim 60$.

After first passage, in addition to forming the extended tidal tails, the galaxies themselves develop a strong internal response to the interaction. The passage of a companion seeds an $m = 2$ gravitational perturbation in the disk of each galaxy; these perturbations can then be amplified into strong spiral arms or even dramatic central bars by the self-gravity of the disk. The detailed response of the galaxies depends crucially on their internal structure: if the stellar disk dominates the mass distribution in the inner portion of the galaxy, the disk self-gravity can easily amplify the perturbation into a strong bar. On the other hand, if the galaxy is bulge or dark matter dominated in its interior, the disk is more stable against growing $m = 2$ bar modes, and spiral structure is the more likely outcome.

What causes the rapid merging of the two galaxies? Certainly there is a transfer of orbital energy to internal motions of the stars in each galaxy—it is this energy transfer that provides the energy necessary to launch the tidal tails. The amount of energy carried away by the tidal tails amounts to only a few per cent of the total orbital energy, however; if this was the sole energy sink, interacting galaxies would slowly spiral together over many orbital periods, rather than exhibit the rapid merging seen in figure 2. Indeed, early investigations into the collisions of galaxies argued that subsequent mergers would be quite rare, unless the collision happened to be extremely penetrating.

In fact the luminous portions of galaxies represent only a small fraction of the total galactic mass—galaxies are embedded in massive, extended 'dark matter halos'. These dark matter halos extend to many tens or even hundreds of kiloparsecs, such that encounters where the luminous galaxies seem to pass by one another may in fact be penetrating encounters for the dark halos. When this happens, dynamical friction ensures rapid orbital decay. As the galaxies pass through each other's dark halos, they set up a trailing wake in the halo mass distributions, creating a gravitational drag on the galaxies' relative motion. As a result, energy and angular momentum are transferred from the binary orbit to the internal motions of the dark halo—the orbit decays and the halos are spun up. It is this ability for dark matter halos to absorb orbital energy and angular momentum that makes galaxy mergers possible; without halos, mergers would be rare indeed (see DARK MATTER IN GALAXIES).

Starbursts and active nuclei in interacting galaxies

With the launch of the infrared astronomy satellite (IRAS) in 1983, a new population of galaxies was identified which have extremely high, quasar-like luminosities ($\geq 10^{12}\ L_\odot$) in the infrared (8–1000 μm). This emission is believed to come from hot ($T \sim$ 50–60 K) dust reradiating energy from a central starburst or active nucleus. The exact details of the energy generation—starburst versus AGN—remain controversial, and many ultraluminous infrared galaxies (ULIRGs) show evidence for both starburst *and* AGN activity. The difficulty of course lies in the fact that the nuclei of ULIRGs are, almost by definition, extremely dusty environments, and seeing into the central regions is a very difficult task. Evidence suggests that in some cases the nuclear dust is optically thick even at x-ray wavelengths; finding unequivocal evidence of an AGN in such systems will be very hard indeed.

While the details of the energy source in ULIRGs remain elusive, the causal connection between ULIRG activity and galaxy interactions is clear. Nearly all ULIRGs show morphological evidence for strong interactions, through double nuclei, severely distorted isophotes or strong tidal features. Yet the converse is *not* true; that is, not all strongly interacting galaxies show ultraluminous activity. In fact, the most dramatic nearby mergers, such as the Antennae (NGC 4038/39) or NGC 7252, have experienced violent collisions, yet have infrared luminosities an order of magnitude less than the extreme ULIRGs. Clearly the detailed triggering mechanism for ultraluminous activity must depend on a variety of factors.

How do mergers trigger ultraluminous activity? Regardless of whether the central engine is a starburst or an AGN, the first prerequisite is a large supply of fuel in the form of nuclear gas. If galaxy collisions can drive gas inwards from the galaxies' disks into their nuclei, this nuclear inflow can feed the central engine. Once the gas reaches the inner kiloparsec, it can either fragment

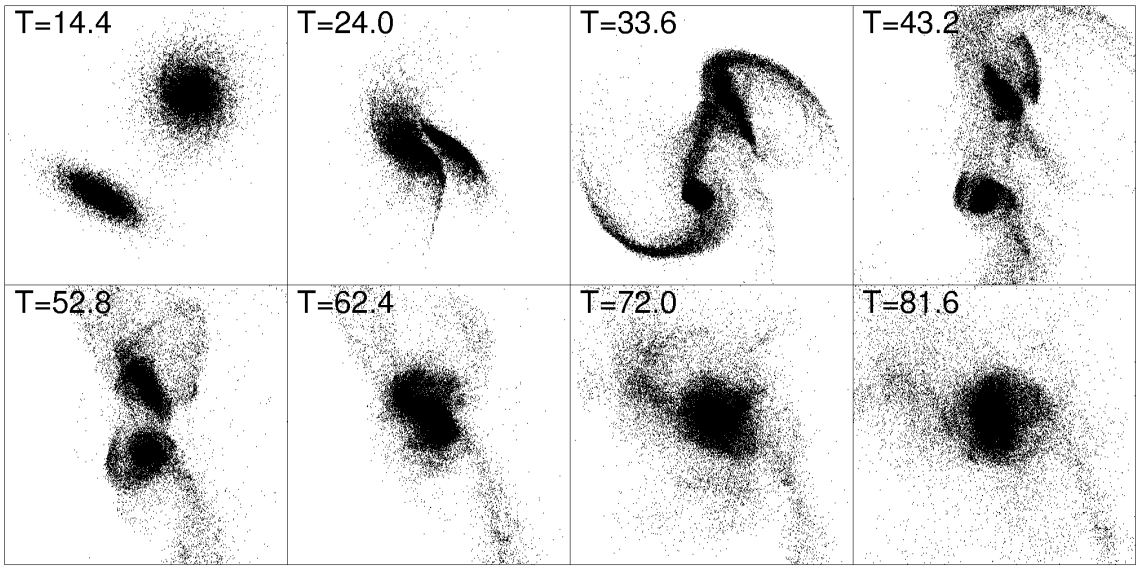

Figure 2. An N-body model of two equal-mass merging disk galaxies. Time is shown in the upper left of each panel, where unit time is ∼10 million years. After first collision at $T \sim 24$, the galaxies pass by one another before turning around on their orbits and merging to form an elliptical-like object in the last panel. From Mihos and Hernquist 1996 *Astrophys. J.* **464** 662.

and form stars (at a rate of $\sim 100 M_\odot$ yr^{-1} to provide the observed luminosity) or continue to flow inwards and fuel an AGN.

The first step, then, is to drive gas inwards from the disk to the nucleus. Computer simulations have demonstrated the efficacy of interactions and mergers at driving these nuclear gas flows. These simulations must also describe the hydrodynamic evolution of the interstellar gas, and do so using a Langrangian technique known as 'smoothed particle hydrodynamics', in which the gas is represented by discrete fluid elements (particles) which carry the local thermodynamic and hydrodynamic properties of the fluid. These properties are updated according to hydrodynamic conservation laws, and artificial viscosity is included to model shocks. This technique is ideal for simulating gas flows in interacting galaxies, which lack the symmetry and geometry needed for efficient grid-based hydrodynamical algorithms.

As an example, figure 3 shows the evolution of the interstellar gas in the merger model of figure 2. Shortly after the galaxies first collide, and the strong bars and spiral features form from the self-gravitating response of the disks, gas shocks and crowds along the leading edge of these features. Because of the offset between the stellar and gaseous density peaks, the gas feels a strong gravitational torque from the stars, losing angular momentum and flowing inwards towards the nucleus. How far inwards it can flow depends on the detailed response of the disk. If the disk develops a strong bar, the gas can flow into the central kiloparsec on a dynamical timescale; however, if the disk is stable against bar formation, the gas tends to 'hang up' in the inner few kiloparsecs. In this case, once the galaxies ultimately merge a second phase of inflow occurs, as gas is driven further inwards to the nucleus owing to the strong hydrodynamic and gravitation torques at work.

Because the inflow is tied to the (largely internal) gravitational response of the galaxies to the interaction, the triggering of inflow and nuclear activity depends on a variety of factors, such as the internal structure of the galaxies involved and the orbital geometry of the collision. Prograde collisions drive inflow and activity more rapidly than retrograde collisions, owing to the spin–orbital coupling of the encounter. If the encounter involves DISK GALAXIES with massive central bulges, the inflow should be delayed until the galaxies merge, owing to the disk stability provided by the central bulges. Conversely, without bulges, disk galaxies should be more prone to early bar formation, inflow and central activity. Similarly, galaxies in which the disk contributes little to the dynamical mass (e.g. low surface brightness disk galaxies) will also be more resistive to inflow, as the self-gravity of the disk is much weaker. Of course, in any case the galaxies themselves must have sufficient disk gas to drive inwards to begin with; collisions of gas-poor spirals will be less effective at fueling ultraluminous levels of activity.

Once triggered, the ultraluminous infrared phase probably does not last long—less than $\sim 10^8$ yr. A variety of arguments support this claim. Stellar population synthesis models successfully explain the optical and infrared spectra of ULIRGs with a burst of star formation $\sim 10^7$–10^8 years old. Similar numbers come from gas depletion arguments: if the luminous activity arises from star formation, the gas depletion time is given by $\tau_{\rm gas} \sim M_{\rm gas}/\dot{M} \sim 10^7$–$10^8$ yr. Of course, if the luminosity comes from accretion onto an AGN, the same amount of gas can sustain ultraluminous activity for a much longer period

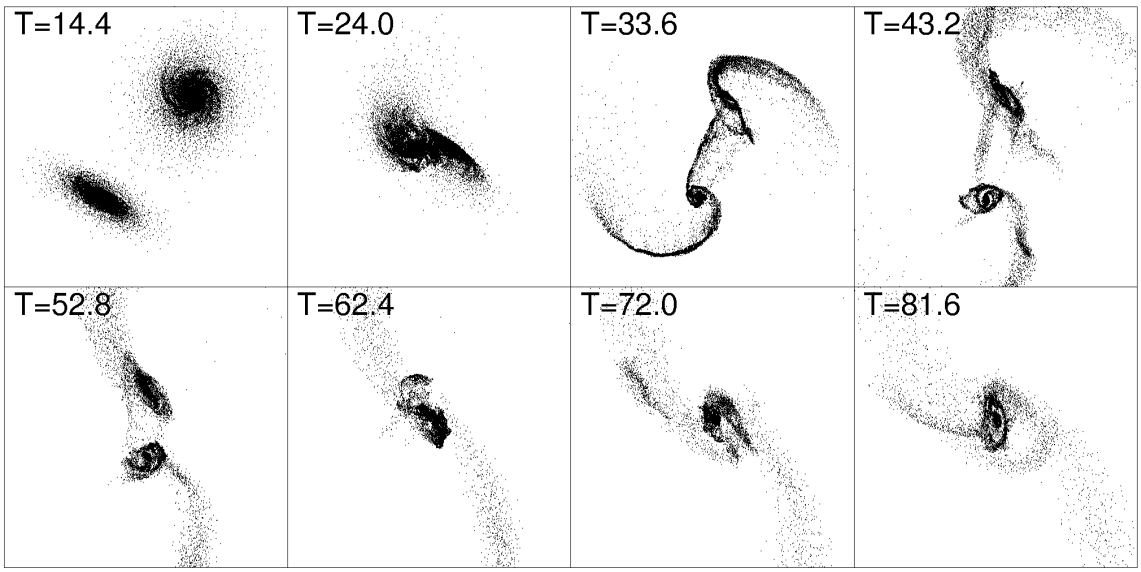

Figure 3. The evolution of the gas in the *N*-body model shown in figure 2. Time is shown in the upper left of each panel, where unit time is ∼10 million years. After the first collision, gas shocks along spiral arms and flows inwards into the inner few kiloparsecs ($T \sim 48$) and then finally into the nucleus itself when the galaxies ultimately merge. From Mihos and Hernquist 1996 *Astrophys. J.* **464** 662.

of time. However, the fact that nearly all ULIRG systems show strong dynamical evidence that they are in the late stages of a merger—evidence which fades rapidly once the merger is complete—argues that the ultraluminous phase cannot last much longer than a half-mass dynamical timescale, $\sim 10^8$ years. In the latter case of AGN accretion, the end of the ultraluminous IR phase may be marked by either an end to AGN fueling or else the destruction of the 'dust shroud' by the intense UV radiation field of the AGN. In this second scenario, rather than running out of gas, the ULIRG may simply evolve into a *bona fide* optical quasar. The detailed evolution of ULIRGs is a subject of intense current study.

Merger remnants and elliptical galaxies

Once a merger is complete, and the ULIRG phase (if any) is over, what is left behind? In 1977, Alar Toomre suggested that the remnants of disk mergers could account for the population of elliptical galaxies in the universe. Because of violent relaxation, the merging process would effectively 'scramble' the stellar disks, giving the remnant the surface brightness profiles and large velocity dispersions characteristic of elliptical galaxies. Toomre argued that if the merging timescale is $\sim 5 \times 10^8$ yr, extrapolating the number of nearby on-going mergers (∼10) over the total age of the universe (assuming the merger rate scales like the $t^{5/3}$ expected from a flat distribution of binding energy) yields a total of ∼750 merger remnants, similar to the number of elliptical galaxies found in the nearby field. Furthermore, Toomre argued, if the remnants of these spiral mergers did not constitute the present-day elliptical galaxy population, where are they now?

This 'merger hypothesis' for the formation of elliptical galaxies idea also had observational support from studies of the peculiar galaxy NGC 7252 (see figure 4) by François Schweizer. While this galaxy possesses two gas-rich tidal tails (indicating a merger of two late-type spirals), it also has the surface brightness profile expected for an elliptical galaxy. Schweizer argued that we were catching the elliptical formation process in the act and that NGC 7252 would evolve into a normal elliptical galaxy given time.

While the merger hypothesis could explain many of the qualitative properties of ellipticals, several detailed objections were raised. The central phase space density of spirals is lower than that of ellipticals; since violent relaxation preserves phase space density, merger remnants should have phase space densities too low to compare well with elliptical galaxies. Also, the specific frequency of GLOBULAR CLUSTERS (the number of globular clusters per unit luminosity) is much larger for ellipticals than spirals. Finally, because of the high relative velocity of galaxies in clusters, mergers should be less common in these environments, yet that is where the elliptical fraction is highest. How then could mergers of disk galaxies produce the present-day elliptical galaxy population?

Recent developments have relieved some of these concerns. While it is true that stellar phase space density is preserved during mergers, this constraint does not apply to the interstellar gas, which can dissipate energy and flow inwards. Subsequent star formation can raise the central phase space density in the merger and in principle produce an elliptical-like nucleus. Interaction-induced star formation may also account for the differing globular cluster specific frequencies of spirals and ellipticals.

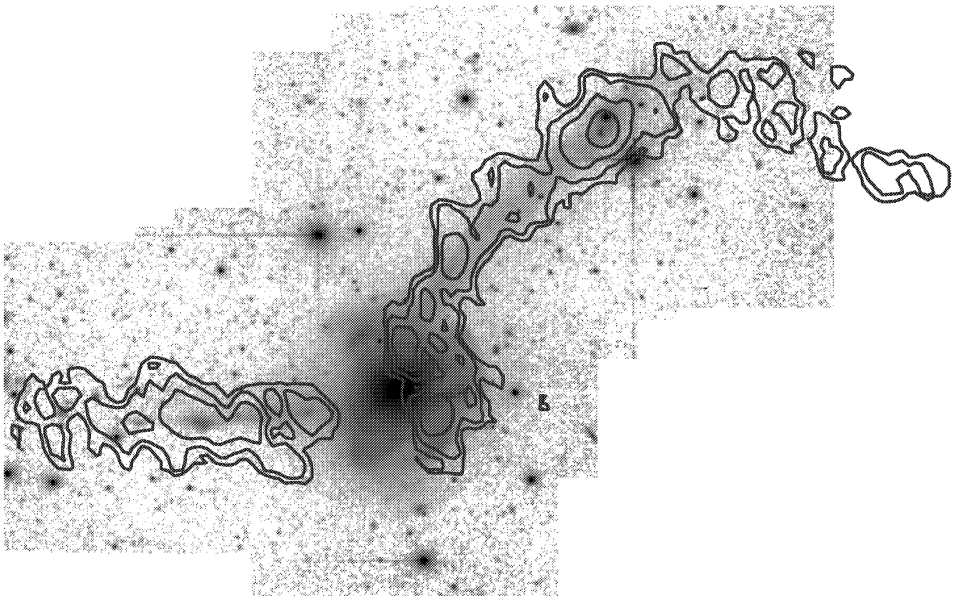

Figure 4. The merger remnant NGC 7252. The image shows the optical light from NGC 7252, while the contours show the distribution of neutral hydrogen gas. Note the gas-rich tails, the loops of starlight surrounding the main body and the smooth, elliptical-like appearance of the inner regions. From Hibbard *et al* 1994 *Astron. J.* **107** 67.

Recent Hubble Space Telescope observations indicate that galaxy collisions can result in the formation of a large number of young, compact star clusters. If these clusters can survive the dynamical environment of tidal shocks and mass loss, perhaps they are the progenitors of the old globular clusters observed in elliptical galaxies. Finally, the problem of the high relative velocity of galaxies in clusters can be surmounted by realizing that structure forms hierarchically. Galaxy clusters are the last objects to form; galaxies first assemble into smaller groups which fall together to form a larger galaxy cluster. The galaxy mergers which produce the current cluster ellipticals may have occurred long ago in small groups (with low velocity dispersions), before the cluster formed as a single virialized structure.

The merger hypothesis thus remains a viable mechanism for the formation of elliptical galaxies. We can now ask whether the merging process leaves behind any signatures which can be used to constrain the fraction of ellipticals which formed in this manner. The nuclear starbursts should result in the formation of a central population of stars which is distinct in a number of ways from the older stars in the original galaxies. This population may manifest itself through features ('seams') in the surface brightness profiles of ellipticals, through strong age and metallicity gradients, and through kinematically distinct nuclear kinematics. On larger scales, unless the starburst completely processes the interstellar gas into stars, a small but significant amount of cold gas may remain in the remnant. In the outer portions of the remnant, the relaxation timescale is long and low surface brightness tidal feature—'shells' and 'loops'—can survive for many billions of years, indicating a strong collision in the galaxy's past. Observationally, a significant fraction of elliptical galaxies show kinematically distinct cores, residual gas and dust, and large-scale tidal features. Through studies such as these, it may be possible to constrain the fraction of ellipticals formed through disk mergers.

Of course, in a universe where structure forms hierarchically, all objects form from the coalescence of smaller objects. From this point of view, it may be wiser not to ask 'did mergers form ellipticals?'. but rather 'what merged to form ellipticals?'. Observational studies have shown that cluster ellipticals must have formed very early, perhaps even before massive disk galaxies had formed. If so, the merging objects were probably very different from the types of galaxies we see involved in nearby mergers. Because the collapse time for structure is faster in high-density environments, cluster and field ellipticals have a different formation timescale, and (under the merger hypothesis) should have different progenitors. Cluster ellipticals may form from the rapid assembly of many small progenitors, while field ellipticals may form through the more classical merger hypothesis picture of two merging spiral galaxies. These different histories should manifest themselves through differences in the structural, chemical and stellar population mix between cluster and field samples. The observational data, however, do not show as strong an effect as that predicted by models of hierarchical structure formation. The question of whether most ellipticals were formed through major merger events remains open.

Minor mergers and satellite accretion

So far we have focused on so-called 'major mergers'—mergers of two large, roughly equal-mass disk galaxies. While these represent some of the most spectacular collisions we observe, they are far from the most common. Because of the shape of the galaxy luminosity function, which rises at fainter luminosities, encounters more commonly involve a galaxy interacting with a small satellite companion. However, it turns out that even these 'minor mergers' can have a dramatic impact on the evolution of galaxies.

That minor mergers occur frequently can be seen from even a casual inspection of the environment of our own MILKY WAY. The Milky Way is surrounded by 14 known satellite galaxies, the largest and most massive being the LARGE and SMALL MAGELLANIC CLOUDS. At a galactocentric distance of 50 kpc, the Magellanic Clouds are believed to orbit our Galaxy once every few billion years. The effect of this interaction is clear: tidal forces from the Milky Way have torn a long stream of gas—the MAGELLANIC STREAM—from these companions, and it has been argued that some of the younger Milky Way globular clusters may have been tidally stripped from the Magellanic Clouds. Recently, the discovery of the SAGITTARIUS DWARF GALAXY plunging through the galactic disk on the far side of the Galaxy has given us an up-close view of the tidal destruction of a merging dwarf galaxy. A similar system of companions surrounds the nearby Andromeda Galaxy, including the bright dwarf elliptical galaxies NGC 205 and M32. Indeed, if models of structure formation in the universe are to be believed, all bright galaxies should have a large number of satellite companions.

Unlike major mergers, where dynamical friction is so efficient that the galaxies merge after only a few perigalactic passages, the extreme mass ratio (>10:1) of minor mergers ensures that the orbital decay of the satellite's orbit is slow. For example, it is estimated that the orbit of the Magellanic Clouds will decay in another ∼10 Gyr, giving the Clouds a total 'survival time' of ∼10 orbital periods. Rather than the sudden violence of a major merger, these minor mergers are more properly a relatively slow accretion event, and the dynamical evolution of these systems is markedly different. In particular, the tidal field of the host galaxy will act to gradually strip material from the orbiting companion, such that the merger may not play to completion—the companion may be totally destroyed before reaching the inner portion of the host galaxy. Since the tidal radius of a orbiting companion is roughly proportional to $(\rho_s/\rho_G)^{1/3}$ where ρ_s and ρ_G are the average mass density of the satellite and host galaxy, respectively, it is the low-density, diffuse satellite companions which are preferentially destroyed as they orbit their host. Low-density DWARF IRREGULAR and DWARF SPHEROIDAL GALAXIES will certainly be tidally disrupted at relatively large distances from their hosts, while compact companions (such as Andromeda's M32) may survive the accretion process well into the host.

As the satellite is stripped on its orbit, this stripped material can be incorporated into the luminous halo of the main galaxy. Over several orbits, this stripped material will gradually spread out along the satellite's orbital path, making a kinematically distinct 'tidal stream' in the halo. In 1978, Leonard Searle and Robert Zinn proposed that, rather than forming in a single monolithic event, the halo of the Milky Way formed through continual accretion of material much like the infall of satellite galaxies. To reproduce the observed halo luminosity of the Milky Way ($L_B \sim 10^9 L_\odot$), the Milky Way must have accreted on the order of a few hundred small satellites during its lifetime to build the halo in this manner. Whether or not such an evolutionary picture is consistent with the Milky Way's dynamically cold disk (see below) or with the long dynamical friction timescales involved remains unclear, but a variety of observations argue that some fraction of the Milky Way's halo—and presumably those of other spirals as well—formed through satellite mergers. Observations of halo stars show the presence of substructure, moving groups and possible streams of globular clusters and dwarf galaxies in the halo. The presence of young A stars in the otherwise-old halo also argues for recent accretion events, while tidally stripped material from the Sagittarius dwarf extending out more than 30° from the core demonstrates explicitly how satellite accretion can feed the Galactic halo.

If the satellite is sufficiently dense and massive, its accretion can do more than simply build up the stellar halo of a galaxy. Such satellites more readily survive into the inner galaxy; once there, they can strongly influence the dynamical evolution of the disk. An N-body simulation of such an accretion event is shown in figure 5, where a prograde satellite with mass 10% that of the disk merges with a larger disk galaxy. As this massive satellite plunges through the disk, it scatters disk stars off their orbits, heating and thickening the stellar disk. As the satellite galaxy falls to the plane of the disk through dynamical friction, conservation of total angular momentum dictates that the disk warp and tilt in response. The resulting warped, thickened disk is qualitatively similar to those seen in some nearby galaxies (such as NGC 3628) and inferred in our own Milky Way.

As a massive satellite spirals into the inner disk, it can also induce strong spiral arms and bars through a resonant response in the disk. Interstellar gas can be compressed along these features and flow inwards towards the nucleus owing to gravitational torquing from the bar and arms, similar to, but at a more modest level than, the major-merger-induced nuclear inflows. Thus these minor mergers can also drive increased disk and nuclear star formation rates or activate a central engine. When the merger is complete, a significant fraction of the disk gas may have been swept from the disk and into the nucleus. The disk itself has been kinematically heated, and spiral structure destroyed, by the passage of the companion through the inner disk. The induced bar may buckle in three-dimensional space, scattering stars above and below the disk plane, in a pseudo-bulge. The

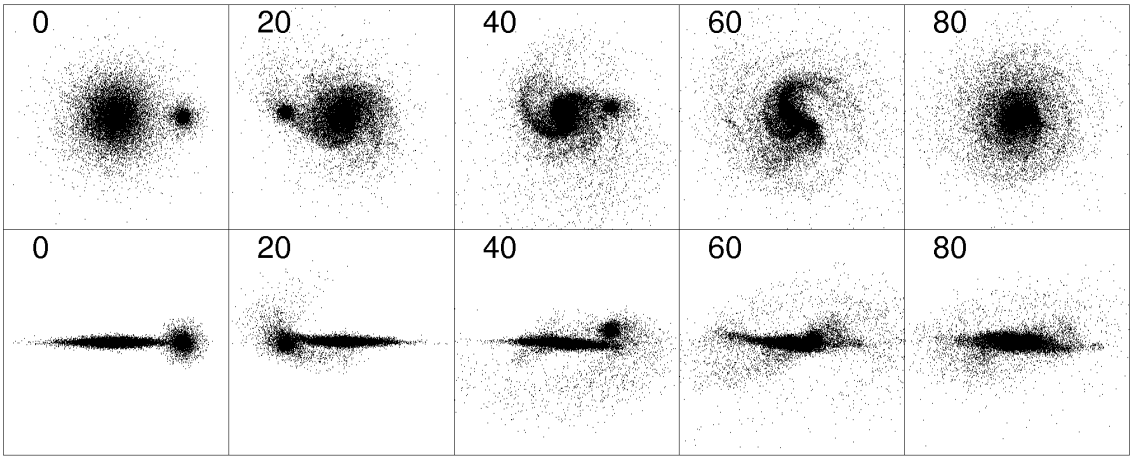

Figure 5. An N-body model of a large disk galaxy accreting a small satellite companion. The companion is initially on a circular orbit around the primary, inclined 30° from the disk plane. Top row shows a face-on view of the accretion; bottom row shows an edge-on view. As the satellite falls into the inner regions of the host, it excites strong spiral arms and a central bar, and thickens and warps the disk. Note also the stripping of material from the companion as it is accreted. From Hernquist and Mihos 1995 *Astrophys. J.* **448** 41.

morphological, kinematic and star-forming properties of the disk have all been radically altered by this interaction, suggesting that even minor mergers can drive significant evolution in disk galaxies.

Bibliography

The subject of galaxy interactions covers such a wide range of topics that it is impossible to give a comprehensive literature review. Instead, I have attempted to outline some of the original material in the field, while also giving more recent reviews on the broader subjects.

Recent reviews on the subject of galaxy interactions include

Galaxy

A large assemblage of stars, gas and dust that is held together by the mutual gravitational interaction between its constituents. Galaxies contain between a few million and about ten trillion (10^{13}) stars together with differing proportions of interstellar material (gas and dust).

Most galaxies can be categorized as *normal* galaxies, but a few percent (those that exhibit unusual characteristics such as having a compact, variable nucleus, radiating predominantly non-stellar radiation, and having a disturbed appearance) belong to the category of *active* galaxies. Normal galaxies may be classified in a number of ways, the most common system being the Hubble classification scheme, which divides galaxies into the following principal types: elliptical, spiral, barred spiral and irregular. Elliptical galaxies are spherical or ellipsoidal in shape, are dominated by old red stars and contain very little interstellar gas. Spiral galaxies consist of a central nucleus of relatively closely packed stars surrounded by a flattened, disk-shaped distribution of stars, gas and dust, within which luminous gas clouds and the brightest, youngest, stars are gathered into spiral-shaped 'arms' that appear to spread out from the nuclear region. In barred spirals, the nucleus is elongated, or bar-shaped, and the spiral arms emanate from either end of the nuclear bar. Irregular galaxies display no obvious pattern or structure. Spirals and barred spirals contain a larger proportion (typically about 10%) of gas and dust than ellipticals. The gas content of irregulars varies considerably, but is typically about 20%.

The masses of galaxies range from a few million solar masses, in the case of dwarf ellipticals, to a few trillion (10^{13}) solar masses, in the case of the most massive ellipticals. Their luminosities range from about 200 000 to a trillion (10^{12}) times that of the Sun and their diameters mostly range from a few thousand light-years to a few hundred thousand light-years. Although most of the ellipticals are relatively small, 'giant' ellipticals are found in the cores of clusters of galaxies, a subset of these, the 'supergiant' (cD) galaxies, having diameters of up to five million light-years.

Measurements of the rotation curves of spiral galaxies (graphs of the velocities at which stars and gas clouds revolve at different distances from the centers of galaxies) indicate that stars and gas clouds in the outer regions of galaxies are moving as fast as, or faster than, those that are located closer to their centers. These results imply that up to 90% of the mass of a galaxy consists of dark matter (matter that emits no detectable radiation but exerts a gravitational influence), much of which lies in its outer regions.

The galaxy to which the Sun belongs is known as the Galaxy (with a capital 'G'), or the Milky Way Galaxy. It is a spiral or barred spiral system that contains more than 100 billion stars and which has an overall diameter (measured across its disk) of about 100 000 light-years.

Galaxy Clusters

Galaxy clusters are the largest stable structures in the universe. Galaxy clusters have been key astrophysical objects in the development of our current understanding of a host of issues.

- Dark matter was first detected in galaxy clusters.
- Galaxy clusters contain gas at a temperature of about 10^8 K and are very luminous x-ray sources.
- The theory of gravitational instability, which is the current paradigm for the formation of all structure, was first developed to understand galaxy clusters.
- Clusters contain a unique mixture of galaxy types, including the biggest and many of the oldest.

Galaxy clusters were first tentatively recognized in the sky surveys of NEBULAE in the 19th century. The two most prominent in the northern sky are the VIRGO CLUSTER, which is the approximate center of the local supercluster at a distance of about 20 Mpc from the Milky Way, and the COMA CLUSTER (figure 1), which is a spectacularly 'rich' cluster at REDSHIFT of about 6900 km s^{-1}. The Virgo cluster lies near the north Galactic pole and provides us with a convenient local sample of a relatively low-richness cluster. Coma is also located in the north Galactic cap and stands out as an unusual structure in the whole northern extragalactic sky.

When galaxy clusters were first noticed in the 1800s, the size and structure of our own Galaxy was not known, let alone the distinction between various types of nebulae in our Galaxy and the extragalactic nebulae, which turned out to be other galaxies. Hubble's distance scale of the late 1920s was an essential underpinning to the physical investigation of galaxy clusters. The first step was momentous. ZWICKY measured the velocities of individual galaxies in the Coma cluster. Then, making the somewhat bold assumption that the cluster was in a stable equilibrium, he derived its total mass. The ratio of the mass to the total luminosity of cluster galaxies is an astonishing value of about $200M_\odot$ per $L_\odot$ (adjusted to current-day values of the HUBBLE CONSTANT). The Sun itself has a mass-to-light ratio of unity, and mixes of stars in an average galaxy have M/L values ranging from about 1 to about 10, depending on their Hubble type. Zwicky's conclusion was that most of the mass was 'missing' from the census of visible light. This conclusion was controversial until the 1970s, the primary issue being the dynamical state of clusters which was unclear partly because there was no clear theory of how such massive objects could come together. In the late 1960s Peebles (1970) did one of the first n-body simulations to show how a cluster could form from small density fluctuations in an expanding universe. Then, with the first imaging x-ray telescopes in space it was conclusively established that large clusters of galaxies contained gas at a temperature of about 10^8 K. Such hot gas required that there be a large, deep potential well to keep it contained. X-ray observations of clusters have become one of the major tools for first finding galaxy clusters and for investigating the structure of the DARK MATTER distribution.

In the 1980s GRAVITATIONAL LENSING was discovered in galaxy clusters, more or less as predicted by Zwicky. This elegant technique is both simple and powerful. The data consist of nothing other than a picture of a cluster at a moderate redshift, say roughly 1/2, where the lensing effect has a reasonable 'lever arm'; the picture will have a high density of background galaxies without too many foreground sources (which suffer no lensing effect). The gravitational field of the cluster causes the background galaxies to be slightly tangentially elongated (on the average), which directly measures the mean surface density of the cluster. Very deep images with exceptionally high angular resolution (such as from the Hubble Space Telescope) reveal more detail which can be used to investigate smaller-scale structure in the dark matter distribution.

A famous theoretical paper of Sunyaev and Zeldovich (SZ) predicted that as COSMIC MICROWAVE BACKGROUND (CMB) radiation passes through a cluster its radiation would be affected in two ways. First, the very hot electrons in the cluster would Compton scatter the 3 K photons of the CMB, leading to a slight increase in the energy of each photon. If the cluster is moving with respect to the CMB, then there is an additional Doppler effect of light being red- or blueshifted by reflection from a moving mirror. By comparing the CMB radiation near to the cluster with that seen coming through the cluster the SUNYAEV–ZELDOVICH EFFECT can be used to map the distribution of hot gas in clusters. This technique is best done at fairly short wavelengths where the confusing effects of radio sources are minimized. Radio telescopes that operate efficiently for these measurements at very high frequencies are now being constructed.

The galaxy content of clusters is unique. The GALAXY MORPHOLOGY–DENSITY RELATION (Dressler) states that the low-density field is dominated by spiral-type galaxies but as one moves to regions of ever higher density the fraction of spirals declines and elliptical and S0 galaxies dominate in regions of very high galaxy density, such as the centers of galaxy clusters. Spirals are actively forming stars whereas E and S0 galaxies have very low star formation rates. Understanding this relation is a key consideration in theories of GALAXY FORMATION. Although E and S0 galaxies are fairly rare outside of clusters, they do provide about 15% or so of the field galaxy mix. The cD galaxy type, a supergiant elliptical with an extended envelope, is unique to clusters. Relative to field galaxies, cluster galaxies are older and contain a larger fraction of their stars in a spheroidal component as opposed to a flat disk. One possible inference is that galaxy merging was more important in clusters than in the field.

Finding galaxy clusters

Clusters are rare objects, containing about 1% of all galaxies. Finding them efficiently with minimal biases remains a research problem. The problem is that the

Figure 1. The color image of the central region of the Coma cluster was taken at KPNO with 0.9 m telescope and T2KA CCD in the B, R and I bands as part of Omar López-Cruz's PhD thesis. The field of view covers 23 arcmin × 23 arcmin. Preprocessing was done with IRAF by López-Cruz and the color composition was done by Ian Shelton. **This figure is reproduced as Color Plate 22.**

method of finding the clusters can significantly influence the properties of the cluster sample. A trivial sampling bias is that practical samples are only complete to some limiting flux as measured in some waveband which usually, but not always, leads to a declining number of clusters with increasing redshift.

The Abell catalog

The Palomar Sky Survey of the 1950s provided the first nearly uniform optical coverage of the northern celestial sphere. Abell's 1958 paper describing his use of this huge database remains a classic of experimental design which in many ways has served as a prototype for other surveys for galaxy clusters. Abell's opportunity at the time was exceptional; however, the fact that his catalog has remained the fundamental low-redshift sample even today is testament to the care which he approached this problem at a time when the nature of galaxy clusters was far from clear. Earlier work of Zwicky at Caltech and Neyman, Scott and Shane at Lick had made it clear that separating galaxies into cluster and field populations was an ambiguous process. On the other hand, prominent clusters such as Virgo and Coma were readily identifiable physical objects, of which there must be other examples scattered throughout the universe. Abell devised a set of approximately redshift-independent criteria for

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

identifying galaxies. The technique makes the reasonable and verifiable assumption that the tenth-brightest member has a statistically constant luminosity. From the apparent brightness an approximate distance can then be deduced, allowing clusters at different redshifts to be considered on the same basis. Abell made the inspired choice of 1.5 Mpc (for $H_0 = 100$) for the characteristic projected radius inside which he counted galaxies to measure the richness. For the range of cluster memberships he considers, from 50 to about 500, this is comparable with the 'virialization' radii of the clusters. The result is Abell's exceptionally durable list of about 3000 clusters, culled from approximately 10 000 square degrees of sky. From this catalog Abell draws the important conclusion that clusters are not randomly distributed (see ABELL CLUSTERS).

X-ray cluster catalogs

X-ray astronomy transformed the study of clusters. Since the Abell clusters have internal line-of-sight velocity dispersions ranging from about 500 to 1000 km s^{-1} any gas within them is, in equilibrium, heated to a temperature of between 10^7 and 10^8 K. Gas at these temperatures radiates primarily in the x-ray part of the spectrum, with characteristic energies of a few kiloelectronvolts (keV). The first x-ray satellites found that clusters were very bright, implying x-ray luminosities in the range from 10^{43} to 10^{45} erg s^{-1}. This x-ray luminosity is about 2–4 orders of magnitude less than the luminosity of all the visible galaxies. However, the galaxies are powered by nuclear energy whereas the x-ray gas ultimately derives most of its energy from its gravitational energy release as it falls into the cluster.

Normal galaxies in the field produce little x-rays. Therefore at low redshifts clusters of galaxies are readily found, since the field is effectively 'dark'. However, the x-ray sky is fairly 'bright', probably as a result of large numbers of x-ray-emitting galaxies and ACTIVE GALACTIC NUCLEI (AGN) at high redshift. However, these distant sources effectively act to provide a uniform background, upon which the clusters are superposed. On the whole, the result of x-ray cluster finding at low redshift is to confirm the reality of most of Abell's clusters. The x-ray data are not sensitive to the projection of unrelated field galaxies and so usually give a better indication of the overall size of the cluster.

X-RAY TELESCOPES have not had very large apertures. Consequently it is difficult to do deep surveys over large sky areas. The Einstein Medium Sensitivity Survey (EMMS) and the Rosat Deep Cluster Survey (RDCS) are both 'serendipitous' surveys, which take advantage of deep x-ray exposures of unrelated objects, such as M stars. After imposing strict limits on any association, one sorts through the 'other regions' of the x-ray image of such an object. EMSS examined about 800 square degrees and RDCS about 100 square degrees, but to an x-ray flux limit about an order of magnitude fainter. The EMSS clusters extend from about redshift 0.05 to 0.55. The RDCS clusters extend nearly up to redshift 1. However, both of these samples contain only about a dozen sources at redshifts beyond about half of their highest redshift.

The x-ray surveys helped to clarify the issue as to where galaxy clusters 'end'. They have a characteristic radius of about 1 Mpc, inside of which the gas is hot and the galaxies are on approximately random orbits, as opposed to infalling nearly radial orbits outside the cluster. This distinction between cluster and field leads to the result that about 1% of all galaxies are in rich clusters.

New x-ray satellites will probe to much higher redshifts. In particular there are plans for the XMM satellite to use x-rays to detect clusters to redshift 2, where most other techniques become unreliable and inefficient.

New techniques

The hot gas in galaxy clusters is also seen in projection against the 2.7 K CMB radiation. Zeldovich and Sunyaev (1969) pointed out that as the CMB photons traverse the cluster they will, on average, be heated slightly. Therefore the Planck spectrum of the CBR is boosted upward slightly in energy. The result in the Rayleigh–Jeans tail at low frequency is that the cluster appears to be 'cool' with respect to the surrounding sky. The temperature decrement is of order a few hundred microkelvin. The unique power of the technique is that the SZ effect has no redshift dependence and can in principle find clusters to very high redshift. In practice a serious limitation is the sensitivity and the sky coverage of existing mm-wave radio telescopes. Mapping even a single square degree is a considerable challenge today, but will become nearly routine with future facilities.

Weak gravitation lensing directly 'images' the dark matter in the universe (Kaiser and Squires 1993) based on the gravitationally induced distortions of distant galaxies viewed along a line of sight that passes close to a mass concentration. This technique obviously depends on having observations that reach to high enough redshifts that large numbers of galaxies behind the clusters of interest are reached. There is the practical complication that galaxies are themselves non-circular so one must observe sufficient numbers so that the shear induced by a cluster, say of order 10% image distortion, can be confidently detected. As large-area CCD cameras become available this technique will probably become very important.

The galaxy population of most clusters contains far more relatively red, 'early-type' galaxies than are present in the field. An imaging survey with color information (Yee *et al* 1999) therefore can seek out concentrations of these objects on the sky. Because the red sequence changes its color with redshift it also provides a redshift indicator. Large-area optical and infrared imaging surveys will make this technique feasible.

There should be a dramatic change in the availability of carefully defined samples of galaxy clusters to redshifts well beyond 1 in about the year 2000. Up to the year 2000 Abell's sample has stood alone as the only really large one. X-ray selected samples have found objects slightly beyond

redshift 1, but the numbers beyond even redshift of 0.5 are only of order one dozen. These new samples will open up a huge new range of astrophysical investigations.

Galaxies in clusters

The properties and evolutionary scenarios of cluster galaxies are a large and significant subject in their own right. A fundamental observation is the morphology–density relation (Dressler 1980) where it is noted that spheroid-dominated 'early-type' galaxies are much more frequent in clusters than the disk-dominated 'late-type' galaxies which predominate in the field. Quantitatively there is a smooth trend of fraction of early type as a function of the local environmental density. This relation is an important clue that the clustering environment plays a significant role in determining the properties of galaxies. This relation implies that most clusters have a radial gradient in their galaxy populations, with the central region largely composed of early-type galaxies and the outer regions beginning to resemble the field in the mix of galaxy types and colors. The red ELLIPTICAL GALAXIES in the centers of clusters are generally agreed to be the oldest normal galaxies in universe, as indicated by their exceptionally red colors in most photometric bands, which reflects the continuum light of the dominant stars of the red giant branch, and the strength of various lines which are fairly well calibrated against a similar mix of stars that have individual age dates within our own Galaxy. Of course the age of the stars does not necessarily tell when the galaxy was assembled into a single unit. Clusters contain many examples of the S0 type of galaxy, which was originally suggested by Hubble as a hypothetical type needed to fill out his tuning fork diagram. The S0s resemble the larger bulge DISK GALAXIES, Sa and Sb, but have disks that are somewhat thicker and have essentially no spiral features.

A second important observation is that clusters contain an increasing fraction of star-forming, late-type galaxies with increasing redshift (Butcher and Oemler 1984). This is possibly related to the increasing numbers of blue galaxies in the field with increasing redshift, which, through infall, could mix in with the cluster galaxies. In both cases the detailed mechanisms leading to these observational effects need to be better understood, which has provided part of the motivation for building new telescopes.

Clusters, by definition, have a brightest cluster galaxy (BCG). Besides being extremely luminous, the BCG is generally found at the center of the cluster, which is probably a consequence of dynamical friction on the large mass of the BCG. Generally the BCG is an elliptical-type galaxy, quite frequently of the unusual subtype 'cD' (cluster dominant), which is an elliptical with an extended envelope about the normal surface brightness profiles of elliptical galaxies, de Vaucouleurs' $r^{1/4}$ relation. These envelopes of extended stellar light are sufficiently faint that its detailed properties have not been studied in any detail. Two intriguing possibilities for the origin of the envelope are that it formed out of a 'cooling flow' in the x-ray gas in an extended galaxy formation period and that it is composed of stars that were originally part of other cluster galaxies but subsequently tidally stripped from them by the strong gravitational field in the central region of the cluster.

Dark matter in clusters

The Coma cluster has been a Rosetta stone for understanding the contents of the universe, in particular as an indicator of the total mass and gas density in the universe. Zwicky (1933) obtained spectra of a number of galaxies in the cluster from which he deduced that the galaxies were probably moving at random in a virialized potential with a line-of-sight velocity dispersion, σ_1, of about 1000 km s^{-1}. He estimated the virial radius to be somewhat more than $1/h$ Mpc, leading to a virial mass estimate, $M_V = 3G^{-1}\sigma_1^2 r_v$, of about $10^{15} M_\odot$. The sum of the luminosities of the cluster galaxies was about $5 \times 10^{12} L_\odot$. These numbers indicate that the mean amount of mass per unit luminosity is about $200h^{-1} M_\odot/L_\odot$, whereas both observation and modeling indicate that the stars themselves have a mean mass-to-light ratio of about $10 M_\odot/L_\odot$. The discrepancy is huge, highly significant and confirmed many times over in independent observations. One is led inexorably to the conclusion that the bulk of the mass of clusters is of some unknown 'dark' form.

On the basis that clusters were large, massive systems whose physics is entirely dominated by gravity, Oort (1958) proposed that the mass-to-light ratios of galaxy clusters were representative of the universe as a whole. Arithmetic then indicates that the mean mass density of the universe is the luminosity density times the mass-to-light ratio. The Canadian Network for Observational Cosmology (CNOC) survey established that the virial mass was a reliable indicator of the total mass in a cluster and simultaneously measured the luminosity density of the field, finding that $\Omega \simeq 0.19 \pm 0.06$ (Carlberg *et al* 1996, 1997). The two interesting implications of this result are that the total mass of clusters is well beyond what could be formed by the baryons created in the big bang (Copi *et al* 1995) and furthermore that it is well below $\Omega = 1$, the value that a flat, matter-dominated universe would have and the simplest result of an inflationary cosmology.

Dark matter has only been detected by its gravitational influence in astronomical observations. If general relativity were seriously in error then dark matter need not exist. However, we hastily add that general relativity has been both experimentally and theoretically scrutinized at length with no flaws having yet emerged. The physical makeup of dark matter is completely unknown at this time, although there are a wide range of particle physics candidates for its possible constitution.

Hot gas in clusters

The discovery that clusters emitted prodigious amounts of fairly hard x-rays conclusively demonstrated that clusters were bound, substantially virialized structures. The x-ray emission is produced via thermal bremsstrahlung in the

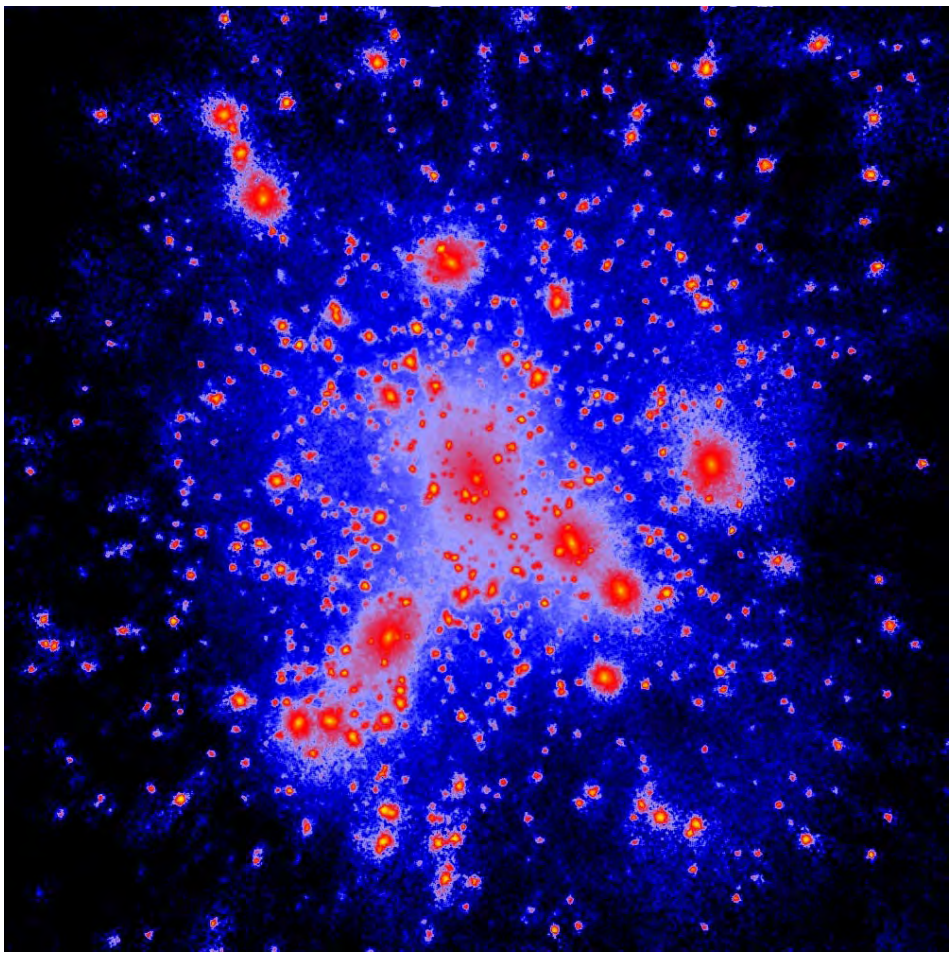

Figure 2. An n-body simulation of a cluster in a CDM model universe, courtesy of Ben Moore (University of Durham), Tom Quinn, Joachim Stadel, George Lake (University of Washington). The picture is color coded with the local density of dark matter. As the dark matter halos fall into the cluster their outer envelopes are tidally stripped off to join a cluster background but the very dense cores remain intact and orbit within the cluster. **This figure is reproduced as Color Plate 23.**

hot gas. The temperatures of around 10 keV imply that the electrons are slightly relativistic, which becomes an issue for some precision measurements of the state of the gas, particularly in the SZ effect. A public access computer code allows anyone to do a detailed computation of the emitted spectrum from an optically thin astrophysical plasma (ftp://heasarc.gsfc.nasa.gov/software/plasma_codes/raymond). One substantial result is that the x-ray temperature is identical (within the current errors) to the thermalized mean motion of the galaxies, indicating that both are in the same equilibrium with respect to the dark matter. X-ray emission drops as the density squared, meaning that the x-rays rapidly become hard to measure towards the edge of the cluster.

One of the most intriguing and controversial inferences from the x-ray data comes from the straightforward calculation of the cooling time of the cluster gas. In quite a few clusters the gas within the central few hundred kiloparsecs will cool in less than a Hubble time, in the absence of a heat source. The implied mass deposition onto the center of the cluster ranges up to as much as $1000 M_\odot$ per year. Where does this mass go? It seems very unlikely to be completely dark, and, in spite of evidence that there is some residual star formation in the BCG, it is far below the massive amount in the cooling flow. The increasing sensitivity and angular resolution of x-ray satellites should help resolve this issue.

As the CMB radiation with a Planck spectrum at 2.7 K passes through a cluster Compton scattering boosts the mean energy of the photons slightly (Zeldovich and Sunyaev 1969; Sunyaev and Zeldovich 1980). Even at the center of a rich cluster the decrement is slightly short of 1 mK. Of great value is that the thermal effect, which measures the electron pressure along the line of sight, $\int p_e \, dl$, has a frequency dependence that is different from the kinematic SZ effect, which depends on the peculiar velocity of the cluster with respect to the CMB. The result is that precision measurements of the flux difference from

the CMB as a function of frequency can provide a precise estimate of the cluster's peculiar bulk flow velocity, which is of great interest for constraining the amount of large-scale clustering in the universe.

Clusters also contain magnetic fields which become dynamically important near the centers of clusters (Kim *et al* 1990). The origin of this field is not known. If it is intrinsic to the cluster, as opposed to, say, being expelled from galaxies, it is quite puzzling.

The clustering of clusters

Abell noted that within his catalog of clusters the clusters had a tendency to lie near one another. Hauser and Peebles (1973) re-examined this and concluded that the clustering could be described with the two-point correlation function with a correlation length probably larger than that of galaxies, later refined by Bahcall and others. The strong clustering of clusters posed a puzzle, which ultimately helped inspire Kaiser's (1984) theory of biasing. The idea is quite simple, just that clusters are much rarer than galaxies themselves. Within a Gaussian random field the rare objects, such as galaxy clusters, will be more correlated than more typical objects. The clustering data are in quite good accord with the theoretical expectation. The clustering data are then consistent with a hierarchical theory for the formation of clusters from an expanding dark matter distribution. Much more work remains to be done on larger samples to check the theory in much more detail.

Formation and evolution of clusters

Clusters are such massive aggregations of matter that in the absence of a theory for their formation it was argued that they were simply chance superpositions of unbound galaxies. The idea of gravitational instability led to a plausible solution. At some early stage in the universe very small amplitude density fluctuations are imposed upon the dark matter. With time these grow as a power law, eventually reaching an overdensity of about 5 times the critical value, after which they begin to collapse. Both the amplitude and the timescales for this process work out quite reasonably.

In the early 1980s a particular fluctuation spectrum, the cold dark matter (CDM) spectrum, became a widely accepted basic description of many of the large-scale structural properties of the universe. The CDM spectrum flows from a consideration of how a scale-free spectrum created at some early time should be altered as the universe expands (see, for instance, Kolb and Turner 1990). Clusters, because they fairly accurately reflect the dark matter properties of the universe, are often used to normalize the amplitude of the spectrum on scales where the spectrum is strongly non-linear.

Beyond fairly simple analytic approaches such as the Press–Schechter theory (1974) for the numbers of clusters the most powerful approach to detailed predictions of the outcome of a CDM theory and clusters is to do a detailed n-body simulation (figure 2). Because clusters are relatively rare, one per $10^6 h^{-3}$ Mpc^3, one must simulate a large segment of the universe to find a single cluster (Colberg *et al* 1999) or do a specialized simulation of a small segment of the universe (Moore *et al* 1998). The agreement with the data is generally strikingly good, leading to an overall impression that the basic picture is in place and can serve as a powerful tool to test the cosmological model.

Although the basic physics of the hot gas in clusters is in place its detailed simulation and how the galaxies form remains a very active field of research. The combination of new x-ray satellites, precision SZ measurements, increased computer power and increasing sophistication of simulation will lead to rapid progress over the next decade or so.

Galaxy Evolution

The galaxies that we observe in the universe at the present time exhibit a remarkable variety of properties, such as morphology, colors, luminosity and dynamics. There are galaxies which are one hundred times brighter than our own Milky Way and others that have one thousandth its luminosity. Some galaxies have very regular shapes, other are amorphous. There are galaxies with spheroidal shape that have little amount of rotation, and whose stars have large 'thermal motions' (like the molecules of a hot fluid), and galaxies that resembles rotating disks, where self-gravity and centrifugal force balance each other. There are galaxies with high amounts of gas (mostly hydrogen and helium) and dust, and a vigorous activity of STAR FORMATION. Other galaxies consist mostly of old, evolved stars, indicating that the activity of star formation in these systems ended in a remote past.

Why do galaxies show such a variety of properties? How could they form and diversify in this way, and when did they do so? Is a given property an indication of a specific evolutionary phase in the life of a galaxy, or have galaxies with different properties formed and evolved in different ways? Which physical mechanism is each property the manifestation of?

Such questions are among the most important in the study of cosmology, and yet they still elude a consistent and complete explanation. There was a time during the cosmic evolution that followed the BIG BANG when there were no galaxies, and the universe was filled with matter and radiation uniformly distributed throughout the space. Only very tenuous perturbations of the density of matter and radiation altered this otherwise almost perfect homogeneity. Then the universe underwent a transition from this phase to the highly structured one that characterizes the current epoch. GALAXY FORMATION and evolution are the results of a complex sequence of events that occurred during this transition. Their importance rests in the fact that the chronology and dynamics of these events are intimately linked to the global cosmological properties of the universe (i.e. the age of the universe, if it will expand for ever or if it will eventually collapse again in a Big Crunch, or if the expansion is an accelerated one or not) and to those of the matter that fills the cosmic space (e.g. the composition of the dark matter and its abundance relative to the ordinary, visible matter). The goal of galaxy evolution is to reconstruct back in time the physical mechanisms that led to the present-day galaxies and to explain them in terms of the properties of the matter and of the cosmology.

The morphology, structure and luminosity of galaxies

The galaxies in the present-day universe have been extensively studied for more than seventy years and, as a result, we have now a fairly accurate knowledge of their physical properties, such as the distribution of luminosity, abundances, morphology, age, chemical composition, and internal kinematics. This knowledge forms the background against which observations of the properties of galaxies at earlier cosmic epochs are compared to test and quantify galaxy evolution.

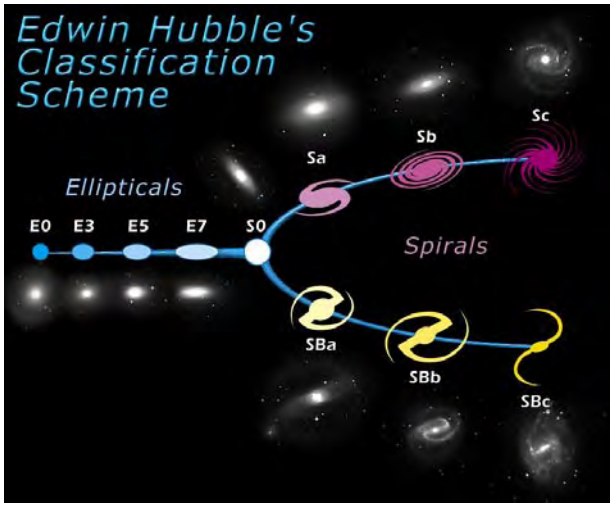

Figure 1. The Hubble morphological classification. Elliptical galaxies are ordered from E0 to E7, according to their ellipticity. The S0 type essentially represents elliptical galaxies that also have a disk. Spiral galaxies are divided into normal and barred types, and are ordered from the 'a' to the 'd' sub-types (including mixed type such as 'bc' and 'cd' not shown in the figure), according to the increasing importance of the disk component over the bulge. Irregular galaxies are not shown. (Photo credit: STScI OPO.)

Galaxy morphology

The morphology of the luminous component of galaxies, namely stars, gas and dust, is probably the most obvious manifestation of the diversity of galaxy properties. During the first half of the 19th century, EDWIN P HUBBLE classified galaxy morphologies into the four principal types of ellipticals, lenticulars, spirals and irregulars. Figure 1 shows the classical representation of the Hubble classification, also referred to as the *Hubble sequence*.

Essentially, the HUBBLE CLASSIFICATION scheme is based on the relative proportions of the two major structural parts of the luminous component of galaxies, namely the bulge and the disk. The bulge is generally made of relatively old and evolved stars, which are characterized by red colors, and is shaped like an ellipsoid with various degrees of flattening and oblateness (ellipsoids with no flattening and oblateness are spheres). In general the bulge contains no appreciable amount of dust and gas, and therefore has no activity of star formation. The disk is composed by a mixture of old and young stars and by gas and dust, and it is frequently site of star formation activity. Its colors are generally bluer than those of the bulge. The most visually striking feature of the disk is the frequent presence of the 'SPIRAL ARMS', density waves that generate in the disk and which contain active regions of

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

star formation. Other articles in this encyclopedia discuss galaxy morphology in greater detail.

Bulge and disk do not only differ for the composition of their stellar populations and interstellar medium, but also for their dynamics. Galaxies are large concentrations of mass, and they would collapse under the effect of their own self-gravity if some opposing force were not there to keep them in dynamical equilibrium. Disks are kept in equilibrium by rotation, which provides the centrifugal force to oppose gravity. Bulges have modest or no rotation, and are sustained against gravity by the 'velocity dispersion' of their stars, which is similar to the motions of molecules in a hot gas. These motions provide the pressure that contrasts gravity and keeps the structure in dynamical equilibrium.

ELLIPTICAL GALAXIES consist only of the bulge component and have no disk. LENTICULAR GALAXIES are essentially ellipticals with a very thin, often almost invisible disk, which gives them the shape of a lentil. SPIRAL GALAXIES have both a bulge and a disk with spiral arms. If a bar is present, this contains the bulge at its center and has the spiral arms departing from its extremities. IRREGULAR GALAXIES tend to resemble spiral ones, except that the bulge, the disk and the spiral arms are not regularly defined. There are also amorphous galaxies, which have morphology that cannot be easily classified into any of the main types.

Initially, it was believed that the Hubble sequence was the manifestation of an evolutionary process such that galaxies originated as ellipticals, which were therefore called the 'early types', and evolved to become spirals and irregulars, which were called the 'late types'. Although it has been shown that such ideas were incorrect, nonetheless the nomenclature has remained, and today it is common, for example, to refer to ellipticals and lenticulars as 'early-type galaxies'.

The luminosity function

One very powerful tool that describes in a quantitative way two of the most important properties of galaxies is a statistic called the *luminosity function*, which provides information on the relative frequency in space of galaxies with given luminosity. The reason to couple together luminosity and abundance is an important one. As will become clear later, the luminosity of galaxies is a measure of either their stellar content or of their current activity of star formation or of both (depending on the evolutionary phase of the galaxy). The stellar content, in turn, is generally correlated to the total mass of the galaxy, to its star formation history as well as to the history of merging with other galaxies. Finally, the current activity of star formation provides a measure of the rate at which the stellar content of galaxy is increasing.

The abundance of galaxies in space (or volume density) reflects another set of important physical properties. Galaxies form within virialized structures, namely systems that have collapsed under the effect of their self-gravity and have decoupled their dynamical evolution from that of the cosmic mass distribution (for example, they have stopped following the cosmic expansion). The theory of gravitational instability predicts that the number of virialized systems that have formed at any given time depends on their mass, with more massive systems being less abundant than less massive ones. It also predicts that, for a given mass, the number of systems depends on the density parameters Ω and cosmological constant Ω_Λ and on the spectrum of the primordial density perturbations that emerged from the Big Bang[1]. However, only galaxies that have formed enough stars or that have enough star formation (and whose light is not obscured by dust) can be observed. Thus, by coupling together the information on the luminosity and abundances of galaxies, the luminosity function provides synthetic information on the formation and evolution of both the structural and visible components of galaxies as well as on the cosmological parameters. A more detailed discussion on the luminosity function can be found in the article LUMINOSITY FUNCTION OF GALAXIES.

The luminosity function of local galaxies has been directly measured with good accuracy. It is found that fainter galaxies are much more common than brighter ones. For example, although galaxies with luminosity similar to that of the Milky Way or the Andromeda galaxy[2] are relatively common, fainter galaxies such as the Magellanic Clouds are much more frequent. Bright galaxies such as the big ellipticals often found at the centers of clusters of galaxies are much rarer. Irregular galaxies are typically fainter and more abundant than galaxies with regular morphology.

Star formation and merging: the engines of galaxy evolution

Clearly, a morphological classification is useful only if it reflects some important physical property that can be directly linked to the origin and evolution of the galaxies. What are the physical properties of the Hubble sequence? We have seen that the age of the stellar populations and the dynamical state play an important role, but how do they relate to the history of star formation and how can we use them to reconstruct its evolution? How can we exploit the information contained in the luminosity function?

Star formation

Let us illustrate the role of star formation with an example. Let us consider the case of a spiral galaxy which contains 10^{11} stars similar to the Sun. This would be approximately the size of a galaxy like the Milky Way. Let us imagine that

[1] The cosmological parameters Ω and Ω_Λ measure the total mass content of the universe and the strength of the cosmological constant, a form of repulsive force that may cause the universe to keep expanding at an accelerated pace. Their combined value decides if the universe will expand for ever or it will collapse into a Big Crunch. Together with the Hubble constant, they determine the age of the universe

[2] Such galaxies are commonly referred to as 'L^* galaxies'. The symbol L^* is used to indicated the value of the blue luminosity of galaxies similar to the Milky Way. Its value is $L^* = 10^{12} L_\odot$, where $L_\odot$ denotes the luminosity of the Sun or 4×10^{33} erg s^{-1}

this galaxy is experiencing an episode of star formation, and that it is generating new stars at a rate of, say, 10 solar masses per year or $M_\odot\ \mathrm{yr}^{-1}$ (this is the total stellar mass, not the number, of new stars). The STELLAR MASSES of freshly produced stars are not all equal, but vary approximately between 100 solar masses to about one tenth of solar mass (i.e. stars whose mass is between one hundred times and one tenth the mass of our Sun. The symbol that indicates the mass of the Sun is $M_\odot$). The relative proportions of stars of a given mass produced during an episode of star formation are, to first approximation, the same everywhere and are described by the so-called initial mass function (IMF). These proportions are such that for every star of mass M being produced, there are about 2.5 times as many stars with mass $M/2$ being also produced, implying that low-mass stars are formed much more frequently than high-mass stars. Another way to state this is that when a given total amount of stellar mass is being produced in a galaxy, this is distributed prevalently in low-mass stars.

While low-mass stars carry the bulk of the new stellar mass produced during an episode of star formation, they contribute very little to the luminosity of the event. This is because high-mass stars are much more luminous than low-mass ones. A star of 100 $M_\odot$ is about 1000 000 times brighter than the Sun. Even if there is only one star of 100 $M_\odot$ every 500 stars of 1 $M_\odot$, it alone outshines all of them, whose contribution to the total luminosity is negligible. After the first million years of continuously forming stars at a rate of 10 $M_\odot$ per year, the galaxy of our example has put together a total stellar mass equal to $10 \times 1000\ 000 = 10^7 M_\odot$, about one ten-thousandth of its initial stellar mass. Of these, about 20 000 are massive stars. Because each of these massive stars is 1000 000 times brighter than stars like the Sun, their total luminosity will approximately equal that of 2×10^{10} of these. Thus, during the star formation activity the galaxy increases its luminosity by $\sim 20\%$. Its colors also become bluer, because the radiation emitted by massive stars is very rich of light at short wavelengths, which include the blue and ultraviolet ones. Had the galaxy initially been fainter, containing say 10^{10} Sun-like stars, the same episode of star formation would have trebled its initial luminosity.

Although fainter, however, low-mass stars live much longer than high-mass ones. A star of 100 $M_\odot$ lives about one million years, after which it explodes as supernova, while a star like the Sun keeps burning its hydrogen nuclear fuel for about 10 billion years, one hundred thousand times longer. Thus, about one million years or so after the end of the star formation, when all the massive stars have died out, the luminosity of the galaxy eventually becomes again dominated by low-mass stars, both the recently created new ones and the ones that existed before the episode of star formation. If star formation continued at the same rate for one million years, the galaxy of our example, which started with 10^{11} Sun-like stars, would create another 10^7 of them, or only 0.1% of the original amount. Once the massive stars have died out, the luminosity of the galaxy in its post-starburst phase is again powered by these stars and it returns to the original value. Of course, star formation of longer duration would result in a larger increase of final luminosity and stellar mass. The luminosity of the galaxy during the phase of star formation, however, depends only on the rate at which stars are being produced because this is what determines the amount of massive stars that can be observed at a given time. Also, after star formation ends, the colors of the galaxy also return to be dominated by the light of the low-mass stars, which is redder than that of the massive stars whose colors dominated the spectral energy distribution of the galaxy during the star-forming phase.

Luminosity, stellar mass and color are not the only changes induced in a galaxy by star formation. Another fundamental product is the creation of the 'metals', namely of elements heavier than helium. The chemical composition of the universe as it emerged from the Big Bang practically consisted only of hydrogen and helium, in the proportion of about 80% and 20% by mass, respectively. Essentially all the heavier elements that we observe, both on Earth and elsewhere in the universe, have been synthesized in the interiors of stars by reactions of nuclear fusions at epochs subsequent to the Big Bang. The metals synthesized in the interiors of stars are released to interstellar space during SUPERNOVA explosions. Once the chemically enriched material has been dispersed, it becomes available to fuel further star formation and, with successive generations of star formation episodes, the general metal content of the galaxy (and of the universe as well) increases with time.

Merging

Another important mechanism that drives galaxy evolution is merging, which can transform the morphology of galaxies and promote a substantial amount of star formation over a short period of time. It also induces changes in the volume density and stellar content, and therefore affects the evolution of the luminosity function. Merging of galaxies is observed at all cosmological epochs where galaxies have been detected, and it is also predicted in all theories of galaxy evolution. See GALAXIES: INTERACTIONS AND MERGERS.

When two or more galaxies merge, the final structure that forms may not bear any resemblance to the original components. The outcome of the process depends on the relative masses of the mergers and on their types. If two galaxies with approximately the same mass merge, the perturbation to the gravitational equilibrium of the two systems is very large and takes place on a relatively short time scale (of the order of the free-fall time scale, which is $\sim 10^7$–10^8 years for a galaxy similar to the Milky Way). The gravitational potential of the forming system varies very rapidly throughout the whole structure during the event, a process known as *violent relaxation*, and when this happens the final equilibrium configuration of the system is a spheroid, similar to a bulge or an elliptical galaxy, supported against its self-gravity by the velocity dispersion. If the two merging systems were two spiral

Dirac House, Temple Back, Bristol, BS1 6BE, UK

galaxies, their disks would be destroyed during the event, and the gas contained in them transformed into stars on a time scale of the order of a few free-fall times, giving origin to a very powerful burst of star formation. In this case, depending on the gas content, the stellar mass of the final galaxy can increase to significantly larger values than the sum of the two mergers, and the luminosity during the event can reach prodigious values.

If the merging systems have largely different masses, and consist of one massive galaxy and one or more sub-massive ones, the event is not as traumatic as above. Although the small galaxy is destroyed and loses its identity, it only causes a relatively minor perturbation to the structure of the massive galaxy, which in general retains its properties and morphology. If there is available gas, either in the large galaxy or in the accreting one, the perturbation can induce episodes of star formation that may significantly increase the luminosity of the galaxy, even if they do not in general appreciably change its stellar mass.

Reconstructing the evolution from present to past

The morphological and dynamical differences of present-day galaxies have been interpreted as evidence of different evolutionary history (Kennicutt 1998). The STELLAR POPULATIONS of elliptical and lenticular galaxies as well as the bulges of spirals are very old, and hence the activity of star formation must have ended rather early during cosmic evolution. Direct estimates of the age of the stars place the epoch of their formation to when the universe was about $\sim 20\%$ of its current age. For example, if the universe is 14 billion years old, most ellipticals, lenticulars and bulges already assembled the bulk of the stars by the time the universe was about 3 billion years old. This means, for example, that to form a total stellar mass of $\sim 10^{11} M_\odot$ in a few billion years, star formation rates must have been very high, of the order of $10^{11}/10^9 \sim 10^2\ M_\odot\ \mathrm{yr}^{-1}$. Thus, the 'spheroids' must have have formed their stars during intense but relatively short bursts of star formation.

In the disk of spiral galaxies star formation is observed to proceed at a relatively low pace but in a continuous fashion, and the age and composition of the stars suggest that this was the case in the past as well, although the rate of star formation was probably higher in the past. Luminosity and colors (the so-called spectral energy distribution) of DISK GALAXIES, therefore, largely reflect those of the forming stellar population. At the onset of the first episode of star formation, the spectral energy distribution closely resembled that of young massive stars, since only these objects populated the galaxy. At more advanced stages, when a significant older stellar population had built up, the spectral energy distribution became redder, reflecting the presence of the low-mass stars. For such a mechanism to take place on a time scale comparable to the age of the universe it requires a reservoir of gas to be continuously available to feed the activity of star formation. This gas is thought to accrete on the disk from the outer regions of the galaxy.

The morphological and dynamical properties of galaxies are decided when the body of the structure forms by gravitational collapse of a proto-cloud or of discrete sub-structures as in the case of merging. If the collapsing structure has enough angular momentum (in other words, enough rotation), it eventually settles on a final equilibrium configuration which has the shape of a disk, where the centrifugal force balances gravity. On the other hand, if the structure does not have enough angular momentum, there is no centrifugal force to oppose gravity, and the collapse continues until the velocity dispersion of the sub-components of the structure can halt it. The equilibrium configuration in this case is that of a spheroid, whose morphology is significantly more compact than that of a disk.

This difference in the collapse dynamics have consequences in the star formation mechanisms as well. The violent collapse that gives origin to a spheroid deeply changes the gravitational potential of the forming structure in a short time scale (of the order of the free-fall time). This large perturbation can drive a violent burst of star formation throughout the structure that converts all the available gas into stars on a time scale of several free-fall times (i.e. 10^8–10^9 yr). When the burst ends because of gas exhaustion, no more significant star formation is possible if the galaxy does not accrete additional gas by interaction and merging with other galaxies. The stars, which are essentially coeval, then begin a phase of passive evolution.

Observing the evolution from past to present

Directly comparing the properties of earlier galaxies with the present-day ones is another powerful avenue of investigation which has been made possible by the technological advances in telescopes and instrumentation achieved over the last 30 years. Thanks to the travel time imposed by the finite speed of light, approximately 1.6 billion miles per year, galaxies at earlier cosmic epochs can be studied simply by looking at distant galaxies. This is because a distant galaxy appears to an observer as it was in the past, at a look-back time equal to the travel time of the light from the galaxy to the observer. For very distant galaxies the look-back time is a large fraction of the entire age of the universe. Table 1 one shows the relationship between the luminosity distance[3], redshift, cosmic age, look-back time, and fractional age of the universe. These quantities have been calculated assuming a universe with a Hubble constant equal to $H_0 = 65\ \mathrm{km}^{-1}\ \mathrm{Mpc}^{-1}$ and with density parameter and cosmological constant equal to $\Omega = 0.3$ and $\Omega_\Lambda = 0.7$, respectively. It is common practice to use the redshift, rather then the distance, to provide a measure of the look-back time (for more information about the redshift see the article on GALAXIES AT HIGH REDSHIFT in this volume). Galaxies with redshift smaller than $z \sim 0.1$,

[3] This is the distance that enters in the inverse-square law, which states that the observed flux ϕ of the source is inversely proportional to the square of the distance d from the source to the observer, or $\phi = L/4\pi\ d^2$, where L is the luminosity of the source.

or distance shorter than $\sim$ 500 Mpc, are considered to be local systems observed in the present-day universe. Note that the epoch when the universe was half its present age (which is 14.5 billion years with the adopted cosmological parameters) corresponds to redshift $z \sim 0.7$, or to a distance of $\sim$ 4600 Mpc, and that the bulk of the cosmic evolution, say $\sim$ 80% of the cosmic age, took place from redshift $z \sim 2$ to the present time (redshift $z = 0$). Note also the little increment of look-back time at very high redshifts. Finally, we recall that the cosmic microwave background radiation originated at $z \sim 1300$.

Table 1. Relationship between luminosity distance D in Mpc, redshift z, cosmic age (in billion years), look-back time (LBT) (in billion years) and fractional age as % of the present age. $H_0 = 65$ km s^{-1} Mpc^{-1}; $\Omega = 0.3$; $\Omega_\Lambda = 0.7$.

Faint blue galaxies

Currently, the observations have studied relatively well galaxies at redshifts up to $z \sim 1$. From $z \sim 1$ up to $z \sim 2.5$ there is a gap of systematic observations due to the difficulty, with current technology, of measuring redshifts of faint sources in that range. At redshift higher than $z \sim 2.5$, and up to $z \sim 5$, star-forming galaxies have been observed and studied in large numbers (but not other types of galaxies, if they existed at those epochs) thanks to a special observing strategy called the 'Lyman-break technique' (see the article GALAXIES AT HIGH REDSHIFT in this volume), fine-tuned to be sensitive in that redsfhit range. More recently, there have been a few reports of identification of star forming galaxies with redshifts as high as $z \sim 6.2$, and also of candidates at redshifts $z \sim 10$. Great efforts are currently being put into the design and construction of very large telescopes, such as ground-based ones with mirrors of 30 meters or more, or the 8-meter space-based Next Generation Space Telescope (NGST), capable of detecting galaxies at $z \sim 20$, if they exist there.

The first surveys of very faint galaxies were carried out in the late 1970s and early 1980s, following the advent of the first CCD detectors, and consisted mostly of deep imaging surveys (Tyson 1977). Although they did not provide direct information on the distance to the galaxies (and thus on the epoch at which they were observed), these observations found evidence that galaxies' properties have changed over time. If the distribution of *intrinsic* luminosities and the abundances of galaxies did not evolve, then from the knowledge of the luminosity function at the present time one can accurately predict the numbers of distant (i.e. earlier) galaxies that have a specified distribution of *apparent luminosities*. This is due to the fact that the apparent luminosity of a galaxy is related to its intrinsic luminosity by the inverse-square law. Thus, under the assumption that the distribution and abundances of absolute luminosties (i.e. the luminosity function) is the same at any epoch, one can compute the distribution of apparent luminosities of galaxies expected in a deep survey simply by summing together the contribution of the luminosity function from each epoch. Very interestingly, the observations revealed that the number of faint galaxies is much higher than one would expect from such a calculation, with the excess increasing at fainter galaxies and being more pronounced at bluer wavelengths than at redder ones. Figure 2 shows this effect by plotting the number counts of galaxies per square degree observed in the sky at various wavelengths versus their apparent luminosity, expressed in magnitude[4] (bottom) or physical units (top). Plotted in the graph are the observed counts in the K, I, B and U bands, respectively, corresponding to wavelengths of 22 000 (near-infrared), 8000 (red end of visible radiation), 4000 (blue radiation) and 3600 Å (violet end of visible radiation). The different symbols represent data from various observers, and provide an indication on the uncertainties of the observations. The curves are the theoretical predictions based on the local luminosity function. As can be seen, the excess in the counts over the predictions is very strong in the U and B bands, where it becomes noticeable already at around magnitude 22 and it sharply increases at fainter levels. The excess becomes progressively smaller towards redder wavelengths, and in the K band it is noticeable only at the faintest levels.

While deep multi-band imaging showed that the number density and/or the luminosity of blue galaxies is rapidly evolving going towards earlier epochs, without an indication of the distance to these faint galaxies, however, it is not possible to understand from these data alone when such evolution took place and whether the evolution of the blue galaxies was synchronous or not with other types.

The advent of more sensitive CCD detectors and advanced instumentation during the late 1980s and early 1990s made it eventually possible to carry out large faint spectroscopic surveys and measure the redshifts of

[4] The magnitude m of a galaxy with apparent luminosity f is defined as $m = -2.5 \log(f) + c$, where c is an arbitrary number that sets the zero point. Because of the negative sign, the scale of magnitude is such that brighter sources have smaller magnitudes and vice versa.

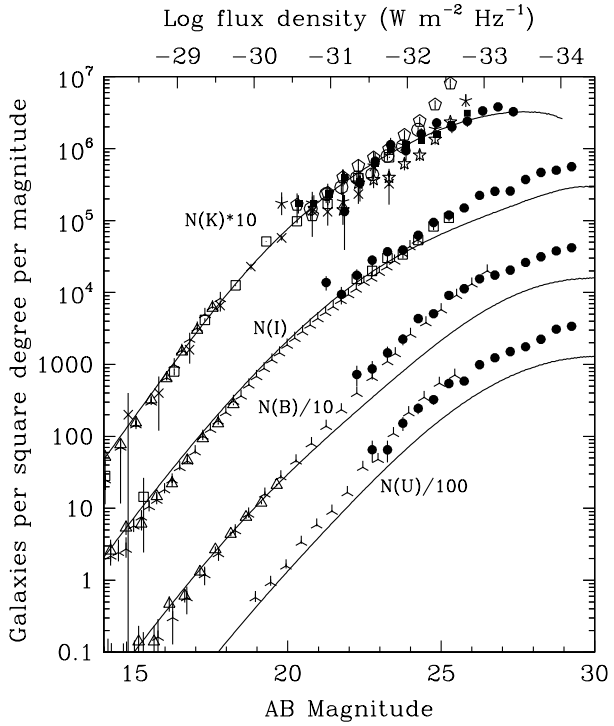

Figure 2. The excess of blue galaxies in the faint counts. The vertical axis reports the surface density of galaxies in the sky in units of galaxies per square degree per magnitude interval. The horizontal axis on the bottom reports the magnitude (faint is to the right, bright is to the left), the one on the top reports the luminosity in logarithmic scale expressed in physical units of Watts per square meter per Hertz. Counts in the K, I, B and U bands are plotted. Different symbols denote different observations. The curves are the theoretical predictions of the counts assuming that the galaxies of the present-day universe have not evolved. The faint excess is very strong in the U and B band and becomes progressively weaker in the I and K bands. (From Ferguson 1998.)

the galaxies, and hence their distance. This, in turn, made it possible to measure the intrinsic luminosity of the galaxies, and hence to derive their luminosity function at various cosmic epochs, mapping its evolution in time (Lilly *et al* 1995). These works showed that most of the faint blue galaxies observed in the imaging surveys are intrinsically relatively small systems located at moderate to intermediate redshifts, i.e. $z \sim 0.3$ to $z \sim 1$, which are undergoing a robust activity of star formation. Their closest counterparts in the local universe are the irregular galaxies, similar to the Magellanic Clouds. Interestingly, the luminosity function of blue galaxies was found to evolve very rapidly from the present epoch up to the earliest epoch studied ($z \sim 1.3$), implying that the luminosity (and hence the star formation rate) and abundance of these galaxies were progressively higher and higher in the past.

The observations also showed that the luminosity function of galaxies that have the same intrinsic spectral energy distribution as the ellipticals and spirals of the local universe, hence which are redder than the faint blue galaxies, is characterized by a much more modest evolution over the same cosmic epochs. This is shown in figure 3, which plots the measures of the luminosity function of red and blue galaxies in a number of reshift intervals, as specified in the labels (note that there are not red galaxies in the range $z = 1.00$ to $z = 1.30$). The vertical axes represent the number density in units of galaxies per cubic Mpc, the horizontal ones the luminosity expressed as absolute magnitudes (this is the apparent magnitude a source would appear to have if placed at a distance of 10 pc from the observer). The circles show the data, the continuous line is the fit to the data, the dashed line is the fit to the data of the redshift bin $z = 0.2$ to $z = 0.5$ (used to show the relative evolution), and the dotted line is the fit to the luminosity function of local galaxies. Thus, galaxies with colors similar to those of the Milky Way (or redder) were already formed and in place by redshift $z \sim 1$ (namely for the last two-thirds of cosmic time) and have been evolving very modestly since then. Blue galaxies, on the other hand, have undergone a spectacular evolution over the same epoch, progressively diminishing their abundances and dimming their luminosity (i.e. reducing the star formation rate) towards the present time.

Solving one piece of the puzzle

With the repair of the *Hubble Space Telescope* (*HST*) in 1994 it eventually became possible to image distant galaxies with enough spatial resolution to classify their morphology and compare it to that of the local galaxies (Abraham *et al* 1996). The unprecedented angular resolution of the *HST* imaging has shown that galaxies up to redshifts $z \sim 1$ have morphologies that can still be classified according to the traditional types of ellipticals, lenticulars, spirals and irregulars (Glazebrook *et al* 1995). Consistently with what was found in the redshift surveys, the *HST* imaging surveys showed that elliptical and lenticular galaxies underwent essentially only passive evolution[5] during the last half of the universe lifetime (Schade *et al* 1999). Over the same period of time, the disks of spiral galaxies showed some moderate evolution induced by an overall increased of the activity of star formation, although their abundance was found to be comparable to that in the present-day universe (Lilly *et al* 1999). In sharp contrast to the modest evolution of ellipticals and spirals, however, the *HST* images showed that irregulars galaxies underwent a spectacular amount of evolution, both in luminosity and abundance, over the same period of time (Ellis 1997). Thus, *HST* has clarified the nature of the faint blue galaxies by showing that they consist of irregular galaxies, and has provided an independent confirmation that these systems were much more abundant in the past than they are today, and that they were also forming stars at a higher pace. These galaxies, in effect, have been the drivers of the

[5] The expression 'passive evolution' denotes the evolution in luminosity of a galaxy induced by the natural evolution of its stars

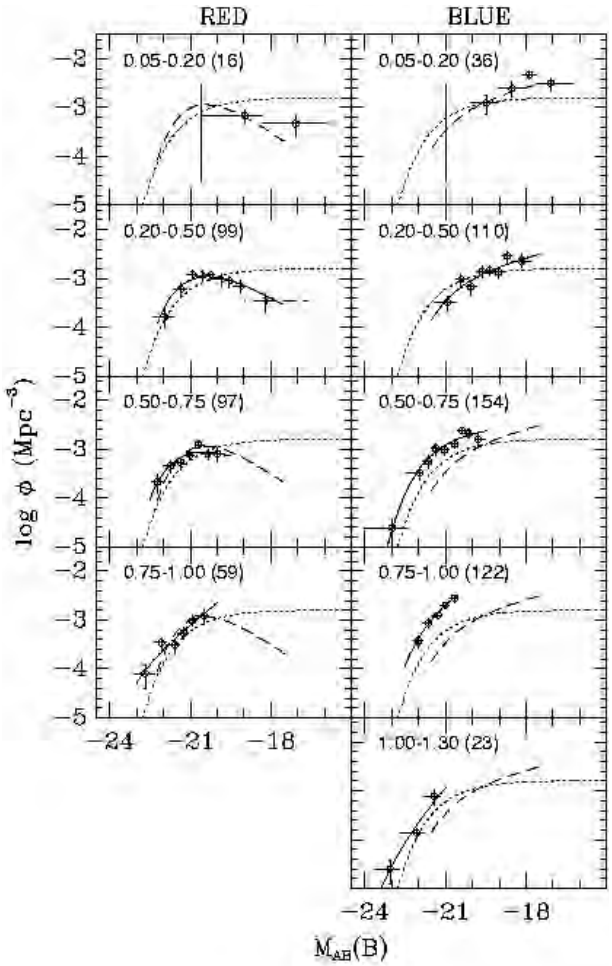

Figure 3. The evolution of the luminosity function of red and blue galaxies. Each panel contains measure of the luminosity function in the specified redshift range (data points) and a mathematical fit to the data point (continuous curve). Also shown is the luminosity function of local galaxies (dotted line) and the fit to the data of the redshift bin $z = 0.20$–$z = 0.50$ (dashed line), useful to see the differential evolution. The vertical axes represent the volume density of galaxies in units of galaxies per cubic Mpc. The horizontal represents the intrinsic luminosity, expressd in absolute magnitudes in the *B* band. The absolute magnitude is the magnitude a source would appear to have if placed at a distance of 10 pc from the observer. (From Lilly *et al* 1995.)

evolution of the overall luminosity function (i.e. that of all galaxies, regardless of their morphology or colors) and of the star formation history of the universe during the last 8 billion years of cosmic age. Figure 4 shows four examples of faint blue galaxies imaged with *HST*. Note the highly irregular and fragmented morphologies, which consist of compact regions that host active star formation embedded in more diffuse structures composed by a mixture of new and older stars and of gas and dust.

Figure 4. Four images of faint blue galaxies taken with the *Hubble Space Telescope* (Griffith *et al* 1998). Images like these helped understanding the nature of these population of galaxies, which underwent a spectacular evolution in luminosity and volume density over the last 8 billion years of the cosmic time. These galaxies are very similar to the Irregular types found in the present-day universe, however they were much more abundant in the past. Where the descedants of these rapidly evolving galaxies are at the present epoch is still precisely not known. (Photo credit: STScI OPO, R Griffiths (Carnegie Mellon University and NASA).)

Looking at the big picture

The study of galaxies over the last two-thirds of the cosmic age has shown clear patterns in the evolution of galaxies. What are today small galaxies seem to have undergone most of their evolution over this time. Although we do not yet know with certainty what and where the present-day counterparts of the faint blue galaxies are at the present epoch, there is mounting evidence that these systems have gradually merged with larger galaxies and have disappeared. As we have discussed earlier, the accretion of a small system onto a large one does not alter the properties of the latter as when a major merging event between two similar systems takes place. Another possibility that has been proposed is that at least a fraction of them have faded beyond detectability of the present intrumentation, once the burst of star formation has ended.

Over the same cosmic time, large galaxies such as ellipticals and spirals evolved much more modestly, being essentially already in place by redshift $z \sim 1$. This implies that they completed most of their formation at earlier epochs, and that to understand their evolution one must search at even earlier epochs.

The search for the progenitors of the so-called 'bright galaxies' has traditionally occupied a central role in observational cosmology (see the article on GALAXIES AT HIGH

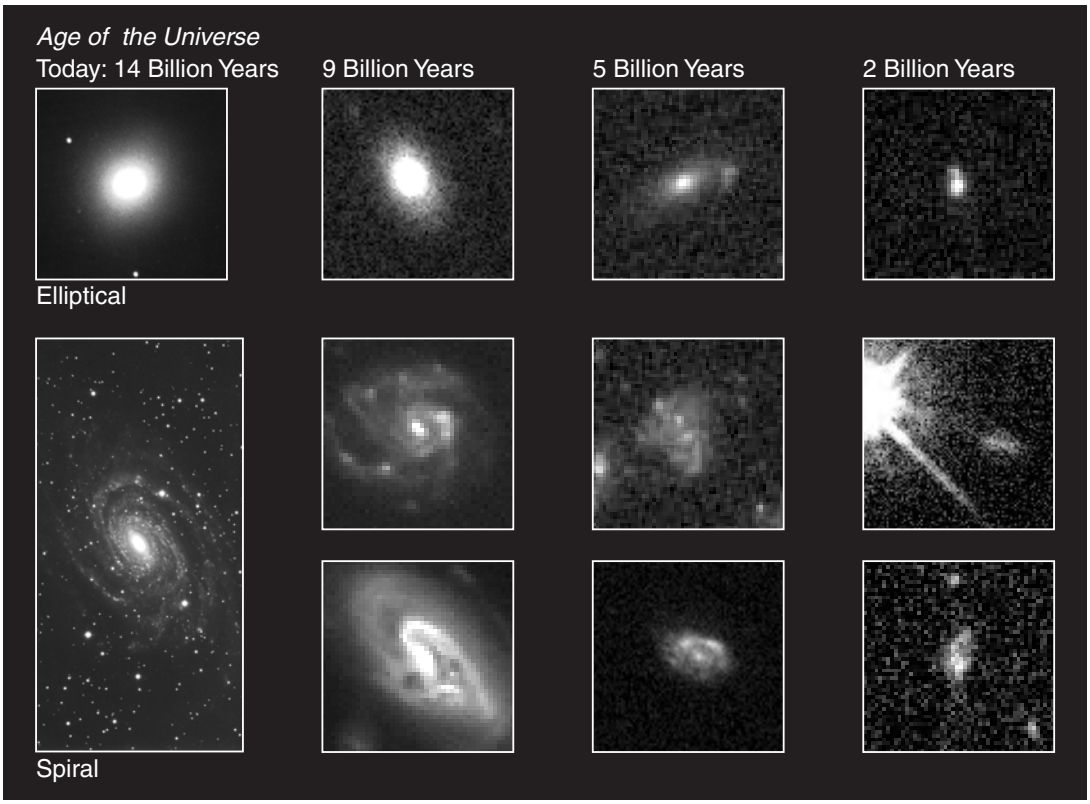

Figure 5. Comparison between galaxies observed at various cosmic epochs (expressed as time after the Big Bang). The traditional morphological types can be recognized already at ~ 5 billion years. At earlier epochs the morphology seems to differ from that of later epochs, although galaxies do exhibit various degrees of compactness and irregularity in their morphologies, ranging from galaxies with light profiles similar to that of ellipticals and bulges to those with disk-like morphology, in resemblance to the Hubble types. (Photo credit: STScI OPO, M Dickinson, M Giavalisco and NASA.)

REDSHIFT in this volume). One of the most important results of the extragalactic research of the last five years has been the identification of a massive population of star-forming galaxies at redshifts larger than $z \sim 2.5$, observed at a time when the universe was younger than 20% of its current age (Steidel *et al* 1996; Giavalisco *et al* 1996). These galaxies, also known as Lyman-break galaxies, are observed during an intense activity of star formation which has contributed a significant fraction of all the stars that we count in the present-day universe, between 20% and 50% according to current measures. Thus, the stars formed in these galaxies can account for a large fraction (if not all) of the stellar mass currently contained in spheroids since, having formed so early in the cosmic evolution, they must necessarily be very old today. These arguments strongly support the idea that the Lyman-break galaxies are the direct progenitors of the present-day spheroids, observed at a time when they were forming the bulk of their stars.

Unfortunately, because of the gap in the observations between redshift $z \sim 1$ and $z \sim 2.5$, this association currently cannot be tested by directly following the evolution of the galaxies at progressively lower redshifts. Equally unknown is whether the Lyman-break galaxies were the first to appear in the universe or if other galaxies preceded them in evolution. These will be major activities of research when instruments of improved sensitivity for ground-based telescopes and the Next Generation Space Telescope will come on line.

Figure 5 shows a comparison between elliptical and spiral galaxies of the present-day universe (observed with ground-based telescopes) with their counterparts observed at progressively higher look-back times (observed with *HST*). The galaxies in the right panels are Lyman-break galaxies at redshift $z \sim 3$. Note that for these objects, a classification into morphological types is not really possible. However, in resemblance to the Hubble sequence, these galaxies do show various degrees of compactness and irregularity in their morphologies, ranging from systems with the light profile similar to that of ellipticals and bulges to systems with disk-like morphology. In the three panels on the right of figure 5 we have represented the cases of a galaxy with the same type of light profile as a present-day spheroid (top), of one with the same light profile as a disk (middle), and of one with an irregular profile (bottom).

One possible evolutionary path is that the Lyman-break galaxies have formed the bulk of their stars in intense

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

bursts of star formation at high redshifts and then evolved mostly passiveley. In this scenario, the final outcome will be an elliptical galaxy when at the end of the collapse the progenitor has exhausted all the gas reservoir. Or it will be a spiral galaxy when the proto-bulge has still sufficient gas around it (or it is able to strip gas from another galaxy it happens to interact with), to give origin to a disk where star formation can occurr with low rate and over a prolonged period of time.

Another possibility is that the Lyman-break galaxies have evolved into the present-day galaxies through successive generations of hierarchical merging. In such a scenario, elliptical galaxies and bulges are easily explained, since we have seen that the outcome of a major merging episode is a spheroid. In order to form lenticular and spiral galaxies, it is necessary that, following the merging episode that originated the bulge, the nascent galaxy has not only a sufficient gas reservoir but also the possibility to evolve undisturbed, with no further merging events, so that the disk can develop (disks are destroyed in a merging event). According to this scheme, elliptical galaxies would be spheroids that have not developed a disk, either because of the lack of gas or because they formed recently and simply did not have the time to do so. They would be, therefore, structurally 'young' systems, even if their stellar populations are old. Spirals, on the other hand, must have had the time to develop the disk, and thus they are 'structurally' old even if they contain a large fraction of young stars in the disk. Interestingly, while the data show that the occurrence of merging seems to be higher in distant galaxies, its relative importance in the evolution of galaxies of different types has not yet been quantified. Thus, it is not known, from an empirical point of view, for which galaxies merging has been instrumental for their formation, and for which it only provided a 'perturbation' in an otherwise structurally passive evolution.

The picture that seems to emerge is that galaxy evolution proceeded along different paths, according to the different types of the galaxies, with massive galaxies forming first and smaller systems later. In other words, the mass seems to be the key parameter that decides the evolutionary destiny of galaxies. This is consistent with the paradigm that gravity has been the primary mechanism for the formation of structure at all scales in the universe, including galaxies. The paradigm states that the cosmic structures form as a result of the amplification and gravitational collapse of density perturbations in the mass distribution. Since perturbations grow as a result of their self-gravity, a prediction of the paradigm is that more massive perturbations grow faster than smaller ones, and hence they can virialize and begin the process of star formation sooner.

The importance of this paradigm goes beyond explaining the formation of galaxies, since it forms the conceptual ground for our understanding of many of the observations in cosmology and, ultimately, of the evolution of the universe as a whole. Yet, despite its importance, this paradigm has never be subject to a rigorous empirical test. Reconstructing the history of the evolution of galaxies from their earliest appearance in space to the present time will provide one the first and most important empirical constraints to the whole theoretical framework of cosmology.

Galaxy Formation

A galaxy is the environment in which stars are born and die, and distant galaxies are the luminous beacons that enable us to probe the distant universe. Our galaxy, the Milky Way, is one of billions of such systems in the observable universe. How galaxies formed represents a central theme in modern cosmology.

At first glance, the universe appears to contain two different types of galaxies: galaxies with disk-like morphologies and galaxies with spheroidal morphologies. This basic distinction breaks down, however, once individual disk and spheroidal galaxies are examined in detail, since most disk galaxies contain small spheroidal components at their centers and most spheroidal galaxies contain small disks at their centers.

Disks in and of themselves contain a wide variety of features. Most DISK GALAXIES exhibit spiral arms with a large range of winding angles and contrast. Approximately half of all disk galaxies also contain a highly elongated bar structure near their center, the bars possessing a variety of axial ratios. Some disks also show moderate deviations from planarity toward their edges (warps) while other disks show significant lanes of dust across their observed profiles. Similarly, ELLIPTICAL GALAXIES, while possessing relatively uniform profiles compared to disk galaxies, show a significant variety of substructure. At least half of ellipticals have detectable shell structure and others distinct cores. Finally, all galaxies, irrespective of type, show great variations in the amounts and spatial distribution of gas, dust, stars, and metal abundances as well as their basic surface brightnesses, luminosities, colours, and masses.

Despite their considerable diversity, galaxies show a remarkable degree of uniformity as well. The profiles of disk and ellipticals are remarkably homologous, the global structural parameters of disk and spheroidal galaxies define a tight two-dimensional plane, and the colours and apparent star formation histories of both spiral and elliptical galaxies show a striking correlation with luminosity. Of great significance is that most galaxies are very slowly evolving structures, both chemically and dynamically. Their properties were acquired long ago, at or soon after the epoch of galaxy formation.

Galaxies began as clouds of primordial gas, hydrogen and helium. Even before galaxies condensed into distinct clouds, infinitesimal density fluctuations were present in the EXPANDING UNIVERSE. These originated at very early epochs in an inflationary phase transition from a universe that initially was relatively uniform. Fluctuations grew in strength under the inexorable influence of self-gravity. Eventually, clouds developed that fragmented into stars. Much of the detailed physics in this schematic of GALAXY EVOLUTION is now understood.

This review begins with a discussion of the cosmological world model in which galaxies form, discusses the processes by which the initial perturbations are established, presents the theory for the growth of these perturbations into collapsing and eventually virialized objects, illustrates the importance of gas cooling in the formation of galaxies, outlines the processes by which galaxies acquire angular momentum, and concludes by summarizing the basic observations and theory of disk and elliptical galaxy formation.

World model

We begin by providing some background on the standard world model and the primordial fluctuations out of which galaxies are believed to have grown.

The apparent homogeneity and isotropy of the observable universe, both in terms of its large-scale structure and the cosmic infrared microwave background radiation—the almost constant 2.73 K blackbody radiation background in which the universe is immersed—motivate the assumption that the universe is both homogeneous and isotropic. By homogeneous, we mean that every point in space statistically resembles every other point in space. By isotropic, we mean there is no point in space where any direction differs statistically from any other direction in space.

Assuming universal homogeneity and isotropy, Einstein's theory of GENERAL RELATIVITY can be used to show that the evolution of the scale of the universe follows the two independent equations:

$$\frac{\dot{a}^2 + k}{a^2} = \frac{8\pi G}{3}\rho \tag{1}$$

$$\frac{2\ddot{a}}{a} + \frac{\dot{a}^2 + k}{a^2} = -8\pi G p \tag{2}$$

collectively known as Friedmann's equations, where a is a measure of the size of the universe, p is the pressure, k is the curvature, ρ is the density, and G is Newton's constant. Combined with the equation of state, these equations completely determine $a(t)$, $\rho(t)$, and $p(t)$.

These equations can be recast into the form:

$$\frac{\ddot{a}}{a} = H_0^2\left[\Omega_{\Lambda,0} - \Omega_0(1+z)^3/2\right] \tag{3}$$

$$\begin{aligned}\frac{\dot{a}}{a} &= H_0 E(z) \\ &= H_0\sqrt{\Omega_0(1+z)^3 + \Omega_{R,0}(1+z)^2 + \Omega_{\Lambda,0}}\end{aligned} \tag{4}$$

where $\Omega_0 = 8\pi G\rho_0$, $\Omega_{R,0} = 1/(H_0 a_0 R)^2$, $\Omega_{\Lambda,0} = \Lambda/3H_0^2$, ρ_0 is the matter density of the universe at the present epoch, Λ is the vacuum energy density or cosmological constant, and R is a constant with units of length. Hubble's constant, denoted by H_0, characterizes the rate at which the universe is expanding at the present epoch. It is the constant of proportionality relating an object's distance D to its rate of recession v:

$$v = H_0 D. \tag{5}$$

Note that $\Omega_{R,0} = 1 - \Omega_0 - \Omega_{\Lambda,0}$.

As the universe expands, the gravitational attraction of the mass inside it slows this expansion. This deceleration may or may not be enough to slow this expansion sufficiently so that the universe recollapses. The case where there is sufficient matter to cause such a recollapse corresponds to a universe where the universal geometry is closed, i.e., $k = +1$. The case where there is not sufficient matter to force such a recollapse corresponds to two separate geometries: one in which the universal geometry is flat ($k = 0$) and one in which the universal geometry is open ($k = -1$). A universe with a flat geometry is known as Einstein–de Sitter.

The time evolution of the universal scale length a is amenable to the following simple analytic solution in the case of an Einstein–de Sitter universe where ordinary matter dominates the energy density ($p = 0; \rho \propto (1+z)^{-3}$):

$$a = a_0(t/t_0)^{2/3} \tag{6}$$

where t_0 and a_0 are the current age and size of the universe, respectively.

For an open universe, the solution is given in terms of the following parametric equations:

$$a = \frac{\Omega_0}{(1-\Omega_0)^{3/2}} \frac{c}{2H_0} (\cosh\Theta - 1) \tag{7}$$

$$t = \frac{\Omega_0}{(1-\Omega_0)^{3/2}} \frac{1}{2H_0} (\sinh\Theta - \Theta) \tag{8}$$

while for a closed universe, the parametric equations are

$$a = \frac{\Omega_0}{(\Omega_0-1)^{3/2}} \frac{c}{2H_0} (1 - \cos\Theta) \tag{9}$$

$$t = \frac{\Omega_0}{(\Omega_0-1)^{3/2}} \frac{1}{2H_0} (\Theta - \sin\Theta). \tag{10}$$

The turn-around time t_m for this universe occurs when $\Theta = \pi$, so from equation (10), we find

$$t_\mathrm{m} = \frac{\Omega_0}{(\Omega_0-1)^{3/2}} \frac{\pi}{2H_0} \tag{11}$$

for the turn-around time.

Requiring that the curvature be identical everywhere in space-time, the most general way of expressing the concept of distance is the Friedmann–Robertson–Walker metric:

$$\mathrm{d}l^2 = a^2R^2\left[\mathrm{d}\chi^2 + f^2(\chi)(\mathrm{d}\theta^2 + \sin^2\theta\mathrm{d}\phi^2)\right] \tag{12}$$

where

$$f(\chi) = \begin{cases} \sin\chi, & k = +1 \\ \chi, & k = 0 \\ \sinh\chi, & k = -1. \end{cases} \tag{13}$$

The two-dimensional analogue to the Friedmann–Robertson–Walker metric is

$$\mathrm{d}l^2 = a^2\left[\mathrm{d}\chi^2 + f^2(\chi)\mathrm{d}\theta^2\right] \tag{14}$$

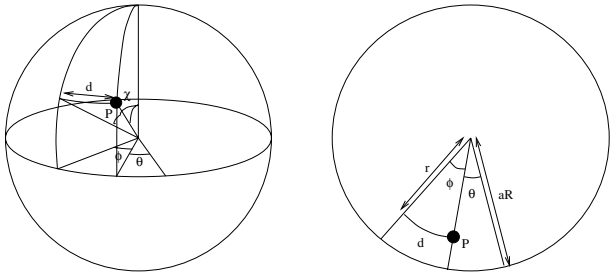

Figure 1. The topology of space in a closed ($k = +1$) two-dimensional universe. The coordinates (χ, θ) define the position of a point P in this universe. The angular width ϕ of an object of size d is illustrated.

which is more amenable to our everyday intuition, especially in the case of a closed $k = +1$ universe where

$$\mathrm{d}l^2 = a^2\left[\mathrm{d}\chi^2 + \sin^2\chi\,\mathrm{d}\theta^2\right]. \tag{15}$$

This is simply the expression for the distance on the surface of a sphere where θ is the azimuthal coordinate and where χ is the tangential coordinate (figure 1).

The wavelengths of photons expand, or REDSHIFT, along with the universe. The redshift of an object is a measure of how much the universe and, therefore, the wavelength of that object's photons have expanded until the present. A redshift of zero indicates the present. Quantitatively, we express the relationship between the size of the universe a and its redshift z as

$$a \propto \frac{1}{1+z}. \tag{16}$$

Using solutions to Friedmann equations, one may derive both the age of the universe and the effective distances to objects which existed at earlier epochs. By integrating up the infinitesimal times

$$\begin{aligned} \mathrm{d}t = \frac{1}{\dot{a}}\,da &= \frac{1}{aH_0E(z)} \frac{a\,\mathrm{d}z}{1+z} \\ &= \frac{\mathrm{d}z}{H_0E(z)(1+z)} \end{aligned} \tag{17}$$

one can compute the age of the universe:

$$t = \frac{1}{H_0} \int_{z=0}^{\infty} \frac{\mathrm{d}z}{E(z)(1+z)}. \tag{18}$$

Similarly, one may readily derive expressions for the distance though there is one subtlety. Two different measures of distance are standardly discussed in cosmology: the angular-size distance and the luminosity distance. Both distances are defined so that the standard expressions involving these quantities apply. The former, the angular-size distance, commonly denoted D_A, is defined in analogy with the expression

$$\theta = \frac{d}{D_\mathrm{A}} \tag{19}$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

where d is an object's intrinsic size and θ is the angular size of the object on the sky in radians. Similarly, the latter, the luminosity distance, commonly denoted $D_{\rm L}$, is defined in analogy with the expression

$$f = \frac{L}{4\pi D_{\rm L}^2} \tag{20}$$

where f is the observed flux and L is the intrinsic luminosity.

We now provide a heuristic derivation of the above equations. Imagine that the light from some object with size d, redshift $z_{\rm obs}$, and tangential coordinate χ converges to $\chi = 0$ and $z = 0$ on paths where $\mathrm{d}\theta = 0$. Along this path, the expression for the metric reduces to $\mathrm{d}l^2 = a^2R^2\mathrm{d}\chi^2$. The integrated coordinate distance χ is then

$$\begin{aligned}\chi &= \int_{z=0}^{z_{\rm obs}} \frac{\mathrm{d}l}{aR} = \int_{z=0}^{z_{\rm obs}} \frac{c\,\mathrm{d}t}{aR} \\ &= \frac{1}{H_0 a_0 R}\int_{z=0}^{z_{\rm obs}} \frac{c\,\mathrm{d}z}{E(z)}.\end{aligned} \tag{21}$$

The object is observed at tangential coordinate χ at some previous time, and the distance of this object (at χ and $z_{\rm obs}$) from the z-axis (see figure 1) is

$$r(z) = a(z)R\sin\chi = \frac{a_0 R}{1+z}\sin\chi. \tag{22}$$

Clearly, the angle ϕ emanating from the top of the sphere intersecting our object of size d at some distance r from the z-axis is d/r, so

$$\phi = \frac{d}{r}. \tag{23}$$

Identifying $D_{\rm A}$ in equation (19) with $r(z)$ in equation (23) yields

$$\begin{aligned}D_{\rm A} = r(z) &= \frac{a_0 R}{1+z}\sin\chi \\ &= \frac{a_0 R}{1+z}\sin\left[\frac{1}{H_0 a_0 R}\int_{z=0}^{z_{\rm obs}}\frac{c\,\mathrm{d}z}{E(z)}\right].\end{aligned} \tag{24}$$

A heuristic derivation of the luminosity distance is similarly possible. Imagine the light emitted from some object at redshift $z_{\rm obs}$ and $\chi = 0$ propagates to some χ reaching it at $z = 0$. This light would have spread out over a ring of radius $2\pi r(0)$, where $r(0)$ is again the distance from the points at χ and the z-axis. Hence, $f = L/2\pi r(0)$. The obvious three-dimensional analogue is $f = L/4\pi r(0)^2$. Multiplying the flux by a factor of $1/(1+z)$ to account for time dilation and $1/(1+z)$ to account for the energy loss due to photon redshifting, one obtains

$$f = \frac{L}{4\pi r(0)^2(1+z)^2}. \tag{25}$$

Identifying $r(0)(1+z)$ in equation (25) with $D_{\rm L}$ in equation (20) yields

$$\begin{aligned}D_{\rm L} &= r(0)(1+z) \\ &= a_0 R(1+z)\sin\left[\frac{1}{H_0 a_0 R}\int_{z=0}^{z_{\rm obs}}\frac{c\,\mathrm{d}z}{E(z)}\right].\end{aligned} \tag{26}$$

As in our derivation of the angular and luminosity distances, it is easy to see that the apparent surface brightness of objects decreases as $(1+z)^{-4}$, a factor of $(1+z)^{-1}$ due to time dilation, a factor of $(1+z)^{-1}$ due to a redshifting of the photons, and a factor of $(1+z)^{-2}$ to account for its larger angular size on the sky.

Origin of fluctuations

INFLATION is a popular scenario for producing the small matter overdensities, or seeds, on which mass accretes and galaxies later form. The popularity of inflation derives from the relatively natural explanation it provides for establishing the initial conditions from which our universe seems to have evolved. Not only does it explain the homogeneity of the universe on large scales, but it also solves the problem of the relative absence of objects like magnetic monopoles or other types of massive topological defects. It provides a natural explanation for the apparent flatness of the universe although the observational evidence for this still might be considered preliminary.

Inflation is initiated at the temperature scale corresponding to the breaking of the symmetry of grand unification ($T \sim 10^{16}$ GeV, at $t \sim 10^{-35}$ s) as the universe expands and cools through a brief period of supercooling. The associated release of scalar field energy results in an exponential increase in the scale factor, and corresponding reduction in temperature, and is followed by a period of reheating when the associated field kinetic energy thermalizes. This early epoch of exponential expansion is driven by the evolution of a scalar inflation field ϕ and potential V, the field evolving as

$$\ddot{\phi} + 3\frac{\dot{a}}{a} + \frac{\mathrm{d}V(\phi)}{\mathrm{d}\phi} = 0. \tag{27}$$

The pressure and density are

$$p_\phi = \dot{\phi}^2 + V \tag{28}$$

$$\rho_\phi = \dot{\phi}^2 - V \tag{29}$$

where the inflation potential is such that $V >> \dot{\phi}^2$, so $\rho = -p = V$ as in the case of a non-zero cosmological constant.

Zero point fluctuations of the scalar field are imprinted on the causal horizon scale, which increases exponentially. The causal horizon is greatly enlarged, to encompass all of the universe observed today, and the reheating process imprints a scale-invariant distribution of energy density fluctuations. A perturbative analysis of this scalar field's evolution predicts a power spectrum with slope close to unity: $P(k) \propto k$, where k is the wavenumber defined via the Fourier transformation of the underlying Gaussian-distributed density field $\rho(x,t)$: $\delta_k = \int \rho(x,t)\mathrm{e}^{\mathrm{i}k\cdot x}\mathrm{d}^3x$. This power spectrum is called the Harrison–Zeldovich scale-free power spectrum. The amplitude of the fluctuations is not predicted by the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

inflationary theory. However the prediction of scale-invariance is generic to many, although not all, inflationary models. Scale-independent curvature fluctuations are equivalent to density fluctuations on the horizon scale of fixed amplitude. On superhorizon scales, an invariant $\delta\phi = G\,\delta M/L\,c^2 = \delta\rho/\rho)(L/ct)^2 = (\delta\rho/\rho)\,L^2_{\rm comoving}\,(a/ct)^2$ can be found which does not change with time.

The energy density of photons and other massless particles scales as $(1+z)^4$ while the energy density of nonrelativistic massive particles scales as $(1+z)^3$. Consequently, there is an epoch of matter-radiation equality before which the energy density of the universe is dominated by radiation (massless particles), and after which the energy density of the universe is dominated by matter (massive particles). The redshift at this epoch is

$$1 + z_{\rm eq} = \frac{\rho_{m_0}}{\rho_{r_0}} = 3 \times 10^4\,\Omega\,h^2 \tag{30}$$

where the matter density is $\rho_{\rm m} = \rho_{m_0}(1+z)^3$ and relativistic density is $\rho_{\rm r} = \rho_{r_0}(1+z)^4$. The horizon scale at this epoch is $L_{\rm eq} \equiv 2\,ct_{\rm eq} = 12\,h^{-1}$ Mpc, in comoving coordinates.

During the radiation-dominated era, perturbations in the primordial power spectrum $(\delta\rho/\rho)$ grow in proportion to the square of the universal scale-factor a^2. The growth of perturbations stalls once they get inside the horizon (Hubble radius) since the time scale for the growth of perturbations $(\propto (\rho_{\rm mat}G)^{-1/2})$ is large compared to the expansion rate of the universe $(\propto (\rho_{\rm tot}G)^{-1/2})$. However once the universe becomes matter-dominated, perturbations resume growth, but now in proportion to a, the universal scale-factor, instead of the square of this scale.

The stalling of growth on small scales within the Hubble radius imprints itself on the power spectrum which survives the transition to a matter-dominated universe. Subhorizon density fluctuations have a distribution with scale $\delta\rho/\rho \propto L^{-2}_{\rm comoving} \propto M^{-2/3}$, on scales $\lesssim L_{\rm eq}$, while on larger scales growth suppression implies that $\delta\rho/\rho \approx$ constant. Mathematically, we include this effect by multiplying the primordial power spectrum $P_{\rm p}$ for linearized fluctuations in a stochastic density field by the transfer function

$$P_{\rm f}(k) = T(k)\,P_{\rm p}(k) \tag{31}$$

to obtain the final processed power spectrum $P_{\rm f}$. An approximate analytical fit of a transfer function calculated numerically is given by

$$T(k) = \frac{\log(1+2.34q)}{(2.34q)} \times \left[1 + 3.89q + (16.1q)^2 + (5.46q)^3 + (6.71q)^4\right]^{-1/4} \tag{32}$$

where $q = (k/{\rm Mpc}/(\Omega h^2))$ (Peacock 1997, Bardeen *et al* 1986) and $h = H_0/(100\,{\rm km\,s^{-1}\,Mpc^{-1}})$. Here we note that the above power spectrum results in a bottom-up sequence of evolution, smaller scale fluctuations reaching large amplitude before the large-scale fluctuations.

Dissipationless non-radiative matter, known otherwise as DARK MATTER, is now a standard part of the paradigm for galaxy formation. It is important in reconciling the power spectrum observed in the COSMIC MICROWAVE BACKGROUND with the local power spectrum observed in galaxies. Nonbaryonic dark matter makes this possible because the growth of fluctuations is able to commence immediately after the era of matter-radiation equality. The growth of fluctuations in the baryonic component is, by contrast, suppressed because of its coupling to radiation background. Eventually, as the universe expands, it becomes cool enough so that radiation decouples from the baryons, an event known as last scattering. At this point, the mass scale above which fluctuations can grow suddenly drops from $\sim 10^{16} M_\odot$ to $\sim 10^6 M_\odot$, and so the fluctuations in the baryonic component are free to grow with the rest of the universe. Since the dark matter component is the densest portion of the universe, it controls the growth of fluctuations, and soon after decoupling, the baryonic component is boosted in amplitude by $\sim (1+z_{\rm eq})/(1+z_{LS})$, z_{LS} being the redshift at last scattering.

Remarkably, the acoustic modes set up in the baryonic component prior to last scattering are observable via their imprint on the cosmic microwave background radiation which provides a snapshot of fluctuations at last scattering. This may be seen as follows. The dispersion relation for fluctuation growth at rate $e^{i\omega t}$ is

$$\omega^2 = k^2 V_{\rm S}^2 - 4\pi G\rho \tag{33}$$

($V_{\rm S}$ being the sound speed) for time scales short compared to the expansion time, or equivalently for wavelengths $2\pi/h \ll ct$. Such wavelengths oscillate as sound waves with amplitude proportional to $\exp(ik\,V_{\rm S}\,t)$. Inflation specifies primordial curvature fluctuations which are time-invariant on superhorizon scales. The corresponding amplitude corresponds to the mode $\cos(k\,V_{\rm S}\,t)$ which is finite as $k \to 0$. At $t_{\rm LS}$ the maximum amplitude in $\delta T/T$ is attained by fluctuations which have entered the horizon and satisfy $kV_{\rm S}t = \pi n$, with $n = 1, 2, \ldots$. Clearly the wave that crests on the horizon at $t_{\rm LS}$ and undergoes oscillations systematically experiences both Compton drag and diffusive damping. The net result is the amplitude is diminished and only the first three or so peaks are detectable. Doppler effects contribute 90 degrees out of phase to the gravitational potential induced $\delta T/T$ peaks, and the net result is a series of peaks corresponding to the maximum in $\delta T/T = |\frac{1}{3}\delta\phi - \underline{r}\cdot\underline{v} + \frac{1}{3}\delta\rho/\rho|$. The predicted enhancement of the first peak of wavelength $2\,V_{\rm S}\,t_{\rm LS}$ is as large as a factor of three relative to the $k \to 0$ or Sachs–Wolfe potential fluctuation limit that corresponds to the inflationary imprint of primordial, nearly scale-invariant curvature fluctuations.

The observational situation is as follows. The COBE DMR experiment measured potential fluctuations on angular scales $\geq 10^\circ$. The last scattering horizon is about 1°. Several experiments report evidence for the first acoustic peak on this scale, and definitive

measurements with large sky coverage that provide adequate foreground discrimination were performed in 2000 by the Boomerang and Maxima balloon experiment collaborations (de Bernardis *et al* 2000, Hanany *et al* 2000). The situation is complicated by the contribution from the time-varying potential perturbations $\delta T/T \sim \int \dot{\phi}\, \mathrm{d}t$ which arise in models with $\Omega < 1$ at curvature-dominated epochs, i.e. $z \lesssim \Omega^{-1} - 1$ and are expected at angular scales $\gtrsim 1^\circ$. A final complication is the possible tensor mode contributions; this gravity wave background contributes to the energy density in the radiation-dominated era and only affects the low order multipoles corresponding to angular scales that are larger than the horizon angular scale at t_{eq}.

Linear evolution of density fluctuations

Gravitation magnifies the initial perturbations in the matter distribution, both dark and baryonic. While these perturbations initially grow linearly, eventually these perturbations stop expanding, break away from Hubble flow, and then collapse and virialize. Galaxies form from the gas which cools onto the center of these collapsed masses, called dark halos.

An analysis of the growth of the initial matter power spectrum begins with the basic fluid equations in terms of the density ρ, the velocity $\boldsymbol{u}$, the gravitational potential Φ, the pressure p, and the time t:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \boldsymbol{u}) = 0, \quad \rho \frac{D\boldsymbol{u}}{Dt} = -\nabla p - \rho \nabla \Phi. \tag{34}$$

For convenience, we change variables to comoving coordinates $\boldsymbol{x} = \boldsymbol{r}/a$, to peculiar velocities $\boldsymbol{v} = a\mathrm{d}\boldsymbol{u}/\mathrm{d}t$, to dimensionless overdensities $\delta = \rho/\bar{\rho} - 1$, and to conformal times $\tau = t/a$. Making these substitutions, the fluid equations become

$$\boldsymbol{v} = \dot{\boldsymbol{x}} \tag{35}$$

$$\dot{\delta} + \nabla \cdot [(1+\delta)\boldsymbol{v}] = 0 \tag{36}$$

$$\dot{\boldsymbol{v}} + \boldsymbol{v} \cdot \nabla \boldsymbol{v} + \frac{\dot{a}}{a}\boldsymbol{v} = -\frac{\nabla p}{\rho} - \nabla \Phi \tag{37}$$

while Poisson's equation reads

$$\nabla^2 \Phi = 4\pi G \bar{\rho} a^2 \delta. \tag{38}$$

The behavior of the modes can be obtained by taking the divergence of Euler's equation, eliminating $\nabla \cdot \boldsymbol{v} = 0$ by the continuity equation, taking Φ, δ, and $\boldsymbol{v}$ to be small, and then linearizing the equations. One obtains

$$\ddot{\delta} + \frac{\dot{a}}{a}\dot{\delta} = \frac{\nabla^2 p}{\rho} + 4\pi G \bar{\rho} a^2 \delta. \tag{39}$$

If we consider a pressure-free universe, this equation involves no spatial derivatives, so its solution can then be written as

$$\delta(\boldsymbol{x}, \tau) = A(\boldsymbol{x}) f_1(\tau) + B(\boldsymbol{x}) f_2(\tau). \tag{40}$$

Using the fact that $\Omega = 8\pi G\rho/3H^2 = 8\pi G\rho a^2/3\dot{a}^2$, we can rewrite equation (39) as

$$\ddot{\delta} + \frac{\dot{a}}{a}\dot{\delta} - \frac{3}{2}\Omega \left(\frac{\dot{a}}{a}\right)^2 \delta = 0. \tag{41}$$

For an Einstein–de Sitter universe ($\Omega = 1$), $a \propto \tau^2 \propto t^{2/3}$ and equation (41) becomes

$$\ddot{\delta} + 2\frac{\dot{\delta}}{\tau} - 6\frac{\delta}{\tau^2} = 0. \tag{42}$$

For solutions, one obtains a growing mode $\delta \propto D(\tau) \propto \tau^2 \propto t^{2/3}$ and a decaying mode $\delta \propto D(\tau) \propto \tau^{-1} \propto t^{-1/3}$. $D(\tau)$ is known as the linear growth factor. Given the small size of the perturbations at the era of matter–radiation equality, one ignores the decaying mode solution and simply considers the growing mode. For the more general case of a universe without a cosmological constant (i.e., $\Omega_\Lambda = 0$), it can be shown (Peebles 1980) that

$$D(\tau) = 1 + \frac{3}{x} + \frac{3(1+x)^{1/2}}{x^{3/2}} \ln\left[(1+x)^{1/2} - x^{1/2}\right] \tag{43}$$

where $x = \Omega^{-1} - 1 \propto a$.

Before finishing this discussion, we examine the evolution in position and velocity of a test particle because these quantities will prove useful later when we look at how galaxies acquire ANGULAR MOMENTUM. Since $\nabla^2 \Phi_0 = 4\pi G \bar{\rho} a^2 \delta$ is a constant in the linear regime for an Einstein–de Sitter universe, the linearized version of Euler's equation can be immediately integrated to give

$$\boldsymbol{v} = -\left(a^{-1} \int D\mathrm{d}\tau\right) \nabla \Phi_0. \tag{44}$$

Integrating the peculiar velocity gives us:

$$\boldsymbol{x} = \boldsymbol{x}_0 - \left(\int \frac{\mathrm{d}\tau}{a} \int D\mathrm{d}\tau\right) \nabla \Phi_0. \tag{45}$$

Since the growth factor $D(\tau)$ is a solution to the fluctuation growth equation $\frac{\mathrm{d}}{\mathrm{d}\tau}(a\dot{\delta}) = 4\pi G \bar{\rho} a^3 \delta$ (see equation (39)), it follows that

$$\boldsymbol{x} = \boldsymbol{x}_0 - \frac{D(\tau)}{4\pi G \bar{\rho} a^3} \nabla \Phi_0 \tag{46}$$

and

$$\boldsymbol{v} = -\frac{\dot{D}}{4\pi G \bar{\rho} a^2} \nabla \Phi_0. \tag{47}$$

This essentially Lagrangian view to the growth of perturbations is due to Zeldovich (1970).

Mean square fluctuations

It is useful to consider the evolution of the mean square mass fluctuations filtered on various spatial scales R because of the information it provides on the collapse of structure on these spatial scales. Due to the scale-free growth of initial perturbations, the power spectrum $P(k, \tau)$

$$P(k, \tau) = \left| \int \mathrm{d}^3 x \delta(\boldsymbol{x}, \tau) \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}} \right|^2 \tag{48}$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

grows as $D(\tau)^2$ just as $\delta(\boldsymbol{x}, \tau)$ does.

Assuming that a section of the power spectrum can be written as

$$P(k, \tau) \propto D(\tau)^2 k^n \tag{49}$$

where n is the power spectrum index, we find that the mean square fluctuations filtered on a particular mass scale are

$$\begin{aligned}\sigma^2(M) &= \left\langle (dM/M)^2 \right\rangle \\ &= \int \mathrm{d}^3 k W(kR) P(k, \tau) \\ &\propto D(\tau)^2 R^{-3-n} \\ &\propto D(\tau)^2 M^{-(n+3)/3}\end{aligned} \tag{50}$$

where $W(kR)$ is a window function that filters out spatial scales of R or smaller. The top hat filter of radius R

$$W(k) = \frac{3}{kR^3}(\sin kR - kR\cos kR). \tag{51}$$

is one commonly used window function. Note that $\sigma(M, 0) = (M/M_{nl})^{-(n+3)/6}$ where $M_{nl} = 1 \times 10^{15}\sigma_8 \Omega h^{-1} M_\odot$ corresponds to mass fluctuations of amplitude unity on $8h^{-1}$ Mpc radius spheres. The factor σ_8 is $\sigma(M, 0)$ at $8h^{-1}$ Mpc for the mass density: galaxy count fluctuations have unit amplitude on this scale.

Halo scaling relations

The growth of fluctuations becomes nonlinear and start collapsing into virialized objects when

$$\left\langle (\delta M/M)^2 \right\rangle = 1. \tag{52}$$

From equation (50), this implies that

$$M \propto D(t)^{6/(3+n)}. \tag{53}$$

The density ρ, size r, and temperature T of collapsed objects then scale as

$$\rho \propto (1+z)^3 \tag{54}$$

$$r \propto (M/\rho)^{1/3} \propto (1+z) D(t)^{6/(3+n)} \tag{55}$$

$$\begin{aligned}T \propto V_\mathrm{c}^2 &\propto \frac{GM}{r} \propto M^{2/3}\rho^{1/3} \\ &\propto (1+z)^1 D(t)^{4/(3+n)}.\end{aligned} \tag{56}$$

These scaling relationships will be useful in later discussions, particularly when we examine the cooling of gas in virialized structures.

Spherical collapse model

To understand the nonlinear growth of structure, it is convenient to consider the idealized spherical 'top hat' collapse model. Here, one supposes there to be spherically symmetric regions of radius R and of uniform overdensity $\bar{\delta}$ in an otherwise uniform universe at some initial time t_i. At these early times, the universe will be approximately Einstein–de Sitter, so we can express this overdensity as the sum of the growing and decaying modes:

$$\delta = \delta_+ \left(\frac{t}{t_\mathrm{i}}\right)^{2/3} + \delta_- \left(\frac{t}{t_\mathrm{i}}\right)^{-1}. \tag{57}$$

We take the matter in this region to be expanding at the approximately the same rate as the universe, and therefore we require that the peculiar velocity be zero:

$$\tfrac{2}{3}\delta_+(t_\mathrm{i}) - \delta_-(t_\mathrm{i}) = 0. \tag{58}$$

Therefore, $\delta_+ = \frac{3}{5}\delta$. According to Birkhoff's theorem, in a spherically symmetric situation, matter external to the sphere will not influence its evolution, so it follows that

$$\frac{\mathrm{d}^2 R}{\mathrm{d}t^2} = \frac{-GM}{R^2} = \frac{-4\pi G}{3}\bar{\rho}(1+\bar{\delta})R \tag{59}$$

which is identical in form to the equation for the evolution of the cosmological scale factor a,

$$\frac{\mathrm{d}^2 a}{\mathrm{d}t^2} = \frac{-GM}{a^2} = \frac{-4\pi G}{3}\bar{\rho}a. \tag{60}$$

Therefore, the size of the region R evolves like the cosmic scale factor a but with an initial density parameter $\Omega_\mathrm{p}(t_\mathrm{i})$ given by

$$\Omega_\mathrm{p}(t_\mathrm{i}) = \frac{\rho(t_\mathrm{i})(1+\bar{\delta})}{\rho_\mathrm{c}(t_\mathrm{i})} \tag{61}$$

where $\rho_\mathrm{c}(t_\mathrm{i})$ is the critical density ($3H_\mathrm{i}^2/8\pi G$ at time t_i). By analogy with the solutions for the universe, the region will collapse if $\Omega_\mathrm{p} > 1$. By analogy with equation (4), the expansion of the region evolves according to

$$\left(\frac{\dot{a}}{a}\right)^2 = H_\mathrm{i}^2 \left[\Omega_\mathrm{p}(t_\mathrm{i})\frac{a_\mathrm{i}^3}{a^3} + (1 - \Omega_\mathrm{p}(t_\mathrm{i}))\frac{a_\mathrm{i}^2}{a^2}\right]. \tag{62}$$

Eventually, the region stops expanding, turns around, and collapses. At the turn-around time t_m, $\dot{a} = 0$, implying that $a/a_\mathrm{i} = \Omega_\mathrm{p}(t_\mathrm{i})/(1 - \Omega_\mathrm{p}(t_\mathrm{i}))$. The density at turn-around t_m is then

$$\rho_\mathrm{p}(t_\mathrm{m}) = \rho_\mathrm{c}(t_\mathrm{i})\Omega_\mathrm{p}(t_\mathrm{i})\left[\frac{\Omega_\mathrm{p}(t_\mathrm{i}) - 1}{\Omega_\mathrm{p}(t_\mathrm{i})}\right]^3. \tag{63}$$

By analogy with the solutions to the cosmological equations for closed universes (see equations (9)–(11)), we can determine t_m as

$$\begin{aligned}t_\mathrm{m} &= \frac{\pi}{2H_\mathrm{i}}\frac{\Omega_\mathrm{p}(t_\mathrm{i})}{[\Omega_\mathrm{p}(t_\mathrm{i}) - 1]^{3/2}} = \frac{\pi}{2H_\mathrm{i}}\left[\frac{\rho_\mathrm{c}(t_\mathrm{i})}{\rho_\mathrm{p}(t_\mathrm{m})}\right]^{1/2} \\ &= \left[\frac{3\pi}{32 G \rho_\mathrm{p}(t_\mathrm{m})}\right]^{1/2}.\end{aligned} \tag{64}$$

For an Einstein–de Sitter universe, the density $\rho(t_m)$ of the universe at turn-around is simply

$$\rho(t_m) = \frac{1}{6\pi G t_m^2} \tag{65}$$

so that

$$\chi = \frac{\rho_p(t_m)}{\rho(t_m)} = \left(\frac{3\pi}{4}\right)^2 \approx 5.6. \tag{66}$$

Formally, after turn-around, the region will collapse to a point at $t = 2t_m$. Of course, before that happens, shell crossings will occur. From the virial theorem, dissipationless matter collapses to a radius that is one-half the turn-around radius. Since $a \propto t^{2/3}$, the universe will expand by $2^{2/3}$. Hence, the density of the region relative to the background universe at collapse t_c is

$$\frac{\rho_p(t_c)}{\rho(t_c)} = (2^{2/3})^3 8\chi \approx 180. \tag{67}$$

An extrapolation of the linear growth estimate at time t_c yields

$$\delta_+(t_c) = \frac{3}{5}\delta_i \left(\frac{2t_m}{t_i}\right)^{2/3} = \frac{3}{5}\left(\frac{3\pi}{2}\right)^{2/3} \approx 1.68. \tag{68}$$

The assumption of a uniform spherical overdensity in an otherwise uniform universe is quite unrealistic; in fact, collapse typically proceeds toward the creation of a large number of two-dimensional pancakes. Nevertheless, numerical simulations show the basic scalings derived here to be roughly correct and useful for making simple analytic estimates.

Form of collapsed structures

For many years, the profiles of collapsed halos were taken to be that of a isothermal sphere:

$$\rho(r) = \frac{V_c^2}{4\pi G r^2} \tag{69}$$

where r is the radius and V_c is the circular velocity. Over the last few years, however, the detailed N-body simulations of Navarro *et al* (1997) have shown that the collapsed matter profile is better fitted by the double power-law profile:

$$\rho(r) = \rho_{crit} \frac{\delta_0}{(r/r_s)(1 + r/r_s)^2} \tag{70}$$

where r_s is the core radius where the slope of the power-law changes from -1 near the center to -3 at large radii and r_{200} is the virial radius of the halo. More recent high resolution simulations find a somewhat steeper innermost slope to the density profile, possibly as steep as -1.5 (Jing and Suto 2000, Moore *et al* 1999).

Press–Schechter model

A convenient and somewhat approximate description of the mass function of halos at particular redshifts is given by the Press–Schechter formalism derived heuristically by Press and Schechter (1974) using linear growth theory and the spherical 'top hat' model. The mass function of non-linear objects is computed with the aid of linear theory on the assumption that the probability distribution of density fluctuations at a given mass and redshift is Gaussian, centered on the mean $\sigma(M, z) \equiv \left\langle (\delta\rho/\rho)^2 \right\rangle^{1/2}$.

Since the set of initial perturbations is Gaussian-distributed and remains so under linear growth, we can write the distribution of mass fluctuations δ_M as

$$P(\delta_M)\mathrm{d}\delta_M = \frac{1}{\sqrt{2\pi}\sigma(M)} \exp\left(\frac{-\delta_M^2}{\sigma(M)^2}\right) \mathrm{d}\delta_M \tag{71}$$

where $\sigma(M)$ is equal to the mean square mass fluctuations $\langle (\delta M/M)^2 \rangle$ defined earlier.

The fraction of points where the mean density inside a radius R exceeds δ_c is

$$P_{>\delta_c}(M) = \int_{\delta_c}^{\infty} P(\delta_M)\mathrm{d}\delta_M. \tag{72}$$

Press and Schechter (1974), using the spherical collapse model as a heuristic guide, took all regions where the mean density exceeded the critical value needed for linear collapse, i.e., $\delta_c \approx 1.68$, to be part of collapsed structures at least as massive as $M = 4\pi\bar{\rho}a^3R^3/3$.

Then, to distinguish the fraction of structures which have just collapsed to a mass M and those that are part of a bigger structure at least as massive as $M + \mathrm{d}M$, we subtract $P_{>\delta_c}(M + \mathrm{d}M)$ from $P_{>\delta_c}(M)$. Notice that by doing this, we completely ignore the possibility that the mass scale just collapsing is contained within a larger mass that is just collapsing, a complication known as the 'cloud-in-cloud' problem. Another problem is that only half of the points are associated with an overdensity and therefore become part of any collapsed structure. Press and Schechter (1974) elected to solve this problem somewhat arbitrarily by multiplying the number of structures at a given mass scale by a factor of 2 with the vague understanding that this represents flow from underdense to overdense regions.

The number of halos $n(M)$ with masses between M and $M + \mathrm{d}M$ is

$$n(M)M\mathrm{d}M = 2\rho_M[P_{>\delta_c}(M) - P_{>\delta_c}(M + \mathrm{d}M)]\mathrm{d}M, \tag{73}$$

ρ_m being the average density at the redshift in question and the mass term M on the left-hand-side accounting for the fact that more massive halos are associated with more points of reference. Rewriting this, we get

$$\begin{aligned} n(M)\mathrm{d}M &= \frac{2\rho_M}{M}\left|\frac{\mathrm{d}P_{>\delta_c}(M)}{\mathrm{d}M}\right|\mathrm{d}M \\ &= \frac{2\rho_M}{M}\left|\frac{\mathrm{d}P_{>\delta_c}(M)}{\mathrm{d}\sigma(M)}\right|\left|\frac{\mathrm{d}\sigma(M)}{\mathrm{d}M}\right|\mathrm{d}M. \end{aligned} \tag{74}$$

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Finally, since the mean square fluctuations $\sigma^2(M)$ evolve as $D(\tau)^2$ according to linear growth (see equation (50)), we can rewrite the expression as

$$n(M)\mathrm{d}M = \frac{2\rho_\mathrm{M}}{M^2}\frac{\delta_\mathrm{M}}{\sigma(M)}\frac{1}{\sqrt{2\pi}\sigma(M)} \times \exp\left(\frac{-\delta_\mathrm{c}^2}{2\sigma(M)^2}\right)\left|\frac{\mathrm{d}\sigma(M)}{\mathrm{d}M}\right|\mathrm{d}\ln M. \quad (75)$$

This is the Press–Schechter mass function at redshift z. Despite the extremely heuristic nature of this derivation and the many problems already discussed, it agrees remarkably well with numerical simulations, and thus has proven very useful in characterizing the growth of structure.

Cooling processes

Galaxies are much less massive than the mass scales ($\sim 10^{14} M_\odot$) going nonlinear in the universe today, so clearly galaxies must be more than simply virialized structures. The key seems to be the process of cooling and the time scale for the settling of baryons into the centers of their dark matter halos. There are several cases to consider. Clearly, if the cooling time of a gas is larger than the Hubble time, the gas cannot have evolved much over the history of the universe. If the cooling time is smaller than the Hubble time but larger than the dynamical time, the gas will suffer slow quasistatic collapse into the center of the virialized halo. On the other hand, if the cooling time is smaller than the dynamical time, the ambient gas will undergo runaway cooling and collapse to the center of the virialized halo. It is this case, where the cooling time is much shorter than the dynamical time scales for ACCRETION or merging (Binney 1977, Rees and Ostriker 1977, Silk 1977) that is relevant for the formation of galaxies.

There are four important processes by which gas in halos cools: Compton cooling, free–free emission (bremsstrahlung), recombination, and collision-induced de-excitation.

We begin with a consideration of the Compton cooling process. When low-energy photons pass through a gas of non-relativistic electrons, they scatter off the electrons with the Thompson cross-section σ_T:

$$\sigma_\mathrm{T} = \frac{8\pi}{3}\left(\frac{e^2}{m_\mathrm{e}c^2}\right)^2 \quad (76)$$

where m_e is the mass of the electron and e is the charge of the electron. Some photons are scattered up in energy and some are scattered down, but the net effect is to slow the electrons relative to the frame of the cosmic microwave background radiation. The mean shift in photon energy per collision is

$$h\overline{\Delta\nu} = \frac{4kT_\mathrm{e}}{m_\mathrm{e}c^2}h\nu \quad (77)$$

where k is Boltzmann's constant, h is Planck's constant, ν is the frequency of a photon, and T_e is the temperature of the electron gas. In a sea of photons with temperature T_γ, the mean rate of energy loss per electron is

$$\frac{\mathrm{d}E}{\mathrm{d}t} = \frac{4kT_\mathrm{e}}{m_\mathrm{e}c^2}\sigma_\mathrm{T}aT_\gamma^4 \quad (78)$$

where a is the Stefan–Boltzmann constant. The cooling time t_cool is

$$t_\mathrm{cool} = \frac{\frac{3}{2}nkT_\mathrm{e}}{n_\mathrm{e}\frac{4kT_\mathrm{e}}{m_\mathrm{e}c^2}\sigma_\mathrm{T}aT_\gamma^4} = \frac{3m_\mathrm{e}c^2}{8\sigma_\mathrm{T}aT_\gamma^4} \sim 2.1\times10^{12}(1+z)^{-4}\ \mathrm{yr}. \quad (79)$$

High temperature (10^6–10^7 K) primordial gases are almost entirely ionized. Under these circumstances, the dominant cooling mechanism is due to the acceleration of electrons off the bare H^+ and He^{2+} nuclei. This results in a cooling rate per unit rate per unit volume:

$$\frac{\mathrm{d}E}{\mathrm{d}t} \propto n_\mathrm{e}n_\mathrm{H}T^{1/2}. \quad (80)$$

The cooling time t_cool here is approximately equal to

$$t_\mathrm{cool} = \frac{\frac{3}{2}nkT}{\frac{\mathrm{d}E}{\mathrm{d}t}} = 6.6\times10^9\frac{T_6^{1/2}}{n_{-3}}\ \mathrm{yr} \quad (81)$$

where $T_6 = T/10^6\,\mathrm{K}$ and $n_{-3} = n/10^{-3}\mathrm{cm}^{-3}$.

On the other hand, low temperature (10^4–10^5 K) primordial gases are only partially ionized. Here cooling is dominated by two processes: one where electrons recombine with ions resulting in the release of a photon (recombination) and one where electrons collide with partially ionized atoms, thereby exciting them to a state which they escape by the release of a photon. The total cooling rate can be expressed as

$$\frac{\mathrm{d}E}{\mathrm{d}t} \propto n_\mathrm{e}n_\mathrm{H}f(T). \quad (82)$$

The latter process is the dominant one, and for primordial abundances, the function $f(T)$ can be approximated as $2.5(T/10^6\,\mathrm{K})^{-1/2}\,\mathrm{erg\,cm^3\,s^{-1}}$. The cooling time t_cool is then

$$t_\mathrm{cool} = \frac{\frac{3}{2}nkT}{\frac{\mathrm{d}E}{\mathrm{d}t}} = 3.0\times10^9\frac{T_6^{3/2}}{n_{-3}}\ \mathrm{yr}. \quad (83)$$

We compare these cooling time scales with the dynamical time scales $t_\mathrm{dyn} \sim \sqrt{1/G\rho}$. We consider a uniform spherical cloud with mass M in virial equilibrium with f fraction of its mass in dissipative baryonic matter and the rest in dark, dissipationless matter, so the gas mass M_g is equal to fM. For this mass configuration,

$$t_\mathrm{dyn} \sim \sqrt{\frac{1}{G\rho}} \sim \sqrt{\frac{1}{Gn/f}} \sim 6.5\times10^9 f^{1/2}n_{-3}^{-1/2}\ \mathrm{yr}. \quad (84)$$

Now, we compare this dynamical time scale with the cooling times derived for each of the cooling processes

discussed above. At early times, $z > 10$, the Compton cooling process dominates, and since

$$n_{-3} = 2.3 \times 10^{-2} f(1+\delta)(\Omega_0 h^2)(1+z)^3 \tag{85}$$

the dynamical time scale goes as

$$t_{\rm dyn} \sim 3.0 \times 10^9 (\Omega_0 h^2)^{-1/2}(1+z)^{-3/2}\ {\rm yr} \tag{86}$$

and the relative time scale τ goes as

$$\tau = \frac{t_{\rm cool}}{t_{\rm dyn}} \approx 6 \times 10^2 (1+z)^{-5/2}. \tag{87}$$

Thus, Compton cooling will be important at $z > 7$ where $\tau < 1$. Notice that the relative time scale does not depend upon mass, temperature, or density. Therefore, if galaxies formed at early times, they would have no preferred scales.

The relevant temperatures for lower mass halos ($\lesssim 10^{12} M_\odot$) are less than 10^6 K. In this case, line cooling dominates and the relative time scale τ goes as $t_{\rm cool}/t_{\rm dyn} \propto (T^{3/2}/\rho^{1/2}) \propto ((M^{2/3}\rho^{1/3})^{3/2}/\rho^{1/2}) \propto M$. Therefore, the $\tau = 1$ line runs parallel to lines of constant mass. To determine the mass limit more precisely, we look at τ:

$$\tau = \frac{t_{\rm cool}}{t_{\rm dyn}} = 0.4 T_6^{3/2} f^{-1/2} n_{-3}^{-1/2}. \tag{88}$$

We can relate this to the mass of a spherical cloud model in virial equilibrium by using the following relation from the virial theorem:

$$\frac{3kT}{2\mu} = \frac{0.3GM}{R}, \tag{89}$$

where μ, the mean molecular weight, is roughly equal to half the proton mass $m_{\rm p}$ since the medium is ionized. From this, it follows that $T^3 \propto \rho M^2 \propto n f^{-1} M^2$ and then that

$$M_{\rm g} = 1.2 \times 10^{13} T_6^{3/2} f^{3/2} n_{-3}^{-1/2} M_\odot. \tag{90}$$

Hence,

$$\tau = \frac{M_{\rm g}}{1.2 \times 10^{13} f^2 M_\odot} = \frac{M}{1.2 \times 10^{13} f M_\odot}. \tag{91}$$

This sets the mass limit below which gas can effectively cool to form structures. For $f \sim 1$, the mass limit is much larger than the typical limiting galaxy mass ($\sim 10^{12} M_\odot$), but for smaller values consistent with constraints set by big-bang NUCLEOSYNTHESIS ($f \sim 0.05 - 0.1$), the mass limit is comparable to these limits.

On the other hand, for higher mass halos ($\gtrsim 10^{12} M_\odot$), the relevant temperatures are greater than $10^6 K$. Here the dominant cooling mechanism is bremsstrahlung, and the relative time scale ratios τ go as $t_{\rm cool}/t_{\rm dyn} \propto (T^{1/2}/\rho^{1/2}) \propto ((M^{2/3}\rho^{1/3})^{1/2}/\rho^{1/2}) \propto R$, so the $\tau = 1$ line runs parallel to lines of constant radius. To determine the limiting radius more precisely, we look at τ

$$\tau = \frac{t_{\rm cool}}{t_{\rm dyn}} = T_6^{1/2} f^{-1/2} n_{-3}^{-1/2}. \tag{92}$$

Using the spherical cloud model again, we solve for R in terms of the other variables,

$$R = \sqrt{\frac{3fkT}{0.8\pi\mu^2 G n_{-3}}} = 610 f T_6^{1/2} n_{-3}^{-1/2}\ {\rm kpc} \tag{93}$$

and so

$$\tau = \frac{R}{610 f^{3/2}\ {\rm kpc}}. \tag{94}$$

Hence, for $f \sim 0.1$, massive gas clouds of radii greater than 20 kpc can efficiently cool. Since this length is smaller than the typical cluster size, cooling is not very efficient in clusters, and therefore the gas simply suffers slow quasistatic collapse.

The galaxy cluster mass function

In the previous section, we discussed two important different regimes for virialized masses, one in which the cooling time was longer than the dynamical time and one in which it was shorter than it. In the former regime, one obtains GALAXY CLUSTERS where most of the gas remains hot and in the latter regime one obtains galaxies where much of the halo gas has apparently cooled. In either case, one can use Press–Schechter theory to calculate the mass function, and with simple assumptions about the conversion of gas into stars or other luminous objects, one can convert this into a LUMINOSITY FUNCTION OF GALAXIES.

Perhaps the most direct comparison with observations is via the mass function of galaxy clusters. The shape, expected to be exponential plus a power law tail, fits the prediction remarkably well, to the extent that cluster masses are well determined. Three techniques are used to estimate cluster masses: galaxy velocity dispersion and distribution, hot gas temperature and distribution, and gravitational lensing maps. The first two methods assume virial equilibrium. All three methods give consistent results, to within a factor of 2 in mass. One can compare the characteristic cluster mass, determined by the fitting function

$$\frac{{\rm d}N}{{\rm d}M} \propto M^{-\alpha} \exp\left(-(M/M_{\rm nl})^\beta\right), \tag{95}$$

with the predicted value of $M_{\rm nl}$ taken from field galaxy counts and a bias factor that has to be empirically deduced. Indeed, $M_{\rm nl}$ corresponds to a typical observed cluster mass. The normalization of the cluster mass function depends both on the mean density and $\sigma(M, Z)$, with an exponential sensitivity to $\sigma(M, Z)$. Only five percent of galaxies are in clusters, which can therefore account for perhaps one percent of the critical density. Clusters are therefore rare objects, typically 3σ fluctuations. The number density of clusters is controlled by both the mean density and σ_8, in the combination $\sigma_8\,\Omega^{0.6} \approx 0.7 \pm 0.2$. The scale $8h^{-1}$ Mpc, corresponding to unit amplitude of the optical counts and the mass M_8 of a typical cluster, is used for normalization, and $\sigma(M, 0) = \sigma_8 (M_8/M)^{(n+3)/6}$ where $M_8 = 4\pi(8h^{-1}{\rm Mpc})^3 \Omega\bar{\rho}$.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

The galaxy luminosity function

The Press–Schechter formulation can also be used to derive the galaxy luminosity function, which is described by the Schechter function

$$\frac{\mathrm{d}N}{\mathrm{d}L} \propto L^{-\alpha} \exp(-L/L_*) \tag{96}$$

where $L_* \approx 10^{10} L_\odot$ and $\alpha \approx 1$ to 1.5 depending on the galaxy selection criterion. There are two ingredients that must be incorporated in connecting mass to luminosity in order to obtain a satisfactory comparison of theory and observation. A characteristic luminosity L_* must be derived, and the formation of low mass objects into luminous objects must be inefficient, since the mass function tail has slope M^{-2} whereas the luminosity function is flatter. The characteristic luminosity follows from the fact that cooling is efficient only for masses up to $\sim 10^{12} M_\odot$. Then, assuming a typical baryon fraction, an age of $\sim 10^{11}$ yr, and a standard mass function for stars, one derives a characteristic luminosity of $\sim 10^{10} L_\odot$.

Angular momentum

As structures grow and collapse in the early universe, they exert tidal torques on each other, and this provides each collapsing mass with some angular momentum. This angular momentum, in turn, is important in determining the final properties of the disk and elliptical galaxies which form inside these collapsed structures.

The angular momentum of a collapsing halo can be expressed as

$$\boldsymbol{J} = \int_{\mathrm{V}} \mathrm{d}^3 x \bar{\rho} a^3 (a\boldsymbol{x} - a\bar{\boldsymbol{x}}) \times \boldsymbol{v} \tag{97}$$

where $\bar{\boldsymbol{x}}$ is the center of mass for the volume. Using equation (47), we express $\boldsymbol{v}$ as $-a\dot{b}\nabla\Phi_0$ where $b(\tau) = D/4\pi G\bar{\rho}a^3$. For convenience we expand $\nabla\Phi_0$ in a Taylor series around the point $\boldsymbol{x}$:

$$\begin{aligned} \nabla\Phi_0|_{\boldsymbol{x}} &= \nabla\Phi_0|_{\bar{\boldsymbol{x}}} + (\boldsymbol{x} - \bar{\boldsymbol{x}}) \cdot \frac{\partial^2 \Phi_0}{\partial \boldsymbol{x}^2}|_{\bar{\boldsymbol{x}}} \\ &= \nabla\Phi_0|_{\bar{\boldsymbol{x}}} + (\boldsymbol{x} - \bar{\boldsymbol{x}}) \cdot \underline{\underline{T}} \end{aligned} \tag{98}$$

where $T_{jl} = \partial^2\Phi_0/\partial x_{\mathrm{j}} \partial x_{\mathrm{l}}$. Rewriting this, we get

$$J_{\mathrm{i}}(\tau) = -a\dot{b}\epsilon_{ijk} T_{jl} \int_V (x_{\mathrm{l}} - \bar{x}_{\mathrm{l}})(x_{\mathrm{k}} - \bar{x}_{\mathrm{k}}) \bar{\rho} a^3 \mathrm{d}^3 x \tag{99}$$

or

$$J_{\mathrm{i}}(\tau) = -a\dot{b}\epsilon_{ijk} T_{jl} I_{lk} \tag{100}$$

where I_{lk} is the inertial tensor.

We now estimate how J_{i} scales. Since I_{lk} scales as a^2 until collapse while T_{jl} continues to scale as $\nabla\Phi/a^2 \sim (D/a)/a^2 \sim 1/a^2$, each structure effectively acquires angular momentum from its neighbors until collapse. Since the collapse of a structure occurs when $\delta \sim 1$, $b \sim D(\tau)/4\pi G\bar{\rho}a^3 \sim 1/4\pi G\bar{\rho}a^2 \sim 1/\nabla^2\Phi$ from Poisson's equation and the relation $D(\tau) \propto a$, so T_{jl} scales as $\nabla^2\Phi_0 \sim 1/b$. $\underline{\underline{I}}$ scales as $MR_0^2 \sim MR^2/a^2$. Hence,

$$\begin{aligned} J_{\mathrm{i}}(\tau) &\sim -a\dot{b} T_{jl} I_{lk} \sim a\dot{b} \frac{1}{b} \frac{MR^2}{a^2} \\ &\sim \frac{\dot{b}}{\dot{a}b} \frac{\dot{a}}{a^2} M(M/\rho)^{2/3} \\ &\sim \Omega^{0.6} H(\Omega H^2)^{-2/3} M^{5/3} \\ &\sim \Omega^{-0.07} t^{1/3} M^{5/3}. \end{aligned} \tag{101}$$

It is standard to construct a dimensionless quantity which characterizes the angular momentum that each collapsed mass has acquired via tidal torques. This quantity is called the dimensionless angular momentum λ, and it can be expressed as

$$\lambda = \frac{|\boldsymbol{J}||E|^{1/2}}{GM^{5/2}}. \tag{102}$$

Noting that $|E| \sim M^2/R \sim M^2(\rho/M)^{1/3} \sim M^{5/3}(\Omega H)^{1/3} \sim \Omega^{1/3} M^{5/3} t^{-2/3}$, we see that $\lambda \sim |\boldsymbol{J}||E|^{1/2} M^{-5/2} \sim \Omega^{-0.07} t^{1/3} M^{5/3} \Omega^{1/6} t^{-1/3} M^{5/6} M^{-5/2} \sim \Omega^{0.1}$. Therefore, the distribution of dimensionless angular momenta λ is essentially independent of a halo's mass, collapse time, or even the basic world model. N-body simulations (Warren *et al* 1992, Cole and Lacey 1996, Catelan and Theuns 1996) and analytical treatments (Steinmetz and Bartelmann 1995) find a distribution which is well fitted by the expression

$$p(\lambda) = \frac{1}{\sqrt{2\pi}\sigma_\lambda} \exp\left[-\frac{\ln(\lambda/\bar{\lambda})^2}{2\sigma_\lambda^2} \right] \frac{\mathrm{d}\lambda}{\lambda} \tag{103}$$

where $\bar{\lambda} = 0.05$ and $\sigma_\lambda = 0.5$.

Disk formation

Disk galaxies make up the dominant component of the local galaxy census. Disk galaxies are known to have exponential profiles ($I(r) \propto \exp(-r/r_{\mathrm{d}})$), to have significant fractions of dust and stars, to still be undergoing some STAR FORMATION, and to be rotationally supported. They are extremely flattened objects and can appear very elongated if viewed edge-on. They also frequently have long bars and spiral structures. It is because of this latter feature that these galaxies are often called SPIRAL GALAXIES.

Most of the global disk properties, e.g., mass, luminosity, size, and metallicity, define a two-dimensional manifold with little scatter about that manifold. It is more well-known in terms of its two-dimensional projections, in particular, the well-known TULLY–FISHER RELATION between luminosity and circular velocity. There are two main views on this tight relationship: one in which these processes as consequences of self-regulating mechanisms for star formation in disks (e.g. Silk 1997) and one in which this is simply the consequence of the cosmological equivalence of mass and circular velocity (e.g. Mo *et al* 1998).

In the past, disk galaxies were thought to have surface brightnesses tightly distributed around 21.65 b_{J} mag/arcsec^2 (Freeman 1970). Shortly after this claim

was made, arguments were made that there was a strong selection bias against low surface brightness galaxies and in reality the spread in surface brightness extended to much lower values (Disney 1976). Recently, there have been a large number of efforts to quantify the bivariate luminosity–surface brightness distribution (de Jong 1996, McGaugh 1996, Dalcanton *et al* 1997, Sprayberry *et al* 1997, de Jong and Lacey 1999). While the results are somewhat different in terms of their details, they suggest that the surface brightness distribution of galaxies peaks around 22 b_J mag/arcsec^2 with a spread of $\sim 1 - 1.5$ mag/arcsec^2. The luminosity function of spiral galaxies is also nicely described by the Schechter function.

The typical values of the dimensionless angular momentum of collapsed halos (~ 0.05) are considerably smaller than that of the largely flattened centrifugally-supported disk galaxies we observe in our universe today ($\sim 0.4 - 0.5$), so considerable dissipation must occur to produce these disks. Without the presence of dissipationless dark matter, the collapse would proceed in such a way that the total angular momentum $\boldsymbol{J}$ and the total mass m would be conserved, but the energy would scale as $1/R$ where R is the collapse factor, so that $\lambda \propto JE^{1/2}M^{-5/2} \propto 1/\sqrt{R}$. The disk would then need to collapse by a factor of $(0.5/0.05)^2 \sim 100$ to obtain its observed dimensionless angular momenta, and this would take longer than the age of the universe for a 10-kpc disk! However, if the gas cloud collapses inside a dark matter halo, for which it represents only a fraction f of the mass, then the angular momentum $\boldsymbol{J}$ and mass $\boldsymbol{M}$ would scale by a factor f and the energy $\boldsymbol{E}$ would scale by a factor f^2, so that $\lambda \propto JE^{1/2}M^{-5/2} \propto 1/(f^{1/2}R^{1/2})$. For a typical estimate of the baryon fraction, $f \sim 0.1$, the gas cloud would then only need to collapse by a factor of 10, easily accommodated in current theories.

Despite the simplicity of this picture, a significant portion of the available gas cools to form GALAXIES AT HIGH REDSHIFT. Detailed simulations which follow the evolution and merging of these galaxies into larger and larger systems produce disks whose sizes are much smaller than those observed (Steinmetz and Navarro 1999) because of substantial angular momentum transfer from the baryons to their dissipationless halos.

Feedback

A nonnegligible fraction of stars end their lives as SUPERNOVAE, injecting much of this energy into the ambient gaseous medium. This energy serves to heat the gas, either expelling it from the star-forming environment or making it too hot to be conducive to star formation. Hence, the formation of stars serves to suppress further star formation and hereby regulates itself. This process is quite logically called feedback. The presence of feedback, particularly in disk galaxies, explains why the conversion of gas into stars frequently requires ten to hundreds of dynamical time scales ($\sim 10^{10}$ yr) instead of just several dynamical time scales ($\sim 10^8$ yr).

Feedback also provides the preferred explanation for the flattening of the luminosity function relative to the mass function at low masses (see the section above on galaxy luminosity function). DWARF GALAXY potential wells are shallow, and interstellar gas is readily energized above the escape velocity and therefore blown out in a galactic wind. Evidence for galactic winds is commonly found for STARBURST GALAXIES, often of relatively low mass.

Elliptical galaxy formation

Ellipticals make up the other principal component of the local galaxy census. Ellipticals possess elliptical isophotes with projected ellipticities $\epsilon = a/b$ (a being the major axis and b the minor) ranging from 0 to 0.7, the former being denoted an E0 and the latter an E7. Low redshift ellipticals possess an abundance of low-mass stars and are therefore very red. The lack of short-lived blue stars is generally taken as an indication that these galaxies are very old and have not formed stars for at least 5–10 Gyr. Like spirals, the luminosity function for ellipticals can also be described by a Schechter function, but with a much shallower faint-end slope (Bromley *et al* 1998, Folkes *et al* 1999). Unlike spirals, ellipticals are predominantly found in dense regions, i.e., galaxy clusters (Dressler 1980).

Ellipticals are known to have approximately de Vaucouleurs surface brightness profiles:

$$I(r) \propto \exp(-7.67(r/r_e)^{1/4}) \tag{104}$$

where r is the radius and r_e is the half-light radius. To higher order, the surface brightness profiles of ellipticals show an important dichotomy. Some ellipticals, known as disky ellipticals, appear to have power-law profiles all the way into their center, and other ellipticals, known as boxy ellipticals, exhibit a sharp break from this power-law at some radius near the center.

Like spirals, the global structural properties of ellipticals are known to populate a two-dimensional manifold, commonly known as the fundamental plane. These are known according to various names: the Faber–Jackson (Faber and Jackson 1976) relationship ($L \propto \sigma^4$), the Kormendy luminosity–radius (Kormendy 1977) relationship, and the D_n-σ (Dressler *et al* 1987) relationship. It has largely been agreed that the fundamental plane is essentially a consequence of the virial theorem and a relatively homologous formation scenario where the mass-to-light ratio varies as a small power of the mass ($M/L \propto M^{1/6}$).

There are two prevailing scenarios for the formation of elliptical galaxies: one in which ellipticals formed as the result of mergers from spiral galaxies and one in which ellipticals formed at high redshift from monolithic collapse. We begin by presenting the monolithic collapse scenario.

Monolithic collapse

One possible mechanism for the formation of elliptical galaxies is the early formation of stars from the gas collapsing onto the center of a dark halo. Early collapse and fragmentation into stars prior to the collapse of the halo can constitute the core of the elliptical while

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

stars formed from the secondary gas infall can constitute the shallower wings. An examination of the velocity-dispersion rotational-rate relationship demonstrates that ellipticals are essentially pressure-supported and that rotational flattening is not important in imparting ellipticity to these galaxies. In fact, detailed comparisons show that the dimensionless angular momenta of slow-rotating ellipticals seems to be no larger 0.05. In order to obtain the typical mass M ($\sim 10^{11} M_{\odot}$), radius R (~ 10 kpc), and angular momentum without recourse to dissipation, it would be necessary for the halo to collapse at redshifts beyond 10. On the other hand, with dissipation, one could easily obtain galaxies of the desired mass and radius, but the dimensional angular momentum would be too large (unless the initial angular momentum for the halo just happened to be particularly small), and the galaxy would resemble a disk.

Merger-based origin

Another mechanism for the formation of ellipticals is through the mergers of spiral galaxies. This mechanism provides a natural way of resolving the angular momentum problem, the crucial point being that since the spin angular momenta are randomly oriented with respect to each other, the resultant spin angular momentum for the formed elliptical can be considerably smaller than the spin angular momentum of the colliding disks. There are a number of other attractive features to this scenario. First, there are numerous examples of disk galaxies merging to form objects with de Vaucouleurs profiles in the local universe (Schweizer 1982, 1986), and it is quite conceivable that mergers were more frequent in the past. Secondly, nearly half of elliptical galaxies (Malin and Carter 1983, Schweizer and Ford 1984) possess features, such as shells or other sharp features, indicative of mergers or an otherwise violent formation. Thirdly, detailed N-body simulations of collisions between disk galaxies embedded in dark halos produce galaxies with de Vaucouleur profiles similar to those found in nearby ellipticals. Fourth, the GLOBULAR CLUSTER populations around ellipticals have bimodal metallicity distributions, indicative of a multi-stage formation scenario (Ashman and Zepf 1992, Zepf and Ashman 1993). All these features point toward the conclusion that at least *some* ellipticals formed by merging.

Before discussing the relative merits of the two formation scenarios for ellipticals, it is interesting to look at several of the difficulties which only arise in the merging scenario because of the close relationship between ellipticals and their progenitors (spirals). First, the energy per particle and phase space density are higher at the centers of ellipticals than any observed spiral, and therefore the merging process must be accompanied by a great deal of gas dissipation and cooling both to form a much deeper central potential and to obtain the high phase space density observed there if we presume this scenario is correct. In fact, nuclear starbursts are frequently observed to accompany such mergers (Schweizer 1990). Second, the number of globular clusters ($\sim 10^4$–$10^5 M_{\odot}$ compact star clusters) per unit luminosity for ellipticals is typically 4–10 times larger than that for spirals (van den Bergh 1990), so disk-disk mergers must result in the formation of a large number of globular clusters if we presume this scenario is correct. Finally, while ellipticals might be expected to show relative alpha-to-iron abundances typical of spirals, ellipticals contain significantly larger abundances of alpha elements than iron elements, so a substantial fraction of the stars present in ellipticals must have formed in the merger events between two spiral galaxies.

A comparative evaluation

The principal observational differences between the monolithic collapse and merger scenarios for elliptical formation concern their predictions for the formation history of ellipticals. Monolithic scenarios tend to form elliptical galaxies at very high redshifts ($z > 3$) while the elliptical population builds up more gradually in hierarchical scenarios.

Consequently, the merger scenarios, with their more diverse and contemporary formation histories, show more scatter in both the colour-magnitude relationship and the fundamental plane than monolithic collapse scenarios. Observationally speaking, ellipticals show a high degree of uniformity both in their small color-magnitude scatter, i.e. $\sigma(U - V) = 0.15$ (Bower *et al* 1992) and their tightness around the fundamental plane (Renzini and Ciotti 1993). This observed tightness about the fundamental plane extends to $z \sim 1$ (Aragon-Salamanca *et al* 1993, Stanford *et al* 1998). The observed tightness supports a monolithic collapse scenario where ellipticals form early and somewhat coevally. Of course, in hierarchical scenarios, most galaxies assemble quite early ($z \sim 2$) in the rich clusters, where the most compelling examples of tight fundamental planes are observed, so apparent difficulties with this scenario are not as strong as they first might seem (Kauffmann and Charlot 1998a).

Due to the different formation times for ellipticals, these scenarios also yield remarkably different predictions for the evolution in the number density of early-type galaxies as a function of redshift. While there has been an increasing number of studies reporting a devolution in the number and luminosity of ellipticals at high redshift relative to that found in the local universe (Kauffmann and Charlot 1998b, Kauffmann *et al* 1996, Zepf 1997, Barger *et al* 1999, Menanteau *et al* 1999) as would be expected in a hierarchical scenario where their formation is more gradual, these results remain somewhat controversial (Broadhurst and Bouwens 1999, de Propris *et al* 2000).

Another important difference between these scenarios is the star formation rates they predict at high redshift. In the hierarchical scenario, galaxies start out small and slowly build up to the massive entities we observe in the universe today. Clearly, we do not expect large star formation rates here at early times except possibly when two galaxies merge. On the other hand, in the monolithic scenario, ellipticals need to undergo huge star formation

rates ($\sim 100\,M_\odot$/yr) to form the typical $10^{11}\,M_\odot$ stars observed in nearby giant elliptical galaxies at high redshift since there is only a period of $\sim 10^9$ yr available. In fact, very few galaxies with these huge star formation rates ($\sim 100\,M_\odot$/yr) have been found in either emission-line searches or Lyman-dropout searches at moderate redshifts ($1 < z < 5$), pointing to either a high redshift of formation or dust-enshrouding. Recently, however, SCUBA results and subsequent follow-up work have revealed a population of ultraluminous infrared galaxies at moderate redshifts with high enough star formation rates ($\sim 100\,M_\odot$/yr) to match those needed in a monolithic collapse scenario. Nevertheless, the exact nature of this population, its number density, and its relevance remain unclear.

Bulges

Many spiral galaxies feature a bulge, or a spheroid, at their centers. Spheroids resemble elliptical galaxies in many important respects including their overall appearance and placement in the fundamental plane. This suggests that bulges are nothing but elliptical galaxies upon which gas has later accreted. Note, however, that somewhat contrary to ellipticals, in particular ellipticals with boxy isophotes, is the presence of considerable rotational flattening in many bulges (Davies *et al* 1983, Davies 1987). This is in agreement with what one might expect from dissipational collapse and, in particular, from the formation of bulges via disk instabilities (van den Bosch 1998).

Summary

While there are many things we do not understand about galaxy formation, many pieces of the picture now seem to be clear. Galaxies seem to form in a homogeneous, isotropic universe that is expanding according to Friedmann's equations. Inflation, though not unique, appears to be a relatively successful way of producing the scale-free spectrum of density fluctuations out of which galaxies have formed. Growth of the fluctuations can be followed initially with linear growth theory and later using a spherical collapse model. Press–Schechter theory provides a relatively successful way of putting these ingredients together to predict the mass spectrum of collapsed objects. The relative magnitudes of the cooling and dynamical time scales are important for determining the mass range of galaxies, galaxies forming when the cooling time is smaller than the dynamical time. Disk galaxies form from the cooling of gas onto the centers of collapsed halos, the gas settling into a disk supported by its angular momentum. Elliptical galaxies, on the other hand, seem to form by disk–disk mergers or by gas cooling within a halo of low intrinsic angular momentum (monolithic collapse).

Many important questions remain. For example, what is the relative importance of different mechanisms for the formation of both ellipticals and bulges? How do the sizes, luminosities, star formation rates, number densities, and metallicities of various galaxy types evolve over the history of the universe? What mechanisms are responsible for the tight correlation between the global properties of ellipticals and spirals? While theoretical simulations are becoming increasingly sophisticated, the inherent nonlinearity of galaxy formation processes make the role of new observations tantamount. To give the reader a taste of the improvements we will see in the next ten years in probing galaxy formation in the most remote regions of the universe, in figure 2 we have included some simulations for a hierarchical merging model using two current generation instruments (WFPC2 and NICMOS) and two future generation instruments (ACS and NGST). The obvious increase in depth will clearly bring our already moderately mature understanding of galaxy formation further into focus.

Galaxy Morphology–Density Relation

The galaxy morphology–density relation describes the strong correlation that exists between the mix of the basic morphological types of galaxy—elliptical (E), spiral (Sp) and lenticular (S0)—in a given volume of space and the local density of galaxies within that volume.

Morphological types of galaxy

As was first recognized by Edwin HUBBLE, galaxies fall into distinct morphological groups fundamental to which are two basic structural features: a more or less flat *disk* of stars and sometimes gas and dust, and a *spheroidal* component. ELLIPTICAL (E) GALAXIES are pure spheroidal systems and were named after the smooth, ellipsoidal shaped light distributions that they project onto the sky. SPIRAL (Sp) GALAXIES comprise both a disk and a spheroid and are distinguished by the conspicuous spiral arm structure in their disks. The LENTICULAR (S0) GALAXIES are, in comparison, somewhat of a transitional object, containing both a spheroid and a disk, but the latter exhibiting no spiral structure.

As well as recognizing these basic morphological types and establishing a classification scheme for them—what is known as Hubble's 'tuning fork' sequence—Hubble was also amongst the first to recognize that the morphological mix of galaxies, that is the relative numbers of E, S0 and Sp types, changed considerably in different environments. The most conspicuous evidence for this came from contrasting the central regions of nearby rich clusters of galaxies—the densest galaxy environments known—with the lower-density regions outside clusters, commonly referred to as the 'field'. The former were seen to be dominated by E and S0 types, with Sp galaxies being almost absent, whereas the field was rich in spirals and E and S0 types were in the minority. A variation also in the morphological mix within clusters has since been well established, with the Sp fraction found to rise and the E and S0 fractions to decrease with increasing radius from the center of rich, regular clusters.

Quantitative studies

The first serious attempt to quantify these well perceived trends was made by Oemler in 1974. He morphologically classified the galaxy populations within 10 nearby rich clusters and derived the global fractions of E, S0 and Sp galaxies in each. These fractions appeared to roughly segregate the clusters into three different classes which Oemler designated 'cD', 'spiral poor' and 'spiral rich'. The cD clusters were those dominated by E and S0 galaxies (making up ∼35% and ∼45% of the cluster population respectively) and corresponded to those with a central cD galaxy and a smooth, centrally concentrated galaxy distribution. In contrast, Sp galaxies constituted about 60% of the population in spiral-rich clusters and these were systems which happened to be highly irregular in shape with little if any degree of central concentration. Spiral-poor clusters possessed intermediate properties both in terms of their overall structure and morphological fractions (E = 15%, S0 = 55%, Sp = 30%). Oemler suggested that these three different types of cluster represented successive stages in the cluster dynamical evolution process which in itself drove a change in the morphological mix.

While this approach of measuring the global morphological fractions in clusters is useful in revealing the gross differences that exist between the different classes of cluster and also between clusters and the field, it falls far short of identifying the fundamental physical variable to which morphological mix is related. For one, radial gradients in the morphological mix are seen within clusters, suggesting that cluster-centric radius is important. On the other hand, this quantity is meaningless in irregular clusters where there is no obvious center and the distribution of galaxies is chaotic and lumpy. Motivated by these problems, Dressler used a sample of 55 rich clusters to further explore the variation of morphological mix and its dependencies. Noticing that the high-density galaxy clumps scattered within the irregular clusters in his sample had a similar morphological mix to the dense cores of the regular clusters, he investigated whether *local galaxy density* was a quantity more germane to the change of morphological mix with environment. This indeed proved to be the case, with strikingly well-behaved and monotonic relations found between morphological fraction and local projected galaxy density over five orders of magnitude in the latter. These are shown in figure 1 and, as Dressler emphasized, they provide very strong evidence that it is the environment *local* to a galaxy that is most fundamental in determining its morphology. It is the behavior encapsulated in this diagram that is commonly referred to as 'the galaxy morphology–local density relation'.

To construct figure 1, Dressler measured some 6000 galaxies, mostly within 2.1 deg^2 fields centered on each of his 55 clusters (all of which were at $z < 0.06$), but also within 15 similarly sized 'field' regions. His imaging material consisted of photographic plates, the majority of which were taken on the 100 inch Du Pont telescope at LAS CAMPANAS OBSERVATORY in Chile. These were used to visually assign each galaxy a morphological type (E, S0, Sp or Irr (irregular)) and to measure its position, the magnitude of its spheroid component and its ellipticity. To measure local density, the 10 nearest (projected) neighbors to each galaxy were identified and the area within which they were contained computed. This allowed the local surface density of galaxies (in galaxies Mpc^{-2}) to be calculated, after having first made a correction for field galaxy contamination. To account for the different redshifts of the clusters, this calculation of the local density was always made down to the same absolute magnitude ($M_V = -20.4$; $H_0 = 50$ km s^{-1} Mpc^{-1}) in each cluster. Marginal distributions were then formed for each morphological type (E, S0, Sp + Irr), giving the number of galaxies as a function of local galaxy density. In combination, these

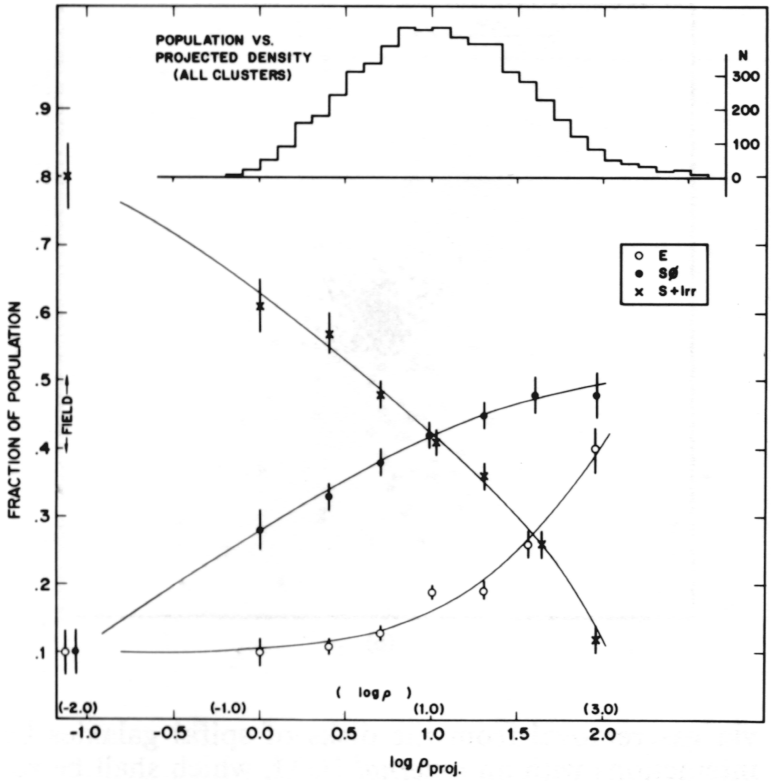

Figure 1. Dressler's galaxy morphology–local density relation. Plotted are the fractions of E, S0 and Sp + Irr galaxies as a function of the logarithm of the local projected galaxy density (see text for details). The upper histogram shows the numbers of galaxies contributing to each of the data points in the lower plot, with the exception of the left-most points which represent the field. The scale shown on the upper side of the horizontal axis indicates the logarithm of the true spatial density of galaxies (in galaxies Mpc^{-3}).

then provided the *fractions* of E, S0 or Sp + Irr types at a given local density value.

The fact that the morphology of a galaxy is closely related to the density of galaxies in its vicinity would also suggest that the local environment is of key importance in the formation and/or evolution of a galaxy (see also GALAXY EVOLUTION, GALAXY FOMATION). However, whether its influence is felt mainly at the time of formation, or as the galaxy subsequently evolves, or during both phases, remains an open question. The paucity of spirals (and the abundance of S0 galaxies) in the cores of regular clusters has long been cited as evidence for the environment playing a large role in their evolution, their encounter with either the hot intracluster gas, other cluster galaxies, or the strong tidal field of the cluster leading to a termination of their star formation and a morphological conversion into S0 galaxies. Dressler, on the other hand, argued that the local environment had its greatest influence at the formation stage, since his galaxy morphology–local density relation showed the S0 fraction to vary slowly with density to the extent that S0s still made up a significant proportion of the galaxy population in regions where the density was too low for gas removal and disruption mechanisms to be effective. Furthermore, the galaxy morphology–local density relation appears to be no different in irregular clusters than in regular clusters, despite the former being insufficiently evolved, dynamically, for these same processes to be in operation.

The relation at high redshift

The study of the galaxy morphology–local density relation at high redshift, and hence at a significantly earlier epoch, provides a direct means of discriminating between these 'formation' and 'evolutionary' scenarios (see GALAXIES AT HIGH REDSHIFT). This became observationally possible for the first time in the early 1990s with the launch of the HUBBLE SPACE TELESCOPE (HST) which, once repaired, provided the one-tenth of an arcsecond spatial resolution necessary to discern the morphologies of galaxies at cosmological distances. Images taken with HST's Wide Field and Planetry Camera of rich clusters at redshifts of $\sim$0.5, have allowed the galaxy morphology–local density relation to be viewed as it was some 6–8 billion years ago. This has yielded a number of major results. Firstly, the fraction of E galaxies seen in these distant clusters is, on average, no different to that seen in present-day clusters. This would imply that ellipticals are old systems which pre-date the clusters and the local environment is more important to their formation, with greater numbers being formed in regions of higher density. In contrast, the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

proportion of S0 galaxies in the distant clusters is two to three times smaller than that observed nearby, with a proportional increase in the Sp fraction. This confirms that certainly the cluster environment, at least, had a major influence on the evolution of spirals, converting them into S0s. It also verifies, morphologically, a well known effect seen in distant clusters both photometrically and spectroscopically, namely the presence of many more blue, star-forming galaxies in comparison to clusters at low redshift (named after its discoverers as the 'Butcher–Oemler' effect). As far as the galaxy morphology–local density relation is concerned, gradients in the morphological mix with changing local density are only found in distant clusters which have a regular and centrally concentrated structure, whereas they are completely absent in irregular clusters. Thus the relationship appears to evolve in a hierarchical way, establishing itself first in the richer and denser galaxy systems and then slowly working its way down into the poorer and less dense clusters and groups.

Remaining issues

The final word on the *local* galaxy morphology–local density relation has not rested with Dressler's original work. As part of the HST-based studies of the relation at higher redshift, Dressler's original data set was reanalysed in order to incorporate better, morphologically dependent field galaxy corrections. This had a small but noticeable effect, reducing slightly the spiral fraction at the lowest projected densities. There has also been debate over whether the local projected galaxy density is the sole determinant of morphological mix. A key point in this regard is that if a relation based on projected density was universal, then that could not be the case for the relationship between morphological mix and three-dimensional space density, implying a dependence on some further property that varied from cluster to cluster. It is of note in this context that in Dressler's original study, some marginal evidence was found for a shift in the population levels in clusters with the strongest x-ray emission and thus highest central concentration.

A strong case has also been made for cluster-centric radius alone being the determinant of morphological mix in clusters on the basis that it gives much tighter correlations than local galaxy density or indeed any other cluster property. However, it is not quite this simple, since while the correlations with radius might be stronger, they show a very different behavior in regular and irregular clusters, with the gradients in population mix being much stronger in the former than in the latter. Furthermore, it remains hard to reconcile with the reality of sub-clustering within clusters which has concentrations of galaxies of very similar morphological mix located over a broad range of cluster-centric radius.

These issues notwithstanding, the galaxy morphology–local density relation still remains one that is recognized as being fundamental to galaxies, their morphology and the relationship of this property to environment. The debate surrounding the relation serves as an important reminder that nature is not so simple that it can be described perfectly by a single relationship, but most likely there are secondary factors that come into play and that there are exceptions to the average behavior that this important relation represents.

Galaxy Redshift Surveys

The aim of galaxy redshift surveys is to map the three-dimensional distribution of many thousands of galaxies, in order to understand the properties of this distribution and what it implies about the contents and evolution of the universe. It has been known since observations by Hubble in the 1930s that galaxies are not distributed at random, but occur in structures of various sizes. For example, our own LOCAL GROUP contains two large galaxies (our Galaxy and Andromeda) and some 20 medium to very small galaxies. The Local Group is located in the outskirts of the Local Supercluster (see SUPERCLUSTERS AND THE LOCAL SUPERCLUSTER), which is a roughly disk-shaped structure containing around 1000 known galaxies and centered on the well-known VIRGO CLUSTER.

In the 1970s, Peebles and coworkers carried out pioneering statistical measurements of galaxy clustering by analyzing the two-dimensional distribution of galaxies on the sky, notably from the Lick catalogue; it is possible to infer statistical information about the three-dimensional distribution from this, although individual structures cannot be mapped in detail as many structures are superposed in projection on the sky. To obtain the third dimension (i.e. distance) for each galaxy, the galaxy REDSHIFT is used as an approximate distance indicator. The recession of galaxies due to the expansion of the universe causes the observed atomic features in a galaxy spectrum to be Doppler shifted to longer wavelengths relative to their laboratory wavelengths. By Hubble's law the recession velocity v of a galaxy is linearly proportional to its distance r, therefore $v \approx H_0 r$ where H_0 is the HUBBLE CONSTANT; the law is not exact as there is a small extra term due to the 'peculiar velocity' of the galaxy due to the gravitational attraction of the galaxy's neighbors.

Therefore, if we make a three-dimensional map of galaxies using their angular positions on the sky and redshift as the radial direction, this will be a fairly accurate map of the 'true' positions; the scale of our map will depend on the Hubble constant, and the galaxies will be slightly displaced radially from their 'true' positions by the unknown peculiar velocities, but the overall picture will be quite realistic.

Redshift–distance relation

Quantitatively, the redshift z is defined by the fractional wavelength shift:

$$z \equiv \frac{\lambda_{\rm obs} - \lambda_{\rm rest}}{\lambda_{\rm rest}} = \frac{\lambda_{\rm obs}}{\lambda_{\rm rest}} - 1$$

where $\lambda_{\rm obs}, \lambda_{\rm rest}$ are observed and rest wavelengths. Typical wide-area galaxy surveys sample redshifts $z \lesssim 0.1$, so the non-relativistic Doppler formula $z \approx v/c$ is adequate, giving $r \approx cz/H_0$. For low redshifts, the redshift is often quoted for convenience as cz in units of km s^{-1} rather than the dimensionless z, e.g. for the Coma cluster $cz \approx 7000$ km s^{-1} or $z \approx 0.0233$. The distance is then $7000\,{\rm km\,s^{-1}}/H_0$, which is generally written in the literature as $70h^{-1}$ Mpc where $h \equiv H_0/(100\ {\rm km\ s^{-1}\ Mpc^{-1}})$; i.e. the uncertainty in H_0 is absorbed into the scale factor $h \approx 0.7$.

Strictly speaking, the redshift is not a 'true' Doppler effect but really a general-relativistic effect arising from the overall expansion of the universe, whereby photon wavelengths are stretched proportionally to the scale factor of the universe:

$$1 + z = \lambda_{\rm obs}/\lambda_{\rm em} = a_{\rm obs}/a_{\rm em}$$

where $a_{\rm em}, a_{\rm obs}$ are the scale factors at the times of photon emission and observation, and thus $a_{\rm obs}/a_{\rm em}$ is the ratio by which the universe has expanded over this interval. This leads to Hubble's law at low z, while the distance–redshift relation becomes non-linear at $z \gtrsim 0.2$ and depends slightly on cosmological parameters, but the essential point of a monotonic redshift–distance relation still applies.

Measurement of redshifts

Galaxy redshifts are usually measured by standard optical spectroscopy (e.g. figure 1) since it is a good compromise between speed and accuracy. The galaxy's spectrum having been taken, the redshift is obtained either by 'cross-correlation' with a template spectrum to obtain the relative shift in log(wavelength) or by directly identifying and fitting the positions of individual spectral features, e.g. emission lines. The typical precision is 50–100 km s^{-1}, which is quite adequate since galaxy peculiar velocities are larger than this. Redshifts may also be measured with radio telescopes using the 21 cm hydrogen line, which gives very accurate redshifts but is somewhat more time-consuming and is generally only possible at lower redshifts. 'Photometric' redshift estimates can also be obtained from multiband photometry: these are useful for evolutionary studies, but their precision is not good enough for detailed mapping of structure.

Density fluctuations

The main reason for the great interest in mapping the distribution of galaxies is that on large scales it provides a clear 'window' back to conditions in the early universe. If the universe had started out perfectly smooth (apart from the random locations of atoms), it was long ago apparent that galaxies and clusters would not have formed by now; so there must have been some mechanism in the early universe causing the density to vary slightly from place to place. Gravity makes overdense regions pull in more matter from their surroundings, while matter is pulled out of underdense regions and they become more underdense, so the amplitude of these density fluctuations grows with time. On small scales, it is difficult to extract information about the initial fluctuations, because old stars in our Galaxy have made some 50 orbits in its lifetime, so any initial substructures have largely been smeared out over time. Likewise, a galaxy in a typical rich cluster has made around five orbits around the center of the

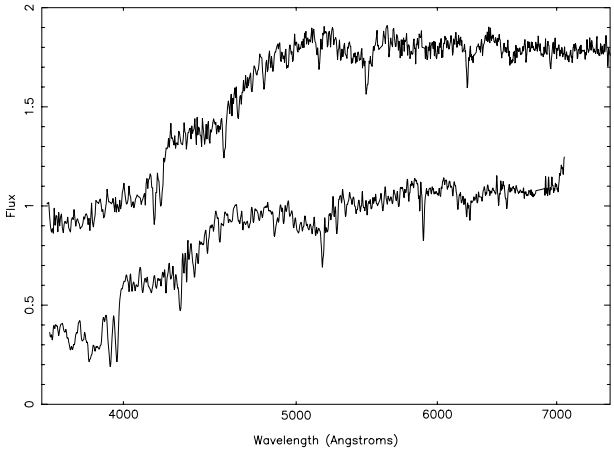

Figure 1. A typical (early-type) galaxy optical spectrum (upper line), with a spectrum of a similar galaxy at zero redshift (lower line). The redshift between spectral features is easily seen as the horizontal wavelength shift, in this case $z = 0.058$.

cluster. However, over the scales of superclusters (tens of megaPARSECS), galaxies have deviated from the pure Hubble expansion by only a fraction of a supercluster's size, so the character of the initial fluctuations is preserved; therefore, mapping the large-scale distrubution of galaxies gives us a clear view of density fluctuations in the early universe. Around 1980, the theory of INFLATION led to some fairly specific predictions about the nature of the initial density fluctuations; the precise way these grow with time depends on the amount and type of dark matter in the universe, so it was realized that the observed pattern of galaxy clustering today provides information about these unknowns.

Recent redshift surveys

Also in about 1980, advances in detector technology meant that a single galaxy redshift could be measured with a moderate-aperture optical telescope in tens of minutes instead of the few hours required with photographic plates, so it became feasible to map the three-dimensional galaxy distribution with surveys of large numbers of galaxy redshifts, notably the first Center for Astrophysics (CfA) survey of Davis and Huchra in 1982. For quantitative measurements, it is necessary for a survey to have well-defined selection criteria such as surveying all galaxies (or a random subsample) to a given apparent magnitude limit over a chosen region of sky. The observed density of galaxies in the survey then falls with redshift, since nearby all but the faintest galaxies are included, while at large distances only rare intrinsically bright galaxies are included; but this 'selection function' may be corrected for in the analysis.

Several important developments occurred from further surveys during the late 1980s, including the discovery that large VOIDS up to 50 Mpc in diameter with a galaxy density below 10% of the mean were quite common; and the discovery of substantial 'bulk flows' of galaxies towards a large supercluster in the constellations of Hydra–Centaurus, known as the Great Attractor. These surveys showed that superclustering is a ubiquitous phenomenon, and that the old picture of isolated clusters in a random 'sea' of field galaxies is not correct. Rather, the galaxy distribution has a sponge-like topology, with both high- and low-density regions forming an interconnected network, with high-density flattened 'walls' separating the voids; clusters are commonly located at the intersections of the walls.

The discovery of anisotropy in the COSMIC MICROWAVE BACKGROUND (CMB) by COBE in 1992 provided a major boost to the field, since the size of the COBE anisotropy was close to the predictions from theoretical models of structure formation 'matched' to the existing measurements of present-day galaxy clustering.

At the present time, the largest existing galaxy redshift surveys are as follows: the CfA-2 survey of Huchra and Geller, containing about 15 000 galaxies selected from photographic plates over most of the Northern hemisphere to a blue magnitude of about 15.5, giving a median depth around $90h^{-1}$ Mpc. This survey discovered a structure known as the 'Great Wall' spanning approximately $100h^{-1}$ Mpc across the northern sky, and containing the Coma cluster; an extension to the southern sky known as SSRS also showed wall-like structures.

The largest current 'all-sky' survey is the IRAS PSCz survey, which contains about 15 000 galaxies detected by the Infra-Red Astronomical Satellite (IRAS); this is a successor to earlier IRAS-based surveys such as the 'QDOT' and '1.2 Jansky' surveys. The PSCz survey consists of a sample of galaxies selected by far infrared brightness (above 0.6 J at 60 μm); these long wavelengths are almost immune to 'extinction' by dust in the plane of our Milky Way Galaxy, which limits the coverage of optical surveys. Also, the IRAS satellite scanned the whole sky, so the problem of matching ground-based northern and southern hemisphere catalogues does not arise. The downside is that IRAS preferentially selects star-forming late-type spiral galaxies; ellipticals contain little dust and so are intrinsically much fainter in the far infrared. The median depth of the PSCz survey is similar to CfA-2, but the average galaxy density is roughly $3\times$ lower so it provides a wider but sparser map of the galaxy distribution. The PSCz survey covers 84% of the whole sky, and so is the main source at present for comparison of the 'local' galaxy density with bulk flow measurements and our Local Group motion with respect to the CMB; the predicted direction of motion calculated from PSCz agrees within 15° of the measured Local Group motion.

The largest survey completed to date is the Las Campanas Redshift Survey: this contains 25 000 galaxies to a greater depth (a median redshift $z \approx 0.08$), covering three long thin 'slices' (about $90^\circ \times 1.5^\circ$) in each of the north and south Galactic hemispheres. This survey made use of the new technology of fiber-fed spectrograph (see SPECTROGRAPHS: FIBER-FED SPECTROGRAPHS), whereby spectra

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of many galaxies (in this case 128) can be obtained simultaneously by placing optical fibers at the known locations of galaxies in the focal plane of the telescope. The other ends of the fibers are then arranged in a line along the entrance slit of the spectrograph, and a two-dimensional detector is used (e.g. a CHARGE-COUPLED DEVICE (CCD)) to record all the spectra simultaneously. A small number of fibers are placed on 'blank' regions of sky so that the night-sky spectrum can be subtracted from the measured (galaxy+sky) spectra.

Statistics of galaxy clustering

Among the simplest statistics describing galaxy clustering is the two-point correlation function $\xi(r)$; given two small volumes of space $\mathrm{d}V_1, \mathrm{d}V_2$ separated by distance r, the probability of finding galaxies in both is defined to be $\mathrm{d}P = [1 + \xi(r)]\bar{n}^2\,\mathrm{d}V_1\,\mathrm{d}V_2$, where $\bar{n}$ is the mean galaxy density. Thus $\xi(r)$ may be thought of as the excess probability (relative to random) of finding a second galaxy at distance r from a randomly-chosen first galaxy. Observationally, it is found that $\xi(r)$ is well approximated by a power law

$$\xi(r) \approx \left(\frac{r}{r_0}\right)^{-1.8}$$

where $r_0 \approx 5h^{-1}$ Mpc is the correlation length. The fractional variance $\sigma^2(r)$ of galaxy counts (above shot-noise) in a randomly placed volume V is given by

$$\sigma^2(r) = \frac{1}{V^2}\int\!\!\int_V \xi(r_{12})\,\mathrm{d}V_1\,\mathrm{d}V_2$$

this is found to be approximately unity for spheres of radius $8h^{-1}$ Mpc. The correlation function and the power spectrum $P(k)$ form a Fourier-transform pair, i.e.

$$\xi(r) = \frac{1}{(2\pi)^3}\int P(\boldsymbol{k})\exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r})\,\mathrm{d}^3k$$

assuming statistical isotropy leads to

$$\xi(r) = \frac{1}{2\pi^2}\int_0^\infty k^2 P(k)\frac{\sin kr}{kr}\,\mathrm{d}k.$$

The importance of $P(k)$ is that if the initial density fluctuations formed a Gaussian random field (i.e. phases of different Fourier modes of the fluctuations were uncorrelated) as suggested by inflationary cosmologies, then $P(k)$, or equivalently $\xi(r)$, suffices to give a complete statistical description.

Many other statistics have been investigated (e.g. three-point and higher correlations, topology, probability distributions of counts in cells etc); the evidence at present is consistent with initially Gaussian fluctuations. While the present-day fluctuations are definitely non-Gaussian on small scales, the amount of this is approximately consistent with non-linear gravitational evolution from Gaussian initial conditions, as estimated from e.g. large N-body simulations.

In reality there are a number of complications to the above, notably biasing (i.e. the uncertain relationship between the distributions of galaxies and the underlying mass) and redshift-space distortions, whereby the galaxy peculiar velocities distort the mapping from real space to redshift space: clustering is smeared out by random motions on small scales, but on large scales it is enhanced because superclusters are expanding more slowly than the Hubble flow, so appear 'squashed' along the line-of-sight direction. The latter effect is marginally detected in current surveys, and can provide a measurement of the parameter $\beta \equiv \Omega^{0.6}/b$ where b is the bias parameter.

Surveys in progress

While the current surveys give us a good general picture of the galaxy distribution, they are still limited in statistical precision because they contain only a modest number (typically a few tens) of individual superclusters and voids. To obtain more precise statistical measurements, especially over the scales ∼50 Mpc which are currently being probed by degree-scale CMB experiments, larger surveys are very desirable. At the present time, there are two much larger surveys in progress: the 2 degree field (2dF) Galaxy Redshift Survey at the Anglo-Australian Telescope, and the Sloan Digital Sky Survey using a special-purpose 2.5 m telescope in New Mexico. The 2dF instrument consists of several components: a set of large corrector lenses giving a 2° diameter field, two sets of 400 optical fibers, and a robotic positioner. The positioner places the fibers with a positional accuracy of 30 μm using magnetic buttons on a metal plate, to correspond to the known positions of target galaxies, which are drawn from the APM Galaxy Survey based on scans of Schmidt plates. The positioner takes about 1 h to position a set of 400 fibers, so to avoid dead-time there are two sets of fibers, and the positioner is at work placing the 'next' set of fibers while the telescope is observing the 'current' set. Observations have been in progress since late 1997, and as of late 1999 redshifts have been measured for 77 000 galaxies and 7000 quasars (see figure 2); when complete at the end of 2001, the survey will contain redshifts of 250 000 galaxies and 20 000 quasars.

The Sloan Digital Sky Survey (SDSS), undertaken by a consortium of some 100 mainly US-based astronomers, aims to measure redshifts for 1 million galaxies and 100 000 quasars using a dedicated 2.5 m telescope in New Mexico. A novel feature of this project is that it will be making an imaging survey using CCDs in five optical passbands from ultraviolet (350 nm) to near-infrared 850 nm, using a very large camera containing 30 CCD detectors; this will be the first CCD survey to cover a substantial fraction (∼25%) of the entire sky. The target galaxies and quasars will be selected from this imaging survey and spectra taken using a fiber-optic spectrograph with 640 fibers over a 2.5° field of view. As of late 1999, the SDSS telescope and instruments are built and now starting a commissioning phase. It is planned to complete the survey in approximately 5 yr of observing.

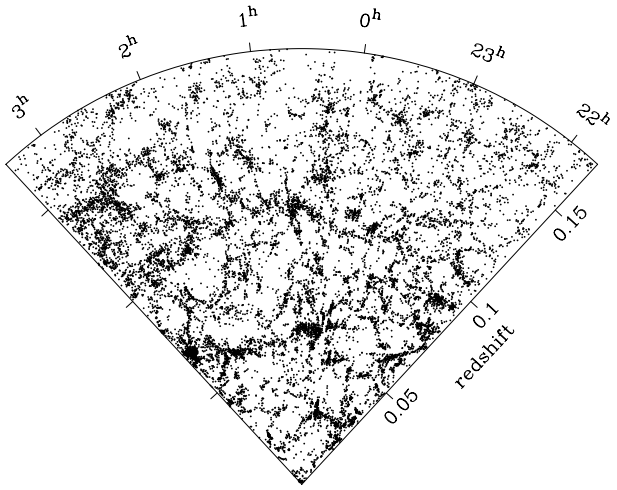

Figure 2. The distribution of 16 500 galaxies in a thin slice of the universe, comprising a mostly complete subregion of the 2dF Galaxy Redshift Survey. Our galaxy is located at the apex: the angular coordinate is right ascension, radial coordinate is redshift. This slice is 4° thick in the 'out-of-paper' (declination) direction. Numerous superclusters, sheets and voids are clearly visible.

For the relatively local universe, a new full-sky survey is planned based on the ongoing 2 Micron All Sky Survey (2MASS) infrared imaging survey. This will use a number of small telescopes in both hemispheres to obtain redshifts for the brightest 100 000 galaxies selected in the infrared K-band (2.2 μm). This K-band selection should combine the high sampling density of the optical surveys with the immunity to Galactic extinction of the IRAS surveys and will give a very detailed map of the local universe within 100 Mpc.

In addition, there are two surveys now planned which aim to study galaxy clustering when the universe was approximately half its present age: using multislit spectrographs on the new generation of 8 m telescopes, the VIRMOS survey on the ESO Very Large Telescope and the DEEP survey on the Keck telescope both aim to survey around 10 000 galaxies at a redshift of $z \sim 0.5$–1, to study the growth of structure over time.

Galaxy Structure

A very large body of information has been collected on the structure of the Galaxy. Here we can only concentrate on a small selection of the most recent and most important observational facts and theoretical findings. The MILKY WAY GALAXY belongs to the Local Group, a smaller group of three large and over 30 small galaxies, and is the second largest (after the Andromeda Galaxy M31) but perhaps the most massive member of this group. The Milky Way is most likely a BARRED SPIRAL GALAXY of Hubble type SBc. We are situated within the outer regions of its spiral disk, only about 14 ly above the equatorial symmetry plane but about 8 kpc or 26 400 ly from the Galactic Center (1 pc ~ 3.29 ly ~ $3 \times 9.5 \times 10^{12}$ km). The Milky Way forms a luminous band spanning all around the sky. This symmetry plane is also called the 'Galactic Equator'. In addition to the luminous stars there is also a dark band due to the obscuration of stellar light via gas and dust within the GALACTIC PLANE. The center of the Galaxy lies in the direction of the constellation Sagittarius, close to the border of both neighbor constellations Scorpius and Ophiuchus. The coordinates of the center (Rogers *et al* 1994) are $\alpha(2000) = 17^h\ 45^m\ 40.045^s \pm 0.010^s$ and $\delta(2000) = -29^o\ 00'\ 27.9'' \pm 0.2''$.

Main structural components

Since the Sun is located within the Milky Way disk it is exceedingly difficult to reliably determine its large-scale structure and dynamics, i.e. characteristics of the main components and the shape of the Galactic rotation curve.

The reason for that difficulty is mainly distance ambiguities and the location of the Sun within the Galactic obscuring dust layer. In summary the main structural components are the disk including the barred bulge with a central cusp, and most likely four spiral arms, a halo as well as a more extended corona including the Magellanic clouds and at least seven nearby dwarf galaxies and a large number of globular star clusters (see figure 1). The total mass of this central section of the Galaxy is (with separations from the center of $\leq$5 kpc) about 2×10^{11} solar masses ($M_\odot = 1.985 \times 10^{33}$ g). Here the molecular gas and dust as well as the youngest brightest stars of POPULATION I are located in a flat disk structure. The older population I stars form a less flattened distribution. This part of the Galaxy is surrounded by a probably ellipsoidally shaped halo of POPULATION II stars out to a radius of about 20 kpc. Population II stars are also found in the barred bulge of the Galaxy. The mass of this system is comparable with the mass in the inner section of the Milky Way. Within the halo the mass of the Galaxy amounts to about $4 \times 10^{11} M_\odot$ (Fich and Tremain 1991). The Galactic Halo may have been formed largely by accretion and tidal disruption of satellite systems. This is supported by numerous observational facts: the discovery of a retrograde rotating stellar group, patchiness in the kinematics of halo stars (Majewski *et al* 1996), and the discovery of an elongated dwarf galaxy in Sagittarius (Ibata *et al* 1994). In addition most of the Milky Way satellites appear to be located near two great circles in the sky (Lynden-Bell 1976). The corona extends out to approximately 100 kpc and may account for as much as $(3–6) \times 10^{12} M_\odot$ (Fich and Tremaine 1991). It exceeds by far the mass contained in the spiral disk and bulge region.

Main tracers of structure and dynamics

The entire solar system is orbiting the Galactic Center at a distance of ~8 kpc, on a nearly circular orbit. It is moving at about 250 km s^{-1} toward $\alpha = 21^h\ 12^m$, $\delta = +48^o$ 19'. Figure 2 shows a rotation curve derived from observations and consistent with model calculations. At this velocity it takes about 220 million years to complete one orbit. The Sun has orbited the Galactic Center about 20–21 times since its formation about 4.6 billion years ago.

There is still a controversy on the shape of the rotation curve of the Galaxy in the deep halo. The rotation velocity may ultimately decay as in accord with the Keplerian law at a distance of 50 kpc. However, measurements indicate that the rotation curve of the Milky Way essentially stays flat. It actually may even still increase at the distance of the MAGELLANIC CLOUDS and the MAGELLANIC STREAM. Murai (1997) has clarified, on the basis of recent observational data on the spatial location of the LMC, SMC and the Magellanic Stream and their radial velocity distribution, that the halo of the Galaxy has a huge dark matter component that results in a flat rotation curve with a terminal velocity of the order of 250 km s^{-1}. However, for the spiral arms found outside the corotation of the bar, the dark halo may very well have some effect. In model calculations that include a halo component (e.g. Englmaier and Gerhard 1999; see below) resulting in a flat rotation curve, the halo contribution to the radial force at the solar circle is 23%.

The main tracers of the Milky Way structure are the stars and the line emission of the molecular (mostly traced via the line emission of the ^{12}CO $J = 1–0$ rotational transition at 2.6 mm) and atomic (traced via the 21 cm hyperfine-structure transition of atomic hydrogen—H I) gas in the disk. Through data from the Hipparcos astrometry satellite great progress has been made in understanding the stellar distribution and kinematics (e.g. Creze *et al* 1998; Bienaymé 1999). The stellar structure of the Milky Way can be investigated much better in the infrared light than in the optical, since the extinction is lower than in the visible light. The COBE satellite has provided an infrared image of the Milky Way's central region. The near-infrared (NIR) is a particularly

advantageous wavelength window for observing the distribution of old, evolved stars in the Galactic disk and bulge. These stars are important because they are tracers of the overall stellar mass distribution. At shorter wavelengths extinction is a serious problem, and at longer wavelengths the flux starts to be dominated by dust emission. As determined from NIR 2.4 μm mapping of the stellar continuum emission (Kent *et al* 1991) the radial surface brightness profile of the disk has an exponential scale length of about 3.0 kpc. In the solar neighborhood, the scale height is about 250 pc and with increasing radius it decreases to about 160 pc at a distance of 5 kpc from the center. This is in agreement with star counts perpendicular to the Galactic plane.

The bar

In the last few years, independent evidence points to the existence of a bar in the inner Galaxy. This evidence results from NIR photometry (Blitz and Spergel 1991; Weiland *et al* 1994; Dwek *et al* 1995), from IRAS source counts (Nakada *et al* 1991; Whitelock and Catchpole 1992; Nikolaev and Weinberg 1997; Stanek *et al* 1997), as well as from the large microlensing optical depth towards the bulge (Paczynski *et al* 1994; Zhao *et al* 1996) and possibly also from stellar kinematics (Zhao *et al* 1994). This evidence is summarized in recent reviews, e.g. Gerhard (1996) and Kuijken (1996).

The best current models for the distribution of old stars in the inner Galaxy are based on the NIR data from the DIRBE experiment on COBE. The gravitational potential of the stars can then be connected with the available gas and stellar kinematic observations in order to study the large-scale structure and dynamics of the Milky Way Galaxy.

Since even at a wavelength of 2 μm the extinction towards the Galactic nuclear bulge is important, the DIRBE data has to be corrected for the effects of extinction. Spergel *et al* (1996) use a three-dimensional model of the dust distribution to clean the data. These data have then been used by Binney *et al* (1997) to fit a non-parametric model of the NIR emission under the assumption of eight-fold (triaxial) symmetry with respect to three orthogonal planes. The best fits to the photometry are obtained when the Sun is assumed to lie ~14±4 pc above the plane. For a fixed geometry the recovered emissivity is essentially unique (Binney and Gerhard 1996; Bissantz *et al* 1997). However, matching physical models are possible over the full range of likely bar orientation angles ϕ. This angle is defined as the angle in the Galactic plane between the major axis of the bar at $l > 0^\circ$ and the Sun–center line. It covers a range from 15º to 35º. Using the most favored angle of $\phi = 20^\circ$, the deprojected luminosity distribution shows an elongated bulge with axis ratios 10:6:4 and semimajor axis of ~2 kpc, surrounded by an elliptical disk extending up to ~3.5 kpc on the major axis and ~2 kpc on the minor axis. Figure 3 shows a comparison between the 3.4 μm flux density distribution as measured by the COBE satellite (full contours) and a model (dashed contours; Binney *et al* 1997) that assumes a bar angle to the line of sight of $\phi = 20^\circ$. The asymmetry of the highest contours is a clear indication for the presence of a bar as seen from the position of the Sun within the Galactic plane. The enhanced flux at positive Galactic longitudes indicates the location of the tip of the bar that is closest to us.

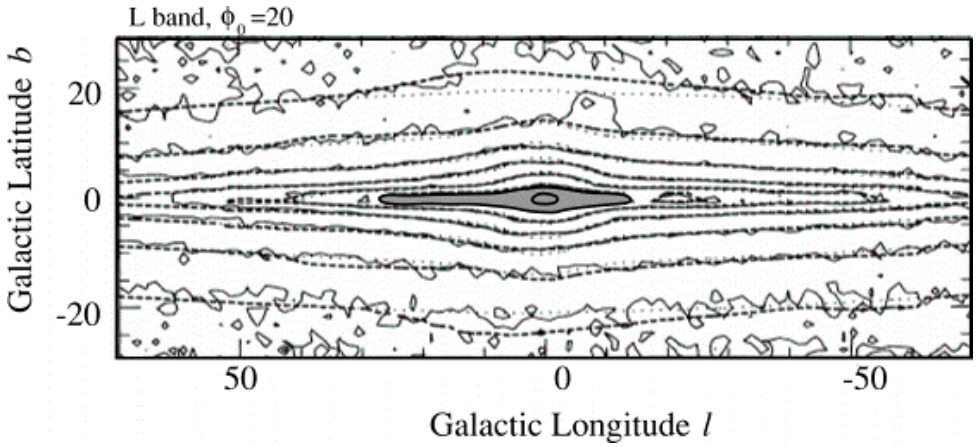

Figure 3. A comparison between the dust-corrected 3.4 μm flux density distribution as obtained by the COBE satellite (full contours, see also Arendt *et al* 1994) and a model (dashed contours; Binney *et al* 1997). In order to demonstrate that the Galaxy is not axisymmetric we filled in the top two contour lines.

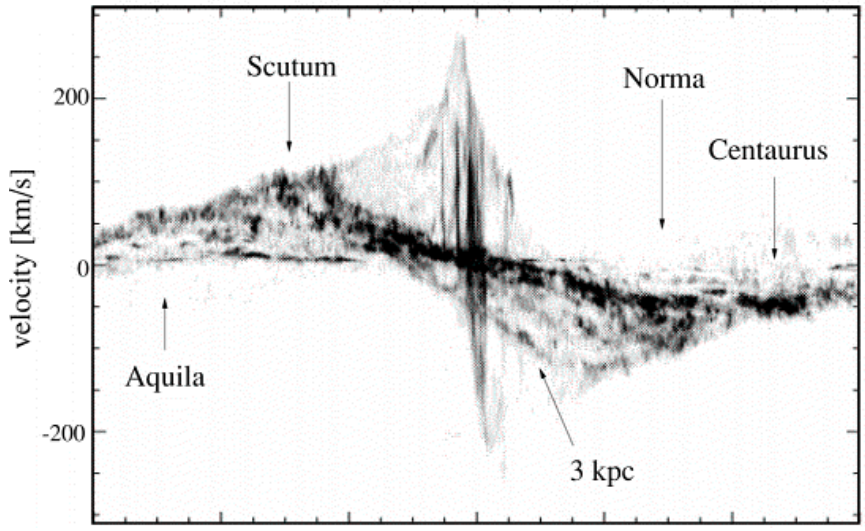

Figure 4. Galactic longitude velocity diagram of the ^{12}CO line emission as a function of Galactic longitude and velocity integrated over latitudes between $b = \pm 2^{\circ}$ (Dame *et al* 2000). The directions of some arm tangents have been indicated. Comparison with figure 5 shows where the spiral arms are located within the Galactic disk.

In all models there is a local density minimum ~2.2 kpc down the minor axis. The subsequent maximum ~3 kpc down the minor axis may be associated with the Lagrange point L_4. The identification of this point as well as the length of the bar are consistent with a bar pattern speed of $\Omega_b \sim 60$–70 km s^{-1} kpc^{-1} (Binney *et al* 1997). Model calculations assuming an eight-fold or four-fold symmetry for the disk spiral structure indicate that the deprojected intensity distributions recovered from the cleaned COBE data could reflect spiral structure within the Milky Way with density contrasts greater than ≥3 in the NIR.

The spiral structure

The SPIRAL ARMS can be traced by the distribution of atomic and molecular gas as well as the distribution of young bright stars and the emission line nebulae. The corresponding directions and distances with respect to the Sun can then be used to map out the local spiral structure. Figure 4 shows the distribution of the ^{12}CO line emission as a function of Galactic longitude and velocity integrated over latitudes between $b = \pm 2^{\circ}$.

The spiral arms manifest themselves via an increase in projected density of brightness of the corresponding tracers especially when the line of sight is tangential to

the spiral arm. This technique was first applied to H I data (e.g. Kerr and Westerhout 1964) and has thereby led to a first picture of the distribution of atomic gas and a first indication of a spiral structure in the Galaxy. More recent modern H I surveys of the Galactic disk (e.g. Stark *et al* 1992; Burton 1985) primarily aim at high sensitivity, low contamination due to side lobes of the antenna beam and a large velocity coverage in order to trace the high-velocity H I gas located towards the center of the Galaxy and in individual clouds in and above the plane. Spiral arms are named after the constellations in which they are most prominent. The results indicate that the Sun lies near the inner edge of the so-called ORION ARM (see figure 5). The Perseus arm is located about 2 kpc beyond the Sun and the Aquila and Carina arm sections are approximately located at a distance from the Sun of 2 kpc towards the Galactic Center (see figure 5). From the study of H II regions, molecular clouds and the Galactic magnetic field it appears that the Milky Way may have four main spiral arms (Georgelin and Georgelin 1976; Caswell and Heynes 1987; Sanders *et al* 1985; Grabelsky *et al* 1988; Vallée 1995).

Dame *et al* (1987, 1999) have combined large-scale surveys of the ^{12}CO(1–0) integrated line intensity of the entire Galactic plane and specific nearby clouds to produce a panorama of the entire Milky Way in molecular gas at an angular resolution of ½º. Their compilation exhibits a sky coverage and resolution which are comparable with those of early 21 cm surveys. A comparison with other population I tracers demonstrates that the currently available CO surveys probably provide an almost complete inventory of nearby molecular clouds. The ^{12}CO(1–0) line, however, traces in most cases the $\tau = 1.0$ surfaces of optically thick molecular gas. A much better census of the amount of molecular gas can be obtained via the optically thinner ^{13}CO(1–0) line. Stark (1987) presents a Galactic survey of 47 000 positions observed in the ^{13}CO(1–0) line emission. The data show a clear presence of voids in the molecular gas disk of the Milky Way. These regions contain many times fewer giant molecular clouds (GMCs) than do adjacent regions of similar size. This is interpreted as a signature of a spiral structure. The difference between the arm and interarm regions in the inner Galaxy is only clearly visible in the distribution of GMCs. Small molecular gas clouds are present throughout the disk. It is possible that GMCs are formed as interstellar gas enters a spiral arm and that they break up into small molecular or atomic clouds when the gas leaves the arm. The molecular gas disk is flatter than the atomic gas disk. The Gaussian scale height (i.e. thickness perpendicular to the plane) at the solar circle within 1 kpc is ~74 pc (Dame *et al* 1987). The H I atomic gas scale height is ~100 pc at 3 and ~220 pc at 9 kpc distance from the center (Malhotra 1995).

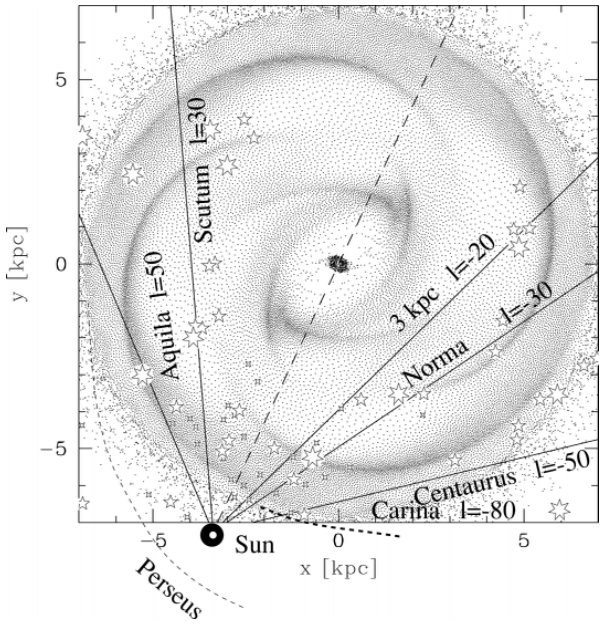

Figure 5. The gas flow in the Galactic disk under the influence of the barred bulge with a bar angle $\phi = 20º$, corotation radius at ~3.1 kpc as well as a dark halo component (Englmaier and Gerhard 1999). The location of the Sun is shown at $x = -2.7$ kpc and $y = -7.5$ kpc just outside the frame. The directions of some arm tangents and the corresponding approximate galactic longitudes have been indicated. The Orion arm is possibly a connection between the Aquila and Perseus arm in the vicinity of the Sun. The image is a result of hydrodynamical two-dimensional modeling using 20 000 particles in a smoothed particles hydrodynamics (SPH) code described in Englmaier and Gerhard (1997). The barred bulge has a size and orientation (4 × 2.4 kpc) which is almost identical to the central region void of particles.

The currently best model of Englmaier and Gerhard (1997) provides a coherent interpretation of most of the observed gas dynamical features. The four-armed spiral structure outside corotation reproduces quantitatively the five main spiral arm tangents at $l \leq 60º$ that are observed in several tracers. In this model the observed 3 kpc arm is part of a spiral arm structure that starts at the ends of the bar and extends into the corotation region. Orbits along the bar are called x1 orbits. They allow transitions to the inner x2 orbits perpendicular to the bar (Contopoulos and Papayannopoulos 1980). This model exhibits an inner gas disk with a cusped orbit shock transition to an x2 orbit disk of radius $R \sim 150$ pc (see inner portion of figure 5). The corotation radius of the bar is fairly well constrained at $R \sim 3.5 \pm 0.5$ kpc. The Galactic terminal velocity curve from H I and CO observations out to $l \pm 45º$ (~5 kpc) is approximately described by a maximal disk model with constant mass-to-light ratio for the NIR bulge and disk.

The center of the Galaxy

At a distance of only 8 kpc the Galactic Center is the closest nucleus of a galaxy, 100–1000 times closer than

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the nearest extragalactic systems. It is thus a unique laboratory in which physical processes that are also relevant for nuclei of other galaxies can be studied with the highest angular resolution possible. The gas and dust on the line of sight to the center, however, make it impossible to observe it at optical or UV wavelengths. It is only accessible in the radio, infrared and x-ray domain. The optical extinction amounts to 30 magnitudes (A_V = 30^m) or an attenuation of visible light by a factor of 10^{-12}. This corresponds in the NIR *K* band at a wavelength of 2.2 μm to an extinction of only $A_K = 3.3^m$.

The central stellar cluster

Catchpole *et al* (1990) showed from NIR star counts that the density distribution of stars near the Galactic Center can be modeled as a power law r^{-p} with $p \sim 2.2 \pm 0.2$ for $K = 6^m$–8^m stars. This is similar to the value of $p \sim 2.0 \pm 0.2$ derived from the distribution of OH/IR stars near the center (Lindqvist *et al* 1992). Using radial velocities of the OH–IR stars and the assumption of isotropy, Lindqvist *et al* determined the mass distribution inside ~100 pc. The corresponding mass density profile has $p \sim$ 1.5 between ~20 and ~100 pc and steepens inside ~20 pc. The overall slope is in approximate agreement with the value of $p \sim 1.8$ originally found by Becklin and Neugebauer (1968). Because of the limited resolution the central cusp cannot be recovered from the DIRBE NIR data and has to be re-introduced to model the dynamics. The total mass, however, is small compared with the mass of the barred bulge. Inside the central parsec of the Galaxy the stellar number density counts show that all the ~ 600 stars in the central stellar cluster brighter than 16^m at 2.2 μm can be described very well by the number density distribution expected for an isothermal stellar cluster with a core radius of approximately 0.2–0.3 pc (Eckart *et al* 1993, Eckart and Genzel 1996).

Phenomena within the central few parsecs

The central few parsecs of the Milky Way is a region full of interesting phenomena (figure 6). A circumnuclear disk or ring consisting of a system of orbiting molecular filaments at a distance of 1.5–5 pc is connected to a dense central stellar cluster via several ridges, filaments and streamers of gas and dust that form the so-called 'mini spiral' close to the central compact (see above) stellar cluster that connects on large-scale NIR images visually to the stellar bulge and disk population at approximately the radius of the circumnuclear ring.

The circumnuclear disk is probably fed by gas infall from dense molecular clouds at distances larger than 10 pc from the center. The mini spiral represents the brightest part of the thermal radio source Sgr A (West). The central 1.5 pc is comparatively devoid of interstellar matter and is referred to as the central cavity. Right at the center of the stellar cluster there is located a compact radio source Sagittarius A* (Sgr A*) with a radio

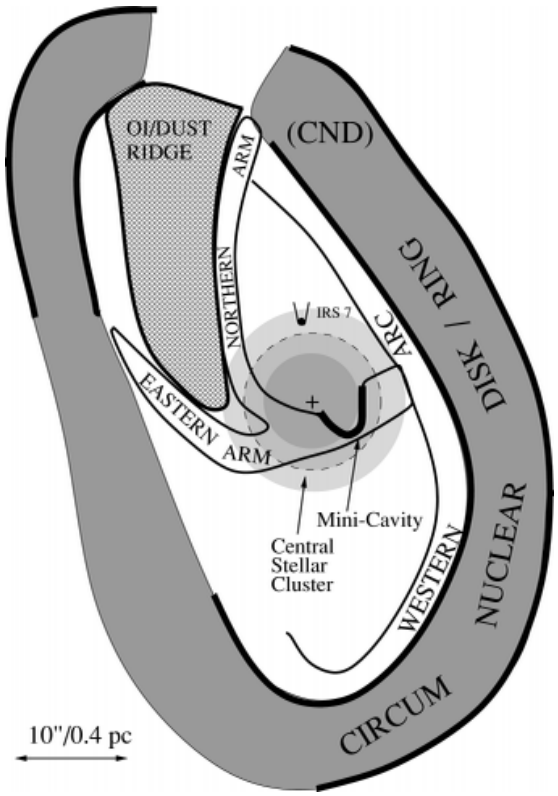

Figure 6. Schematic picture of the different structures in the Galactic Center. The 'mini spiral' arms—the eastern and northern arm as well as the 'bar'—connect the central stellar cluster region with the circumnuclear gas ring (after Genzel *et al* 1994). The brightest star at 2 μm wavelength, IRS 7 (infrared source), has been labeled. The position of the compact radio source Sgr A* is also indicated as a cross.

luminosity of ~2×10^{34} erg s^{-1}, corresponding to a flux density of 1.1 Jy at λ = 2 cm, and a size of less than 2.4×10^{13} cm (Rogers *et al* 1994; Krichbaum *et al* 1994). This source is the most likely candidate for a possible massive black hole at the center of our Galaxy (e.g. Rees 1984, Genzel and Townes 1987; Lo 1989). Along the arms of the mini spiral gas and dust are orbiting about the center where they interact with the intense nuclear wind originating from the central cluster of very massive and luminous stars. Recent subarcsecond angular resolution line imaging (Eckart *et al* 1995; Tamblyn *et al* 1996) and integral field spectroscopy (Krabbe *et al* 1995; Genzel *et al* 1996) have shown that several of the brightest members of the central cluster—the so-called IRS16 complex—are He I emission line stars. These objects show in their spectra prominent broad He I and H I recombination lines in emission. From non-LTE stellar atmosphere modeling of the observed emission characteristics of several of the He I stars Najarro *et al* (1994, 1997) have inferred that these objects are moderately hot (17 000–30 000 K), very luminous ((1–30) × $10^5 L_\odot$) massive stars whose helium-rich surface

layers are expanding as powerful stellar winds with velocities of 200–800 km s^{-1} and mass loss rates of (1–70) × $10^{-5} M_{\odot}$ yr^{-1}. These stars have formed within the last few million years and provide the dominant fraction of the total luminosity of the central parsec. Imaging spectroscopy with the integral field imaging spectrometer shows that within the central 0.3–0.4 pc of the stellar cluster bright late-type stars (supergiants and the brightest AGB stars) are absent but that the core is surrounded by a ring of red supergiants–AGB stars showing strong CO band head absorptions in their NIR spectra (Genzel *et al* 1996; see also earlier work by Sellgren *et al* 1990; Haller *et al* 1996).

The central black hole

The gas and stellar velocities increase toward the position of Sgr A* indicating the presence of a large compact mass. The evidence for a dark central mass of (1–3) × $10^{6} M_{\odot}$ in the Galactic Center has been steadily growing over the last two decades from observations of RADIAL VELOCITIES of gas and stars (Lacy *et al* 1980; Serabyn and Lacy 1985; Genzel *et al* 1985; Sellgren *et al* 1990; Krabbe *et al* 1995; Haller *et al* 1996; Genzel *et al* 1996). A reliable estimate of the enclosed mass and its compactness, however, can only be made if the full velocity field (radial and transverse components) is known. Furthermore, stars as tracers of the velocity field are much more reliable than gas, since they are not influenced by magnetic pressure or frictional forces. Using stars as tracers of the gravitational potential therefore allows us to measure the mass content and mass concentration within the central parsec of our Galaxy. Recent review articles on the phenomena and physical properties of the Galactic Center are Genzel *et al* (1994), Blitz *et al* (1993), Mezger *et al* (1996) and Morris and Serabyn (1996).

The stellar PROPER MOTION (Eckart and Genzel 1996; Ghez *et al* 1998) and radial velocity dispersions (Genzel *et al* 1996) are in very good agreement, indicating that the stellar velocity field is on average close to isotropic. Comparing individual images from different observing epochs one finds within the central arcsecond (0.04 pc) several fast-moving stars with velocities in excess of 1000 km s^{-1} in the immediate vicinity (0.01 pc) of Sgr A*. From the stellar radial and proper motion data, one can infer that a dark mass of (2.61±0.35) × $10^{6} M_{\odot}$ must reside within about a light week of the compact radio source. Its density must be 2.2 × $10^{12} M_{\odot}$ pc^{-3} or greater. There is no stable configuration of normal stars, stellar remnants (neutron stars or stellar black holes) or substellar entities that can account for the combination of both the high mass and the high mass density. The combination of these data—especially the proper motion measurements of the stars in the central arcsecond—now provides compelling evidence for a massive BLACK HOLE at the core of the Milky Way.

In 2001 the Chandra X-ray telescope observed a flare of X-ray energy produced from where the lip of a supermassive black hole at the center of the Milky Way Galaxy should be. The flare dimmed and brightened over a period of ten minutes, the time taken for light to travel about 150 million kilometers, meaning that it originated from an object no larger in diameter than the distance of the Earth to the Sun. This implies that the mass at the center of our Galaxy (about 2.6 million times the mass of our Sun) is crammed into that space. According to the laws of general relativity, only a black hole can be that dense.

Galilean Telescope

A refracting telescope that uses a long focal length converging lens and a short-focus diverging lens to produce a magnified image of a distant object. Named after the Italian scientist Galileo Galilei (1564–1642), who designed and built a telescope of this type in 1609, the Galilean refractor produces an upright image but suffers from having a very small field of view. This particular optical system is still used in opera glasses because the design is compact.

See also: eyepiece, objective lens, refractor, telescope.

Galileo Galilei

Galileo Galilei (1564–1642) is one of the most significant figures in the long history of astronomy. Within a short two years (1609–11), the telescopes he fashioned revealed details of the Sun, Moon and planets that announced the end of ancient astronomy and the direction of the new. The success of the telescope heralded a new era for natural philosophy generally, when it would no longer be constrained by the limitations of the human senses.

Life and works

Born near Pisa, Galileo enrolled in medicine at the University of Pisa in 1581. His interests soon turned to mathematics. When he left the university without a degree in 1585, he began an intense study of mathematics and natural philosophy to prepare himself for a university position. Appointed to the chair of mathematics in Pisa in 1589, he composed a treatise (left unpublished), *De motu*, in which he questioned, on largely conceptual grounds, some of the most distinctive features of the Aristotelian account of motion. In 1592, he was appointed to the chair of mathematics at the University of Padua. There he lectured on, among other things, the application of spherical geometry to planetary astronomy, and busied himself with the design of instruments for practical use in surveying and gunnery, as well as for facilitating rapid numerical calculation.

In a letter of thanks to KEPLER (1597) on receipt of the latter's newly published *Mysterium Cosmographicum*, he associates himself with the Copernican views defended in this work, claiming that these views had already enabled him to explain 'many physical effects' (probably alluding to the tides) but that he had hesitated to publish for fear of public ridicule. Historians are still divided as to whether he really *was* committed to the COPERNICAN SYSTEM at so early a date. In 1604, a new star was observed in Sagittarius, challenging the Aristotelian doctrine of the unchangeability of the heavenly bodies. Already critical of Aristotelian views on motion, Galileo offered three public lectures on the NOVA, his first venture in astronomy. He seems to have concentrated on explaining how the star's lack of parallax implies its great distance from Earth and hence the changeability of the non-terrestrial region. His energies at this time were, however, mainly devoted to mechanics.

In 1609, a chance event diverted him from his researches in mechanics for what would become a 25 year interval. When he heard about a spyglass invented in Holland that made distant objects seem near, he immediately grasped its potentialities for the furtherance of his own career. How much about its mode of construction he learnt from others and how much he worked out for himself is not quite clear. What *is* clear, however, is that his tested skill in instrument-making gave him an advantage over his competitors and a lead in telescope-making that he maintained over the crucial two-year period (1609–11) within which all the major astronomical discoveries within the reach of a telescope of this type were made by him (see GALILEAN TELESCOPE). By August 1609 he could present the Doge of Venice with a roughly 9x telescope. Impressed by the military and commercial potential of the '*perspicillum*', a grateful Venetian Senate promised to double his salary.

However, Galileo saw even greater potential for himself elsewhere. By January 1610 he had constructed a 20x instrument and had discovered Earth-like irregularities on the Moon, four satellites orbiting Jupiter, and stars beyond numbering that were invisible to the naked eye. Later in 1610 came moving sunspots, the phases of Venus and the oddly changing shape of Saturn. Galileo rushed his first discoveries into print, dedicating the *Sidereus Nuncius* (*Sidereal Messenger*) to his former pupil, now Cosimo II, Grand Duke of Tuscany, and dubbing Jupiter's moons the 'Medicean' planets. These shrewd gestures gained him the position he had long coveted as Mathematician and Philosopher to the Grand Duke. His little book caused an instant sensation and made him Europe's most famous astronomer.

Other works quickly followed. His *Discourse on Bodies in Water* (1612) listed his newest astronomical discoveries, notably the periods of Jupiter's satellites, his most considerable contribution to calculational astronomy. His *Letters on Sunspots* (1613) mocked the views of the Jesuit astronomer, Christopher Scheiner, who represented sunspots as clouds circling the (still unchanging) Sun. But trouble was brewing in another quarter. The new discoveries might refute the Aristotelian claim that the Earth is the immobile center of rotation of the planets. But what of the passages in Scripture that describe the Sun as in motion or the Earth as immovable? Aristotelians could and did call theological witness in their support. Galileo immediately grasped the challenge that this could offer to the Copernican system, of whose truth he was now convinced. In a letter to Benedetto Castelli (1613) and a much longer treatise, the *Letter to the Grand Duchess Christina* (1615), formally addressed to his patron's mother, he laid out in persuasive fashion the hermeneutic principles that ought to guide the interpretation of Scripture when a literal reading opposed a finding of 'sense or necessary demonstration'. But it was to no avail. In February 1616, the Roman Congregation of the Index banned Copernicus' *De Revolutionibus* 'until it be corrected', declaring the Copernican theses regarding the Earth's motion and the Sun's rest to be 'contrary to Scripture'. Cardinal Robert Bellarmine, the leading theologian of the Congregation of the Holy Office, was instructed to inform Galileo officially that the Copernican doctrine was not to be held or defended; if he proved resistant, he was to be given a personal injunction not even to discuss the forbidden view. Whether this injunction was delivered, and if so under what circumstances, has been a matter of debate since the Holy Office file on Galileo was made public more than a century ago.

What motivated the Cardinal-members of the Holy Office was not the defence of an ancient and theologically

comfortable Earth-centered cosmology. In their eyes, what was at stake was the authority of Scripture. This was, after all, the time when tensions between Reformers and the theologians of the Counter-Reformation were at their most intense. And the issue that most clearly divided the two sides was the proper interpretation of the Bible. Here was Galileo proposing his own non-literal interpretation of literal-sounding Scriptural passages, and unable to offer a demonstration for the conflicting Copernican claims, the only condition under which the Roman theologians would have been prepared to concede the propriety of a non-literal approach to the disputed passages.

Their error, as we would see it today, was not primarily scientific. It was in the first instance theological, in that their principles of Scriptural interpretation were at fault; they would have done well to heed Galileo's reminder of an older and more sophisticated set of principles going back to St Augustine. Their error was also philosophical in that they, and indeed Galileo himself, assumed that a claim about the natural world had to be demonstrated in order to count as properly scientific. Both errors are understandable in the theological and philosophical contexts of the day. But they were to have far-reaching consequences. What would be needed was a return to the more liberal canons of Scriptural interpretation favored by Augustine and a better understanding of the limits of theory-proof in natural science. Both would be slow in coming.

Forced to abandon his plans for a Copernican treatise, Galileo turned in 1618 to the problem of the nature of comets. Three bright comets appeared in that year, setting off a flurry of speculation. TYCHO BRAHE had carefully tracked the comet of 1577 and had concluded that it lay far beyond the Moon, that it was orbiting the Sun not the Earth, and that its motion was either non-uniform and circular or else perhaps oval. Galileo published the *Discourse on the Comets* (1619) under the name of his friend, Mario Guiducci, claiming that Tycho's parallax arguments would work only if the comet were a physical body, not if (as Galileo himself maintained) they were no more than reflections of sunlight from vapors of earthly origin lying beyond the moon. He criticizes Tycho for suggesting non-circular orbits and non-uniform motions, but has to admit that his own theory does not square with the mass of observational reports. Another target of the *Discourse* is Orazio Grassi, a Jesuit natural philosopher, who responded vigorously to the attack and to whom Galileo replied in devastating style with *The Assayer* (1623). The book was quickly recognized as a literary masterpiece. It is also significant for the exposition it gives of Galileo's own natural philosophy: the Book of Nature is written in the language of mathematics, the qualitative properties of material objects are merely subjective products of human sensation, and matter is composed of minute corpuscles in motion. His treatment of comets, however, the topic that had occasioned the book in the first place, is sprinkled with inconsistencies, his least successful venture in astronomy.

In 1623, Cardinal Maffeo Barberini, an avowed admirer of Galileo's work, was elected Pope, as Urban VIII. Galileo, encouraged, asked permission to resume work on his Copernican treatise. Urban allowed him to proceed, with the proviso that the treatment be hypothetical. The two men appear to have understood this restriction in very different ways. Galileo evidently took it to mean that he could make the best case possible for the Copernican hypothesis. Urban wanted to ensure that an explanation of observed effects in terms of causes not themselves observed would not be presented as demonstrative; to do so would, in his view, challenge Divine omnipotence. (This type of objection is traceable to the nominalist critics of Aristotle in the fourteenth century.) God could, after all, have brought about the same effects by means of other hidden causes. Urban may also have had in mind the status traditionally assigned to 'mathematical' astronomy, its goal merely to 'save the phenomena' (describe the observed planetary positions correctly), whereas for true causes one has to turn to 'physical' astronomy.

Galileo's Copernican treatise gradually took shape, delayed by his recurrent ill-health as well as by the complexity of the rhetorical task he faced. Urban's directive meant that he could not claim to demonstrate the Earth's motion, yet he could hardly forget that, according to the theologian-critics of Copernicanism in 1616, the literal interpretation of the debated passages in Scripture had to take priority if the 'scientific' claim fell short of demonstration. There were lengthy negotiations with the censors in Rome and Florence, but eventually the *Dialogue on Two Chief World Systems* made its appearance in 1632. Almost immediately an outcry began among Roman theologians who had not forgotten the prohibition implicit in the 1616 decree: the *Dialogue* clearly *did* defend the proscribed view. But Urban's reaction was more personal; in his eyes Galileo had betrayed the trust placed in him. A commission of inquiry referred the case to the Holy Office; Galileo was summoned to Rome and put on trial in early 1632.

Galileo could claim that his book had, after all, received the censors' approval. But against this, the investigative judge could argue that the censors had not been told about the personal injunction given him in 1616 not even to discuss Copernicanism. Against this in turn, Galileo could introduce in evidence a letter from Bellarmine that seemed to call in question whether in fact a personal injunction of that severity *had* in fact been given him. The depositions continued; Galileo argued, although implausibly, that his book did not really urge the superiority of the Copernican view. Finally, a plea-bargain was struck; Galileo agreed to abjure publicly the prohibited claims of the Earth's motion and the Sun's rest and was sentenced to prison, the sentence promptly commuted to house-arrest.

Back finally at home, he returned to the long-interrupted manuscript on mechanics. In 1638, the *Two New Sciences* was published in Holland. Here he laid out the two laws of fall that were to become the foundation

of modern mechanics, following a method that appealed to experience yet also sought the certainty of geometrical demonstration. It came as final affirmation for one who in his later years had known more than his share of tragedy.

Telescopic discoveries

Galileo's contributions to astronomy were of two very different kinds. First were the stunning observational discoveries of 1609–11. These did not involve the calculational feats of his great predecessors, Ptolemy, Copernicus and Kepler. Galileo was fortunate to be the first to be enabled to see in the heavens what no one before him had seen; what made him a great astronomer was his ability to grasp the significance for cosmology of what he saw. Second was his furtherance of the case for the Copernican system. He did more than any other single person to bring about the displacement of the Earth from its privileged place at the cosmic center with the vast shift in world view that followed.

His lunar observations, vividly chronicled in the *Sidereus Nuncius*, made the greatest impact, perhaps, on the general public. Patches of light and shadow could now be plausibly identified as Earth-like features. Prominent among them were what seemed to be lunar mountains, whose peaks could be seen as spots of light at lunar dawn while the lowlands below them remained in shadow. And the mountains' own shadows shortened as the lunar noon approached, just as one would expect. Further, the faint illumination of the dark part of the Moon's face could best be understood as 'earthlight', sunlight reflected from Earth, at its brightest when the Moon lies between Earth and Sun so that the 'full Earth' is shining on it; Earth and Moon thus reflect sunlight in the same way.

The discovery that four satellites circled Jupiter showed that, contrary to ARISTOTLE's doctrine of natural motion, there is more than one center of rotation in the planetary system. It also eliminated an objection to the Copernican claim that the Earth carried its Moon along as it circled the Sun. Galileo took a great deal of trouble with the difficult problem of computing the periods and the times of occultation by Jupiter of each of the four satellites (see JUPITER: SATELLITES). He hoped that it would allow the compilation of tables of occultation times at a reference base like Florence, constituting a celestial 'clock' sufficiently accurate for the calculation of longitude for ships at sea, a crucial need for navigators on the long sea voyages then becoming common. The practical difficulties involved in making the requisite observations while at sea defeated his plans, but this method of measuring longitude came to be relied on by mapmakers later in the century.

The phases of VENUS from crescent to full and back again became Galileo's most potent argument against the older cosmology. If Venus and the Sun both orbit the Earth, with Venus below the Sun, Venus should always show a crescent shape to Earth, if illuminated by the Sun. If, however, Venus and Earth both orbit the Sun, Venus should run through the same sequence of phases as does our own moon. And this Galileo observed it to do, enough to undermine the Aristotelian–Ptolemaic world system irreparably. The appearances of Venus were, however, compatible with the TYCHONIC SYSTEM which had the Sun orbit the unmoving Earth carrying the entire planetary system with it, a major reason why astronomers who were unwilling, for physical or theological reasons, to embrace the Copernican system, preferred the Tychonic alternative.

Galileo saw the SUNSPOTS as something like terrestrial clouds, close to or on the Sun's surface and constantly changing in shape. Their rotation testified to a solar rotation taking about a month. Here again, the warrant for his hypothesis, suggested by familiar terrestrial analogy, was the observable consequences that could be drawn from it. In the *Dialogue*, he made use of the observed shapes of the sunspot paths to argue that these shapes would follow naturally if the annual motion of the Earth be granted, whereas they would demand an implausible combination of four motions on the Sun's part if the Earth's motion be denied.

These discoveries brought to the fore an issue for which the methodology of Aristotelian science was ill-prepared. How are the natures of distant and unfamiliar objects to be discovered? The intuitive grasp of necessary relations between essence and property on which Aristotle's account depended required a direct familiarity with the natures themselves. But with sunspots, comets and the like, one had to resort, instead, to the imagination and test the resultant construct by the observable consequences drawn from it. Galileo's treatment of the hypothetical analogy between the lunar and terrestrial surfaces offers a particularly elegant example of this sort of retroductive reasoning from effect to cause that relies for its warrant on explanatory success, rather than on deductive derivation from intuitively warranted principle. Galileo never explicitly acknowledged this shift, one with far-reaching consequences for later science.

Arguing for the Copernican system

The *Dialogue on Two Chief World Systems* is a masterpiece of intricately interlocking argument in support of the Copernican system. Galileo had to deal first with the Aristotelian arguments against the Earth's motion. This would require a new mechanics; indeed, some have claimed that such a goal may have prompted his groundbreaking early work on motion. He had to challenge Aristotle's way of distinguishing motions into natural and violent; the EARTH'S ROTATION could be neither. Against the objection that the motion of the Earth, if real, should be perceivable, he had to claim the imperceptibility of shared uniform motion (allowing circular motion to count as uniform). Against the strongest Aristotelian objection that on a rotating Earth objects would tend to fly off, he had to formulate a version of the principle of inertia. But surely if the Earth were to rotate fast enough, experience with spinning millstones showed that objects would fly off? Without an understanding of gravity, Galileo's response to this objection was ingenious but finally unconvincing.

Responding to objection was, of course, not going to be enough. Positive arguments in this domain, Galileo notes, are of two sorts, one based on astronomical observations, the other on terrestrial effects. And the first kind, based on shared celestial motions, can only afford 'greater probability', he admits. If we observe a diurnal motion shared by *all* the celestial bodies, is it not simpler to suppose that the motion is really that of the Earth? The argument here, Galileo emphasizes, is not just from economy. It is based on the ability to *explain* the motion. Whereas *he* can give an account of the Earth's inertial rotation, his opponents have nothing to offer in regard to the complex causes required to keep so large and so complex a system revolving around a relatively small Earth. The carrier spheres are no longer believable (he does not mention Tycho's role in banishing them), so how could the myriad stars (now multiplied enormously in number by telescopic testimony) retain their positional relationship with one another over the ages, as they are observed to do? What sorts of forces could bring this about? Galileo enumerates seven arguments of this general kind in favor of the Earth's rotation. Though he does not say so, these arguments would also tell against the third 'chief world system', that of Tycho, which he studiously ignores throughout the *Dialogue*.

The shared-motion argument for the *annual* motion of the Earth distinguishes between the planets and the fixed stars. It is a harder case to make since Galileo has no explanation to offer for this motion. Further, it leads to awkward questions about the absence of stellar parallax. Galileo conjectures in response that the stars must be at an enormous distance from us. Oddly, he makes no use of the 'coincidence' arguments proposed by Copernicus and Kepler: various features of the planetary motions (e.g. the fact that planets are brightest when in opposition) are 'natural' in the Copernican system, unexplained coincidence in its rival.

He realized that to achieve the sort of proof that his critics, particularly his theological critics, demanded, he would have to produce a causal inference from some terrestrial phenomenon to the Earth's motions as its only possible explanation, the classical Aristotelian requirement for demonstration. As early as the 1590s, he had speculated that the ocean tides might furnish the needed proof. He obviously meant this to be the culminating argument of the *Dialogue*; indeed, he had to be ordered not to work a reference to it into the book title. The double motion of the Earth, allied with the peculiarities of individual sea coasts, could, he labored to show, explain the general features of the TIDES. Though some modern scholars are sympathetic to his tidal argument, his readers were (and still are) on the whole unconvinced. The tie between the tides and the lunar phases had been noted since antiquity and did not easily fit into Galileo's scheme. (He rejected outright the possibility that lunar attraction might be responsible.) More seriously, in order to meet Aristotelian objections he had already asserted, on several grounds, the imperceptibility in principle of terrestrial effects of the Earth's motions. How could he now turn around and rely on such terrestrial phenomena as the tides to provide *demonstration* of these motions?

The cumulative effect of the *Dialogue* arguments was, thus, mixed. The arguments *against* the Aristotelian–Ptolemaic system were decisive; it had no serious support from astronomers from this time forward. The positive arguments *for* the Copernican alternative were much less decisive. The tidal argument did not convince. The shared-motion arguments had to bear the burden, and this they did, provided one settles for a high degree of probability. And this is just what the scientists of Galileo's century were finding it very difficult to do.

Galileo Mission to Jupiter

The Galileo mission to JUPITER provided several historic firsts in planetary and solar system exploration: the first *in situ* sampling of an outer planet atmosphere, the first extended study of an outer planet, its satellites and magnetosphere from an orbiter, the first images of an asteroid, together with the first confirmation that asteroids can have gravitationally bound moonlets and, by an amazing set of circumstances, the only direct view of the impact of comet Shoemaker–Levy 9 with Jupiter.

The spacecraft consisted of two main components: an atmospheric entry probe and a planetary orbiter. The Galileo probe was designed and built by Hughes Space and Communications Group under contract to NASA Ames Research Center. The Jet Propulsion Laboratory designed and built the Galileo orbiter and had overall responsibility for mission design and operations. The German government was a partner in the mission through its provision of the orbiter propulsion subsystem and two science experiments. Scientists from six nations participated in the mission.

The principal scientific objectives of the mission were (1) to study the composition, structure and dynamics of the jovian atmosphere, to a depth having a pressure of at least 10 bar, (2) to study the composition, geology, surface morphology and interior structure of the planet-sized Galilean moons Io, Europa, Ganymede and Callisto and (3) to determine the structure of, and characterize the plasma physics in, the vast jovian magnetosphere. In spite of some serious spacecraft hardware problems which occurred on the way to Jupiter, the Galileo Mission met all these objectives, plus it produced some first-order science prior to arrival at Jupiter. The instrument suites aboard the probe and orbiter are given in table 1. All instruments functioned well.

The Galileo spacecraft arrived at Jupiter on 7 December 1995, after having been launched on 18 October 1989 by the space shuttle Atlantis from Kennedy Space Center. The original launch date for the mission was to have been January 1982, but various delays, many not associated with the spacecraft, led to a target launch date of May 1986. However, the Challenger shuttle accident occurred in January 1986, delaying Galileo's launch for yet another 3 yr. The launch delays meant that the trajectory to Jupiter had to be completely redesigned because of Shuttle payload, safety and launch limitations. The ingenious trajectory redesign resulted in a trajectory that included a close flyby of Venus (February 1990) and two close flybys of Earth (December 1990 and December 1992) for gravity assists to gain sufficient energy to reach Jupiter. By serendipity this trajectory allowed the first-ever flyby reconnaissance of two asteroids and the direct viewing of the impacts with Jupiter of the kilometer-sized fragments of comet Shoemaker–Levy 9.

Table 1. Galileo scientific payload.

Investigation	Purpose
Probe	
Atmospheric Structure Instrument	Jovian atmosphere thermal structure
Energetic Particle Detector	Inner radiation belt parameters
Lightning/Radio Emission Detector	Jovian atmosphere optical–radio lightning properties
Helium Abundance Detector	Jovian atmosphere relative helium abundance
Nephelometer	Jovian atmosphere cloud parameters, location
Net Flux Radiometer	Solar–planetary radiative flux in jovian atmosphere
Neutral Mass Spectrometer	Jovian atmosphere composition, 2–150 amu
Doppler Wind Experiment	Zonal wind profile in jovian atmosphere
Radio Scintillation Experiment	Turbulence, signal absorption in jovian atmosphere
Ground Based Doppler Wind[a]	Zonal wind profile in jovian atmosphere
Orbiter	
Solid-State Imager	Image Galilean satellites, Jupiter circulation
Near-Infrared Mapping Spectrometer	Jupiter and satellite composition, temperature
Ultraviolet Spectrometer	Gases and aerosols in jovian atmosphere
Extreme Ultraviolet Spectrometer	Ion, airglow emissions
Photopolarimeter/Radiometer	Characterize atmospheric aerosols, energy balance
Magnetometer	Magnetic field strength and direction
Energetic Particle Detector	High-energy ions and electrons
Plasma Detector	Characteristics of low-energy particles
Heavy Ion Counter	Fluxes and composition of heavy ions
Plasma Wave Detector	Electric and magnetic waves, wave–particle interaction
Dust Detector	Properties of dust near Jupiter
Radio Science	Celestial mechanics, gravity fields, atmospheric structure

The probe was separated from the orbiter on 13 July 1995. At this point both the orbiter and the probe were about 50 million miles from Jupiter and 5 months away from arrival. The probe plunged into the atmosphere of Jupiter on 7 December 1995, 14:04 PST, at a latitude of 6.5ºN, surviving the most difficult atmospheric entry ever attempted in terms of relative atmospheric entry speed, exceeding 47 km s^{-1}. The probe returned data for just over an hour, until it reached a pressure level in the atmosphere of 22 bar. On the same date, after having received and recorded the probe data, the orbiter was the first ever to be placed in orbit about an outer planet and returned data about the jovian system during a nominal mission lasting until December 1997. The orbiter is still functioning at the time of writing this article. The primary purpose of the extended mission beyond the nominal 2 yr is to reconnoiter the jovian moon Europa. Europa is of high interest because of the possible existence of a subsurface liquid water ocean, which conceivably could harbor biology.

En route to Jupiter, the spacecraft suffered a major anomaly on 11 April 1991, when the high gain antenna (HGA) failed to deploy properly. Until this point, the HGA had been folded against a central mast and was protected by Sun shields so that heat loads on the HGA would be within tolerances. Despite repeated attempts to solve the problem, the HGA was not functional for the rest of the mission. Mission communications were carried out using the low-gain broad-beam antenna, with a subsequent reduction in communication rate by a factor of 1000. It is to the credit of all the mission teams that, in spite of this severe problem, Galileo met almost all its fundamental science objectives. The major impact to data return came in the total number of images returned, reduced from the expected approximately 100 000 during the nominal mission to less than 2000, with another approximately 2000 images to be returned during the 2 yr Galileo Europa portion of the mission.

Science highlights en route to Jupiter

Before reaching Jupiter the spacecraft took the first close-up pictures of two asteroids. On 29 October 1991 the spacecraft flew by asteroid GASPRA at a closest approach of about 1600 km. The images returned revealed a cratered, complex and irregular body approximately 19 km by 12 km by 11 km, apparently covered by a thin regolith. On 28 August 1993 Galileo encountered the second asteroid, IDA, with a closest-approach distance of about 2400 km, and discovered that Ida had a small moon (about 1.5 km in diameter). Dactyl, as the moonlet was named, was the first confirmed moon of an asteroid and was estimated to be about 100 km from Ida's centroid. Ida itself was considerably larger than Gaspra, being approximately 56 km by 24 km by 21 km, and had a rotation period of 4.6 h about an offset axis.

Twenty-one kilometer-sized fragments of comet Shoemaker–Levy 9 collided with Jupiter in July of 1994, at a time when the Galileo spacecraft was about 1.5 AU from Jupiter (see SHOEMAKER–LEVY 9–JUPITER COLLISION). The set of collisions of the fragments of SL-9 with Jupiter was one of the most intensely observed events by astronomers in history, but, because of the geometry of its trajectory, Galileo was the only platform that had a direct view of the impact sites because they occurred on the side of Jupiter facing away from Earth. Galileo returned key data concerning the time history and light curves of several of the fragment impacts, information which otherwise would have been unobtainable.

As Galileo passed close by VENUS and the Earth–Moon system on its way to Jupiter, unique sets of observations were accomplished. Among the measurements at Venus were high spatial and temporal resolution imaging of atmospheric motions at cloud levels and compositional measurements from the near-infrared mapping spectrometer. High spatial resolution images of both the Earth and the far side of the Moon were obtained, and a wonderful set of images of the entire Earth–Moon system produced a movie in which the Earth is seen rotating as the Moon orbits around it.

Science highlights at Jupiter

Jupiter

One of the most important scientific objectives of Galileo was to determine the composition of the jovian atmosphere. Composition information is important in order to develop an understanding of solar system formation and evolution. Prior to Galileo, it was of course known that Jupiter was made mostly of hydrogen and helium, but the precise value of the relative abundance of helium was still uncertain to about 25%. Furthermore, although the jovian abundance of carbon was fairly well established, the jovian abundances of the next most abundant non-noble volatile elements in the solar system, oxygen, nitrogen and sulfur, were poorly constrained, if at all. Noble gases other than helium had not even been detected (see JUPITER: ATMOSPHERE).

The Galileo probe made direct measurements of atmospheric composition between levels in the atmosphere corresponding to pressures from 0.4 bar to 22 bar. Indirect measurements of the ammonia abundance profile with depth were made using the probe telemetry signal strength as received by the orbiter. The He/H_2 mass ratio was measured to be 0.24, somewhat higher than the value near 0.18 inferred from the earlier Voyager flybys of Jupiter and closer to the value thought to be appropriate for the proto-Sun, 0.275. Carbon (in the form CH_4), nitrogen (in the form NH_3) and sulfur (in the form H_2S) were all measured to have relative abundances to hydrogen about 3 times the respective solar values,

Dirac House, Temple Back, Bristol, BS1 6BE, UK

although there is still some uncertainty as to the ammonia determination. Prior to Galileo, remote observations indicated an ammonia abundance less than twice solar. The Galileo ammonia measurements of 3–4 times solar imply that planetesimals which brought heavier elements to Jupiter originated from colder regions of the early solar system than previously thought. Another surprise was the relative abundance of oxygen (in the form H_2O), which was found to be depleted with respect to the solar value, as was the noble gas neon. It is at present thought that the depletion in H_2O does not represent the planet as a whole, but rather local or regional variation in the H_2O abundance. To date, the Galileo orbiter has not detected solar amounts of water in Jupiter's atmosphere either, but all data have not yet been analysed.

Other surprising aspects of the Galileo probe data, which may be related to the region in which the probe descended, were the dependencies on depth of the mixing ratios of the condensibles NH_3, H_2S and H_2O. The probe entered an anomalously clear region of the jovian atmosphere in terms of cloud layers, known as a 5 μm hot spot because emitted radiation from the deeper atmosphere is detected remotely in these relatively clear regions. Three cloud layers were expected, but only one tenuous cloud layer was clearly detected, corresponding most likely to the expected second cloud deck of ammonium hydrosulfide, NH_4SH. The probe probably started measurements below the topmost cloud, expected to be NH_3 ice crystals, and did not encounter an expected water cloud. All the condensible abundances varied dramatically with depth, but the variations were not correlated with condensation levels or with each other. The typical profiles consisted of highly depleted mixing ratios at depths near 0.4 bar, increasing to mixing ratios a few times solar values at depths near and above 10 bar. The one exception was water, which reached a value about 30% solar at the deepest levels probed. Various possible explanations for these observations have appeared, but at the present time there is not a consensus as to the proper interpretations and scientific implications.

The Galileo probe established that the dominant zonal (east–west) winds, which relate to the banded appearance of the planet and which have been observed ever since cloud motions could be followed with telescopes on Jupiter, extend to at least the depth penetrated by the probe. Zonal wind speeds increased from about 70 m s^{-1} at cloud levels near 0.4 bar to 175 m s^{-1} at a pressure level near 5 bar and then remained approximately constant to a depth corresponding to 22 bar. The fact that the winds extend to 22 bar probably implies that the winds are driven from deep in the jovian atmosphere, conceivably very deep.

The thermal structure of the atmosphere below the 1 bar pressure level was measured to be close to that corresponding to a dry adiabat, as had been expected. However, in the upper atmosphere at heights above 1 μbar, temperature rapidly increased with height, reaching a value (depending precisely on choice of temperature at the initial altitude of measurement) of 900 K near 1000 km above the 1 bar level. Solar heating is too small to be the energy source for the upper atmosphere heating. Most probably the energy source is a combination of dissipation of atmospheric gravity waves propagating from the deeper atmosphere with heating of the atmosphere by energetic particle precipitation from the magnetosphere.

Galilean satellites

The Galilean satellites are of high scientific interest for several reasons. In conjunction with Jupiter, these large moons form a system that in certain ways is analogous to the solar system and hence a system that can reveal information regarding the physics of planet formation and evolution (see JUPITER: SATELLITES). Furthermore, these bodies are highly interesting in their own right. IO is the most volcanically active body in the solar system. EUROPA is of major interest because of the possibility, discussed below, of a subsurface water ocean which could harbor biology. GANYMEDE is the largest moon in the solar system, being the size of the planet Mercury. The outermost satellite, CALLISTO, is the same general size as Ganyemede, but appears rather different from the other three satellites in terms of geophysical history.

A much more comprehensive knowledge of the Galilean satellites of Jupiter is now emerging from the Galileo orbiter data. The Galileo orbiter passed close enough to each of these satellites so that tracking of the spacecraft allowed measurement of the quadrupole moment of the gravitational field, from which it is possible to develop models of the satellite's interior. At the same time, magnetic field measurements were made during the satellite flybys which could be used to assess whether the magnetic field perturbation measured was due to an induced field or to an intrinsic field of the satellite itself. Combining these sets of data, the following picture seems to emerge. The inner three satellites, Io, Europa and Ganymede, are strongly differentiated. The best model fit is a three-layer model consisting of a metallic core, rocky envelope and (except for Io) water ice outer shell. The magnetic signature of Ganymede implies an internally generated magnetic field, consistent with the existence of a metallic core. Io's magnetic field has not yet been measured adequately to distinguish what type of magnetic field, if any, it has. The preferred explanation for Europa's magnetic signature is an induced magnetic field driven by time-varying processes in Jupiter's magnetosphere near Europa's orbit. This implies induced currents in Europa flowing in a near-surface conducting layer, such as a salty subsurface ocean. However, an intrinsic field cannot yet be ruled out. Callisto, the outermost Galilean satellite, is partially

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

differentiated with an ice–rock mixture, such that the rock fraction is a slowly increasing function of depth. Callisto's magnetic signature implies an induced field qualitatively similar to that of Europa, requiring a near-surface conducting layer. Such a near-surface conducting layer on Callisto is difficult to understand. Neither an icy crust nor a conducting ionosphere can explain the magnetic observations, and known sources of heating are not expected to be large enough to cause a near-surface liquid or slushy conducting layer.

Spectra of the satellite surfaces imply that, besides water ice, the surfaces of Ganymede and Callisto could contain CH, CO_2, CN, SO_2 and perhaps an SH-radical-containing material. Sulfur-bearing minerals may also be possible constituents. Certain impact scars on Europa seem to contain saline hydrates mixed with the dominant constituent, water ice. Evaporite, hydrated minerals produce good spectral matches to various other features on Europa. The surface of Io of course does not contain water ice because of the active heat release by volcanism, but, besides silicate materials, SO_2 ice grains of size smaller than 500 μm are almost everywhere.

A current question of extreme scientific interest is whether Europa has a liquid water ocean which might harbor biology beneath the frozen surface. Theoretical models of Europa's interior show that the same tidal heating mechanism that produces the volcanoes on Io may act to a lesser degree within Europa to maintain temperatures above the melting point of water ice at depths of a few tens of kilometers. At the present time, probably the most indicative evidence that a subsurface slushy or liquid layer exists consists of Galileo orbiter images, such as that of the Conamara region presented in figure 1. This image shows a chaotic surface terrain, in which it appears that a thin ice crust has been disrupted and moved about in chunks, which resembles disruption of polar ice packs on the Earth during spring thaws. The size and geometry of the 'chunks' imply that a layer of liquid water or soft ice not too far below the surface could have driven the relative motions and rotations apparent in the image. The age of the surface has yet to be unambiguously determined. Depending on which model is used, crater counts imply either a young age of a few million years or less or, instead, a rather old surface of a few billion years. Currently, therefore, evidence exists that at least at some time in Europa's history there existed a 'slushy' near-surface layer. The challenge now is to determine whether that is the present situation.

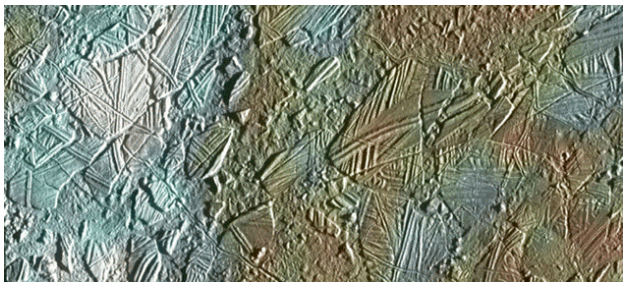

Figure 1. Image of an approximately 70 km × 30 km area of Europa in the Conamara region. The colours in the image have been enhanced for visibility. White and blue colours delineate regions which have been covered by fine dust particles ejected when the crater Pwyll was formed 1000 km to the south (north is to the top of the image, the Sun illuminates the surface from the right). Mineral contaminants are probably responsible for the reddish-brown colours. Crustal plates up to 13 km in size appear to have been created and then moved into new positions, indicating water or soft ice not too far beneath the surface at the time of crustal movement.

Magnetosphere

The magnetosphere of Jupiter is a vast system of plasma and magnetic fields that interacts in one way or another with every object in the jovian system (see JUPITER: MAGNETOSPHERE). The magnetic fields within the magnetosphere originate in Jupiter and the Galilean satellites and from plasma currents within the magnetosphere. The Galileo orbiter has provided key information about magnetospheric geometry which, when combined with previous spacecraft data, can be used to give an overall view of magetopause and bow shock shape and location. On the Sun side of Jupiter, the magnetic equatorial bow shock occurs at about $80R_J$ (jovian radius), and the equatorial magnetopause is near 70 R_J, each value being somewhat time variable depending on solar wind conditions. Galileo measured magnetic perturbations near each of the Galilean satellites, as described above, indicating either internally generated magnetic fields or fields induced by magnetospheric plasma interactions with the satellites. New information obtained within Io's plasma torus revealed a much stronger electromagnetic interaction with Io than had been expected (see IO: PLASMA TORUS). Europa has a tenuous neutral oxygen atmosphere that is both generated and removed by plasma sputtering processes that depend strongly on electrodynamic conditions near Europa. Comparison of modelling results with Galileo and other data implies an oxygen column density of about 5×10^{18} m^{-2}.

Summary

Galileo has been a pioneering mission in many ways. In spite of the early launch delays, the high gain antenna malfunction, and having to wait for many years to get to Jupiter, Galileo has provided a picture of the jovian system that is unprecedented. As with all great planetary missions, the results from Galileo form the basis for, and point the way to, further exploration of the jovian system.

In 2001, the Galileo mission was given the go-ahead for a mission extension that includes five more fly-bys of the Jovian moons before a final plunge into the crushing pressure of the giant planet's atmosphere. Galileo's mission has previously been extended twice. On 25 May

2001, Galileo passed about 123 km (76 mi) above Callisto. in August 2001, the Galileo spacecraft flew past the north pole of Jupiter's moon Io, passing through a swarm of sulfurous particles hurled into space by a previously unknown volcano. Scientists had not expected the spacecraft to encounter volcanic 'ash'. A different volcano named Tvashtar had been lofting a plume seven months earlier, but Galileo saw no sign of that plume during its Io flyby in early August. Instead material was erupting from a previously unknown volcano just 600 km (370 mi) from Tvashtar. On October 1, 2001, at 0123 UT, the Galileo spacecraft approached the closest yet to the surface of Io, to within 181 km (112 mi) of ground level near Io's south pole.

In 2002, having completed its imaging mission, Galileo will continue studies of Jupiter's massive magnetic field with seven instruments. In November 2002, it will swing closer to Jupiter than ever before, dipping within about 500 km (300 mi) of the moon Amalthea. Scientists will use Galileo measurements to determine the mass and density of Amalthea. They will also study dust particles as Galileo flies through Jupiter's gossamer rings and seek new details of the magnetic forces and the densities of charged particles close to the planet. Galileo's final orbit will take an elongated loop away from Jupiter. Then, in August 2003, the spacecraft will head back for a direct impact and burn up as it ploughs into Jupiter's 60000 km-thick atmosphere.

Breaking news update (30 April 2002)

The Galileo spacecraft resumed gathering scientific information at about 4:00 Universal Time on January 18, 2002, after commands radioed from Earth took the Jupiter orbiter out of the passive standby mode it entered on the previous day. On Thursday January 17 at about 13:41 Universal Time, while making a close approach to Jupiter's innermost Galilean moon, Io, the spacecraft detected a computer reset, which caused it to enter a 'safe' mode. In this mode, onboard fault protection software instructs the spacecraft cameras and science instruments to stop taking data and places them in a safe state awaiting further instructions from the ground. The reset was apparently caused by exposure to the intense radiation environment at Io's distance from Jupiter. Since the spacecraft began orbiting Jupiter in 1995, it has endured a cumulative radiation exposure about three-and-a-half times what it was originally designed to withstand. After resuming operations, Galileo passed within about 102 km (63 mi) of Io. Planned observations for the remainder of the spacecraft's current swing near Jupiter include a series of images of the planet's atmosphere, a farewell color study of its icy moon Europa and navigational imaging of the small moon Amalthea.

A recent image from NASA's Galileo spacecraft adds evidence to a theory that Callisto may hold an underground ocean. The image shows a part of Callisto's surface directly opposite from the Valhalla basin where Callisto was punched by a major collision. The opposition point shows no effect from the impact. Points opposite major impact features on some similar-size worlds, such as Mercury and Earth's Moon, show lumpy terrain attributed to seismic shocks from the distant impacts. The new image is consistent with a 1990s' model proposing that a liquid layer could be acting as a shock absorber inside Callisto.

Bibliography

Detailed descriptions of the Galileo spacecraft, its trajectory to Jupiter, and the instruments on the probe and orbiter can be found in articles appearing in

1992 *Space Sci. Rev.* **60** (1–4)

Various observations conducted during the transit to Jupiter were reported in the following publications. Regarding the flyby of Venus, see articles in

1991 *Science* **253** 1457–612

Regarding Earth–Moon, see

Belton *et al* 1994 *Science* **264** 1112–15

Two special issues reporting the Galileo observations of asteroids Gaspra and Ida were, respectively

1994 *Icarus* **107** 1–97
1996 *Icarus* **120** 1–245

Regarding Galileo observations of the impact of Shoemaker–Levy 9 with Jupiter, see

Hord *et al* 1995 *Geophys. Res. Lett.* **22** 1565–8
Weismann *et al* 1995 *Abstr. Lunar Planet. Sci. C.* **26** 1483

Science results and parameters from the probe entry and descent into Jupiter's atmosphere were first published in

1996 *Science* **272** 837–60

Orbiter results at Jupiter were first published in

1996 *Science* **274** 377–403

Subsequently many papers have appeared discussing Galileo observations. The reader is referred here to three special journal issues which should provide good starting points to pursue a particular question. Two special issues

1998 *J. Geophys. Res.-Planet* **103** (E10)
1998 *J. Geophys. Res.-Planet* **103** (E9)

provide comprehensive analyses of probe and magnetospheric observations, respectively. Remote sensing results from the Galileo orbiter appear in

1998 *Icarus* **135** (1)

Galle, Johann Gottfried (1812–1910)

Astronomer, born in Pabsthaus, Germany. In 1846, at the Berlin Observatory, he discovered the planet Neptune, whose position had been calculated by LEVERRIER. Leverrier had written to Galle asking him to search for the 'new planet' at a predicted location. Galle, together with his assistant HEINRICH D'ARREST, began a search on the same night that they received the letter. At D'Arrest's suggestion, Galle used the latest star chart that had only just been produced by Encke. In 30 minutes they had located a star not on the map, confirming that it was the new planet on the following night by its motion relative to the other stars. Galle wrote to Leverrier, saying, 'Monsieur, the planet of which you indicated the position really exists'. Leverrier replied, 'I thank you for the alacrity with which you applied my instructions. We are thereby, thanks to you, definitely in possession of a new world'. Galle also detected Saturn's C-ring and observed minor planets, attempting to determine the solar distance through the observation of the close approach of one (see DAVID GILL, HAROLD SPENCER JONES).

Gamma Draconis

Sometimes known by its ancient name Eltanin (or Etamin), the 'Head of the Dragon', from its description in the revision of Ptolemy's *Syntaxis* published by Ulugh Beigh in the fifteenth century. The star has an apparent magnitude of 2.24 and is of spectral type K5III. At a distance of 148 light-years, it has a parallax of 0.022″ and an absolute magnitude of −1.0.

This second-magnitude star was, for nearly 300 years, of considerable importance to positional astronomers, especially those observing from the Royal Observatory at Greenwich. Due to its declination (51° 29.3′) being approximately equal to the latitude of Greenwich (51° 28.6′), it transits there very close to the zenith: 4′ north of the zenith in the time of the first Astronomer Royal, John Flamsteed (1646–1719), and only 2′ north by the time of the seventh Astronomer Royal, G B Airy (1801–92), who described it as 'the birth star of modern astronomy'.

Transiting zenithally is very advantageous, for not only does it simplify the telescope mounting required, and hence improves stability, but the positional errors caused by the effects of atmospheric refraction are zero at the zenith. These advantages had long been realized. In 1669 Robert Hooke (1635–1703) set up a vertical telescope at Gresham College in the City of London, in an attempt to measure the annual parallax of γ Draconis and hence its distance. It was not then realized how distant the stars are, the parallax of 0.022″ would in fact have been impossible to measure with the instruments of Hooke's time. In 1677 Flamsteed had a 90-foot well dug at Greenwich, to act as the 'tube' of a vertical refractor to observe the star, but observations made with it were fraught with difficulty and proved to be of little use.

In 1725 James Bradley (1693–1762), Savilian Professor of Astronomy at Oxford, wished to observe γ Draconis for the same purpose. He joined the wealthy English amateur astronomer Samuel Molyneux (1689–1728) at Kew, where they used Molyneux's 24.5 foot zenith sector by George Graham (1675–1752). Like Hooke, they obtained varying results for the zenith distance of the star at transit, but these did not seem to be explained by an annual variation due to parallax. Intrigued by these discrepancies, Bradley commissioned an excellent new 12.5 foot zenith sector from Graham, and set it up at his home in Wanstead. After making many more observations of the star Bradley arrived at the explanation of the variations in its observed position—and announced the discovery of the aberration of light. Further work led to his discovery of nutation, announced in 1748. Following his appointment as the third Astronomer Royal in 1742, Bradley persuaded the Admiralty to purchase his zenith sector so that these observations could be continued at Greenwich.

As the principal 'zenith star' γ Draconis continued to be observed at Greenwich for a further two centuries. In 1851 Airy introduced a reflex zenith tube of his own design to continue the observation of this and other much fainter zenithal stars, and visual observations of greatly increased accuracy were made with this instrument over the next 60 years. From 1911 to 1950 it was superseded by the floating zenith tube previously used at Cambridge by Bryan Cookson (1874–1909).

The success of Airy's design for the reflex zenith tube led to the development of the first photographic zenith tube by F E Ross of the US Naval Observatory, Washington, in 1911. A much improved and fully automated version was designed and installed at the Royal Greenwich Observatory at Herstmonceux in 1955, the first of a network of similar instruments set up at major observatories around the world. These proved to be the most accurate instruments ever constructed for the astronomical determination of time and latitude—a remarkable tribute to Airy's design, a century earlier, of an instrument specifically to observe γ Draconis.

Gamma Rays

The most energetic form of electromagnetic radiation. Gamma rays have wavelengths shorter than 0.01 nanometers (10^{-11} m) and individual photon energies greater than about 10^5 electron volts (eV). Despite their high energies and penetrating power, gamma rays from cosmic sources are absorbed well above ground level by the atmosphere. Even the most energetic gamma rays so far detected, with wavelengths of around 10^{-9} nm and energies in excess of 10^{12} eV, are absorbed by the time they have penetrated down to about 10 km above ground level.

The term 'gamma rays' may also be written as 'γ-rays', where γ is the Greek letter 'gamma'.

Gamma-Ray Astronomy

Gamma-ray photons are the most energetic ones of the whole electromagnetic spectrum. Like all photons with wavelengths shorter than 10 nm, they are absorbed by the Earth's atmosphere. Detection of γ-ray emission from space requires then the use of stratospheric balloons, rockets and satellites, which became feasible only with the advent of the space era.

The borderline between the spectral regions of x-rays and γ-rays is sometimes placed at an energy of $E \sim 30$ keV (wavelength $\lambda \sim 4.13 \times 10^{-9}$ cm or a frequency of $\nu \sim 7.2 \times 10^{18}$ Hz). At lower energies, radiation from astrophysical sources is dominated by thermal emission (i.e. resulting from radiation in equilibrium with matter, in optically thick media), while at higher energies non-thermal emission prevails. Alternatively, the x–γ-ray borderline may be placed at 511 keV (the energy equivalent of the electron rest mass); above this 'limit' electrons behave relativistically. In any case, the use of large photon collectors becomes impossible above a few tens of keV: photons have wavelengths smaller than typical interatomic distances in solids and cannot be reflected by any kind of mirror (contrary to what happens at longer wavelengths).

The γ-ray domain extends over 12 decades in energy, as much as all other spectral regions put together. However, above a few tens of GeV, the number of photons received from even the brightest sources is so small that their observation during the limited lifetime of a satellite is no longer possible (see VERY-HIGH-ENERGY GAMMA-RAY SOURCES). Those very high energy (VHE) photons are detected through their interaction with the Earth's atmosphere, producing cascades of secondary particles.

Astronomy in the γ-ray domain faces several serious handicaps.

- The impossibility of using large collectors to focus the γ-ray photons implies that the detector itself should be as large as possible.
- A detector placed outside the Earth's atmosphere is constantly bombarded by energetic cosmic ray particles, coming from the outer space or trapped in the Van Allen radiation belts. The interactions of these particles with the detector induces very high backgrounds, which are difficult to attenuate with passive or active shielding. As a result, the sensitivity of γ-ray detectors increases only as the square root of their collecting area.
- Astrophysical sources emit generally very small numbers of γ-ray photons. Statistically significant detections then require very long exposures, which are not always compatible with the generally short lifetime (a few years) of an observatory in space.

These difficulties explain why γ-ray astronomy is the last window of the electromagnetic spectrum to be opened to our observation of the universe. However, it has undergone a spectacular development in the 1990s and has grown to a mature astrophysical discipline. It offers information that is impossible to obtain in other wavelengths, allowing us to probe the close surroundings of a black hole or the interiors of a supernova, to identify nuclear isotopes and to obtain clues to the origin and acceleration of cosmic rays, either in our Galaxy or in the very active central regions of remote galaxies.

A short history of γ-ray astronomy

The opening of the γ-ray window was preceded by a relatively long period of theoretical studies concerning the γ-emissivity of potential astrophysical sources. Most of these ideas were put forward by scientists working in fields other than astronomy (particle and nuclear physics and cosmic ray physics). Following the detection of atomic hydrogen in the Galaxy (through its characteristic 21 cm line; see RADIOASTRONOMY) Hayakawa realized in 1952 that the interaction of COSMIC RAYS with the hydrogen atoms of the interstellar medium should give rise to γ-ray emission. Six years later, Morisson suggested two known radiosources (the CRAB NEBULA and CYGNUS A) as possible γ-ray emitters. Thus, theoreticians realized quite early that relativistic particles could generate photon emission in both extremes of the electromagnetic spectrum.

Progress in observational γ-ray astronomy has been too slow to test those ideas, because of the smallness of early detectors and underestimated background fluxes. The first γ-ray emission of extraterrestrial origin was detected during the solar flare of March 1958. However, it was only 10 yr later that γ-ray emitters outside our solar system were detected: the US satellite OSO-3 (launched in 1961) recorded a few hundred photons of energy >50 MeV from the inner Galaxy, while a balloon-borne experiment detected photons in the 100–300 keV range from the direction of the Crab nebula. A few months later, radioastronomers discovered the CRAB PULSAR; subsequent analysis of the γ-emission from the Crab revealed a periodicity similar to that in the radio band. During a solar flare in August 1972, a spectrometer aboard the US satellite OSO-7 recorded the first γ-ray spectrum of the Sun, revealing several lines of nuclear origin, as well as the electron–positron annihilation line at 511 keV. Also, the following year a US team reported the detection of γ-ray bursts of extraterrestrial origin by the military satellites of the Vela series (launched to monitor the Earth's atmosphere for nuclear explosions).

After these early discoveries, the γ-ray sky was explored in some detail in the 1970s by the US SAS-2 and the European COS-B satellites, which provided the first high-energy images of the Milky Way, detailed observations of the first known γ-ray pulsars and the first detection of extragalactic γ-ray sources. Extrasolar γ-ray spectroscopy started in the same period, with the discovery of the electron–positron annihilation line from the galactic centre direction by a balloon-borne spectrometer. This discovery was confirmed in the early 1980s by a γ spectrometer aboard the US HEAO-3 satellite, which discovered also the first extrasolar γ-ray

line emission of nuclear origin, namely the 1.8 MeV line of the radioactive nucleus ^{26}Al.

The pace of discoveries slowed down in the 1980s, as a result mainly of the lack of dedicated γ-ray satellites. The explosion of the supernova SN1987A in the nearby galaxy of the Large Magellanic Cloud on February 23 1987 offered the γ-ray community an unprecedented opportunity: the SMM (Solar Maximum Mission) satellite, as well as several balloon borne instruments, detected γ-ray lines from the decay of radioactive ^{56}Co (predicted long ago to be the source of power for the late optical light curves of supernovae). Finally, the early 1990s constitute the golden era of γ-ray astronomy, thanks to the discoveries of the Soviet–French SIGMA mission (see GRANAT) and the US COMPTON GAMMA RAY OBSERVATORY (CGRO).

Emission processes of γ-ray photons

Nature creates γ-ray photons in a variety of ways. If the temperature of the environment is high enough ($>10^8$ K), γ-photons are produced as thermal emission of the astrophysical PLASMA and they generally have a blackbody spectrum. The interiors of stars in their advanced evolutionary stages reach such high temperatures, but they cannot be observed, because the star's dense material makes it opaque to photons of all wavelengths.

The close neighborhood of a strongly gravitating body, such as a black hole accreting matter from a companion star, may also reach high temperatures, as the gravitational energy of accreted matter turns into heat. The detection of γ-ray photons produced in this way is a unique tool for studying the interactions of compact objects with their environment as well as their energetics.

However, astrophysical γ-rays are mainly produced by various non-thermal processes, involving in general the interactions of high-energy particles. For instance, high-energy electrons radiate γ-rays by interacting electromagnetically with nuclei, photons or intense magnetic fields; the corresponding processes are known as bremsstrahlung, inverse Compton emission and synchroton emission, respectively, and they can obviously take place also in a high-temperature plasma. In addition nuclear interactions of protons with energies higher than $\sim$1.2 GeV produce secondary unstable particles, pions and mesons; γ-ray photons are produced by the decay of some of these particles, the most prolific producers being the π^0 pions. The resulting γ-ray spectrum has a characteristic maximum around 70 MeV (corresponding to half the rest-mass energy of π^0).

All these thermal and non-thermal processes give rise to the emission of γ-rays with a continuous spectrum of energy. There are also processes producing γ-rays with discrete energies, involving in general the de-excitation of atomic nuclei. Just as the more familiar optical lines are caused by the electron transitions in atoms, nuclear lines result from the much more energetic transitions (typically, in the MeV range) between energy levels of the atomic nuclei. This makes γ-ray spectroscopy an invaluable diagnostic tool for nuclear astrophysics, since it allows for an unambiguous identification of isotopic species (radiation originating from electrons enables one in general, to identify chemical elements, but not isotopes).

The excited nuclear states are populated either through the decay of an unstable nucleus or through high-energy nuclear interactions. In the former case, we obtain information about the synthesis of radioactive nuclei in various sites (mostly explosive ones such as supernovae) and the physics of these sites. In the latter case, we learn about the nature of the energetic particles (e.g. their composition, spectrum, acceleration mechanism etc). γ-ray lines from the de-excitation of nuclei are routinely observed in the Sun's photosphere during solar eruptions; in some cases, the nuclei are produced through neutron captures, in a medium sufficiently dense to favor these reactions, but also sufficiently thin to allow γ-rays to escape.

Finally, the annihilation of an electron and a positron also gives rise to emission in the γ-ray domain. Positrons may be produced in astrophysical sites through the decay of π^+ pions or through the β^+ decay of radioactive nuclei. Depending on the conditions they may annihilate directly with electrons or combine first with them to form positronium. In the former case (at high temperatures, $T>10^6$ K) two γ-ray photons of energy 0.511 MeV are produced. In the latter case, the resulting emission depends on the state of positronium: in 25% of the cases it is formed in the *para* (singlet, $^1S_0$) state and two photons of 0.511 MeV are again emitted; in 75% of the cases it is formed in the *ortho* (triplet, $^3S_1$) state and a continuous spectrum of three photons, each with an energy of $\leq$0.511 MeV, is then produced.

The γ-ray sky

The poor resolving power of current γ-ray instruments is one of the main problems in γ-ray astronomy (see GAMMA-RAY TELESCOPES). Observations in this energy range usually define 'error boxes', regions of the sky where the source most probably lies. Instruments launched in the 1990s provide error boxes of $\sim$1 arc min at low energies (the SIGMA telescope) and $\sim$5—10 arc min at higher energies (the EGRET instrument aboard CGRO), to be compared with, for instance, $\sim$0.1 arc sec in the visible. Identifying a source in these conditions is much more difficult than at other wavelengths. In the case of a variable source, the time-scale of variability sets an upper limit to the dimensions of the source (which cannot be larger than the distance light travels during this time-scale).

The sources of the γ-ray sky are extremely varied: some of them appear as 'points' (i.e. with angular dimensions smaller than the resolution of γ-detectors) and others as extended sources, both in our Galaxy and in the remote universe.

Stars on the main sequence (i.e. burning hydrogen in their cores) do not, in principle, radiate γ-rays and only the Sun has been observed to do so sporadically. During their advanced evolutionary stages, some stars may eject radioactive isotopes through their powerful

stellar winds and become γ-ray emitters (red giants, Wolf–Rayet stars). However, radioactivity is mostly produced during stellar explosions (supernovae and, to a lesser extent, novae). On the other hand, stellar remnants may produce copious amounts of γ-rays in several cases: rotating neutron stars may convert a fraction of their rotational energy into high-energy photons (γ-ray pulsars), while accreting black holes convert the energy of accreted matter into low-energy γ-rays in their vicinity and present a steady or variable emission. Some of these objects produce jets of high-energy particles which interact with their environment to produce γ-rays. Finally, the emission mechanism of the mysterious γ-ray bursts is not understood yet, although it—most probably—involves compact objects (neutron stars and black holes).

The Sun

Since the first detection of its γ-ray emission, in 1958, the Sun has been regularly monitored by US, Soviet and Japanese satellites (OSO, HEAO, Prognoz, SMM, Hinotori, Yohkoh, CGRO). γ-rays are emitted continuously, but particularly during a brief period of intense activity, associated with the 11 yr cycle of solar flares (see SOLAR FLARES: GAMMA RAYS). During this period the energy stored in unstable magnetic configurations of the solar surface layers is suddenly liberated; particles are accelerated to high energies and their interactions produce γ-rays. The study of the γ-ray emission provides information on the acceleration sites, their physical conditions and their composition.

The low-energy part of the continuum γ-ray spectrum of the Sun results from bremsstrahlung emission of accelerated electrons interacting with the solar atmosphere. At higher energies (100 MeV) part of the emission is due to the decay of π^0s produced by the interactions of high-energy accelerated protons.

The de-excitation of atomic nuclei (excited by high-energy collisions) gives rise to prompt γ-ray lines, which may be narrow (when ambient nuclei are excited by energetic protons and α particles) or broad (when fast nuclei are excited by ambient protons and α particles). The most intense narrow lines are those at 4.438 MeV and 6.129 MeV, resulting from the de-excitation of the abundant ^{12}C and ^{16}O nuclei, respectively; the lines of several other nuclei (^{15}N, ^{20}Ne, ^{24}Mg, ^{28}Si and ^{56}Fe) have also been detected (figure 1). The relative intensities of these lines provide information on the isotopic composition of the Sun's surface.

The most intense solar γ-ray line, at an energy of 2.223 MeV, results from the de-excitation of deuterium nuclei (D), produced by neutron captures on protons; since free neutrons are unstable (they decay to protons within 10 min) the ones involved in the formation of deuterium are ejected by accelerated heavy nuclei. The ejected neutrons have to slow down to the thermal velocities of the ambient medium before being captured by the protons and thus they give rise to delayed γ-ray line emission. The delay time (about 100 s) provides information on the ambient density ($\sim 10^{17}$ particles cm^{-3}) and the location of the emission site in the solar photosphere (at a depth of $\sim$300 km).

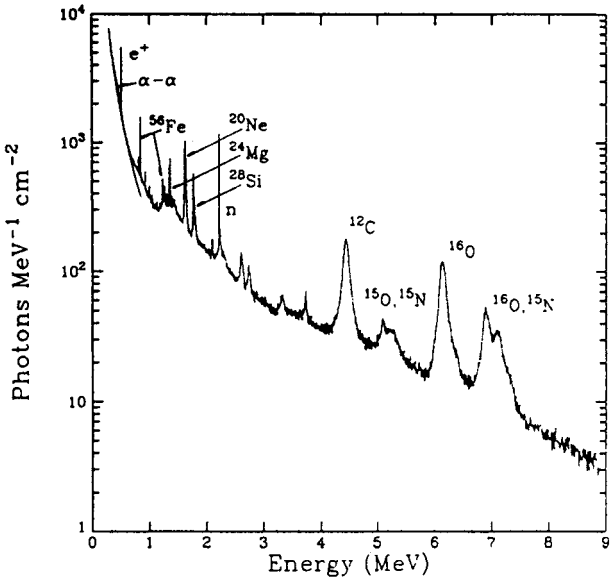

Figure 1. γ-ray spectrum of a solar flare modeled by Murphy *et al* (1991).

The second most intense line observed in the solar γ-ray spectrum results from the annihilation of positrons with electrons. Positrons are produced by β^+ decay of short-lived radioactive nuclei and of π^+ pions (both produced in high-energy interactions). Before annihilating, positrons have to slow down and their γ-ray emission is delayed (as in the case of neutrons).

Stellar explosions and remnants

Radioactive nuclei are produced by thermonuclear reactions in high-density environments, which are opaque to γ-rays. The photons of the radioactive decays interact with the ambient electrons and lose energy via Compton scattering; the medium is heated and the energy is ultimately radiated at longer wavelengths. Only in the case of a site violently expanding after an explosion (SUPERNOVAE, NOVAE) or suffering mass loss through a stellar wind (WOLF–RAYET STARS or stars in the asymptotic giant branch stage) can the γ-ray photons escape, since the opacity decreases with decreasing density.

The characteristic energy of escaping γ-ray lines enables one to identify isotopic species, while their intensity provides information on the amounts that have been synthesized and on the physical conditions of the corresponding stellar zones. The shape of the lines may give information on the structure (velocity and density profiles) of the stellar ejecta. These properties make γ-ray spectroscopy a unique tool for nuclear and stellar astrophysics.

These theoretical ideas, put forward mostly by D D Clayton in the 1960s, were spectacularly confirmed

in 1987: the 0.847 MeV and 1.238 MeV lines of the decay of ^{56}Co were observed in SUPERNOVA 1987A, a massive star ($20M_{\odot}$) that exploded in the nearby galaxy of the Large Magellanic Cloud. Their detection confirmed that ^{56}Fe, the most strongly bound stable nucleus in nature, is produced in the form of unstable ^{56}Ni (through the decay chain ^{56}Ni $\longrightarrow$ ^{56}Co $\longrightarrow$ ^{56}Fe). It also confirmed that the observed late optical luminosity of supernovae (decreasing by a factor of $\sim$2 every 75 days) is due to the energy released by the radioactive decay of ^{56}Co (which has a half-life of 77 days). Finally, the appearance of the γ-ray lines about 6 months earlier than expected from theoretical models suggested that some of the ^{56}Ni nuclei, produced in the dense inner zones of the star, had been mixed into the outer layers.

The extraordinary opportunity offered by SN1987A was due to its proximity; indeed, it was the first supernova visible to the naked eye in the past four centuries, since supernovae are mostly detected in distant galaxies. Moreover, theory suggests that exploding massive stars (characterized as supernovae of type II or SNII) produce moderate amounts of ^{56}Ni ($\sim 0.1M_{\odot}$) and remain opaque to γ-rays for a long time ($\sim$1 yr, i.e. until the radioactivity of ^{56}Co has dropped to low levels). Supernovae of another class, SNIa, are much brighter γ-ray line emitters. They are white dwarfs in binary systems, undergoing a thermonuclear explosion, which is triggered by the accretion of mass from their companion star; they produce $\sim$10 times more ^{56}Ni and become transparent to γ-rays much earlier than SNII, because of their smaller envelope mass. Unfortunately, observations show that SNIa are less frequent than SNII and their occurrence in a closeby galaxy is unexpected, on statistical grounds. The first SNIa to be (marginally) detected in the light of the ^{56}Co lines was SN1991T in the Virgo cluster of galaxies, at an estimated distance of 55 million light- years (by CGRO). Future γ-ray line observations of extragalactic SNIa will provide important information on the physics of those poorly understood objects.

Long-lived radioactive nuclei can emit characteristic γ-ray lines hundreds or thousands of years after the supernova explosion, while they are evolving in an environment transparent to γ-rays. The 1.156 line of ^{44}Ti (half-life 60 yr) has been detected by CGRO in the remnant of Cas-A, presumably a massive star that exploded about 300 yr ago, at a distance of 7000 light-years from the Earth. The ^{44}Ti emission may help to reveal remnants of recent supernova explosions that are unobserved in other wavelengths, because of obscuration by surrounding material (i.e. dense molecular clouds or layers of dust).

Finally, for tens of thousands of years after the explosion the SUPERNOVA REMNANT may radiate high-energy γ-rays, produced by accelerated electrons and protons interacting with the ambient medium. The Crab remnant, observed since the late 1960s, as well as five other sources detected by CGRO, belongs to this class of γ-ray emitters.

γ-ray pulsars

PULSARS are rapidly rotating neutron stars, first detected in the late 1960s through their periodic radioemission. More than 550 radio pulsars are known to day, with periods ranging from a few ms to several seconds. Before the launch of CGRO, only the Crab and VELA PULSARS were known to emit periodically in the γ-ray domain. Since then five more objects have been added to the list and all of them (except Geminga) emit also in the radiofrequencies (figure 2).

The fact that only a small fraction of the radio pulsars emits in γ-rays suggests that a special environment is required for γ-rays to be produced. The required energy is presumably provided by the rotational energy of the neutron star, which slows down in the process; however, the emission mechanism as well as the role of the magnetic field and of the pulsar environment are not well understood. A hint may lie in the fact that the younger pulsars are more active in the low-energy ($\sim$1 MeV) domain than the older ones, which have in general weaker magnetic fields and emit essentially in the $>$100 MeV range.

GEMINGA is the only known pulsar with no detectable radio emission. Many years after its detection in γ-rays (by SAS-2), it represented an enigma, since it had not a counterpart in any other wavelength. Its period ($\sim$0.237 s) was first measured in x-rays by the German satellite ROSAT and confirmed in γ-rays by CGRO. Its distance, evaluated in the early 1990s to $\sim$100 light-years, makes it the closest known neutron star.

Accreting compact objects

NEUTRON STARS and BLACK HOLES are the end products of the evolution of massive stars and they may be found in binary systems (as happens with about half of the stars we observe in the Galaxy). Matter from the companion star may then be accreted onto the compact object, forming around it an ACCRETION DISK. As matter spirals in, heat is generated at the expense of gravitational energy and the inner disk may reach high temperatures. According to theory, disks around neutron stars may never reach temperatures higher than $T \sim 10^8$ K (corresponding to thermal emission in the x-rays), whereas disks around black holes may become much hotter ($T \sim 10^9$ K) and radiate in the low-energy γ-ray domain, up to a few hundreds of keV. γ-ray observations would allow then neutron stars to be distinguished from stellar black holes.

Observations with SIGMA and CGRO allowed a few black hole candidates in our Galaxy to be identified, on the basis of their γ-ray signature. Some of the sources show steady emission, while others present a variable behaviour (presumably as a result of variation in the accretion rate or of instabilities developed in their accretion disk). A typical example of this class of transient sources (or γ-ray novae) is the source GRS 1124-68, alias Nova Muscae. Detected in January 1991, it has been observed in radio, x-rays and γ-rays, its luminosity in the last of these energy ranges exceeding that of the Crab (which is the strongest γ-ray source in the sky).

An extremely important manifestation of variable γ-ray activity is the excess emission detected in the 300–600 keV range from the source 1E1740.7-2942, located

in the galactic center region; observed for 2 days in October 1990 by SIGMA, this 'paroxysmic' activity has been interpreted in terms of electron–positron annihilation in the vicinity of a stellar mass black hole. Follow up radio-observations of the source revealed radio-emitting jets, presumably due to synchrotron emission of accelerated electrons. This behaviour (compact 'erupting' γ-ray source + radio jets moving at relativistic velocities) has also been observed in a few other sites in our Galaxy. These objects form the family of 'micro-quasars' (by analogy with the much more powerful and distant QUASARS) and represent ideal laboratories for the study of gravitational and relativistic astrophysics.

Diffuse γ-ray emission in the galaxy

Some of the 'products' of stellar activity may pervade the interstellar medium and give rise to diffuse γ-ray emission. This is the case of cosmic rays (energetic particles, accelerated by supernova explosions), long-lived radionuclei (decaying away from their production sites) and positrons.

Diffuse γ-ray emission from the Galaxy was first detected in 1968 by OSO-7 and galactic maps were provided by COS-B and CGRO. The emission correlates, in general, with features of the galaxy known from observations in other wavelengths: the molecular 'ring' at a galactocentric distance of 10 000–15 000 light-years, the spiral arms or a few molecular clouds, i.e. sites of rich gaseous content and active star formation. The analysis of the local γ-ray spectrum shows that at low energies (1–30 MeV) it results mainly from bremsstrahlung radiation of cosmic ray electrons; at higher energies, the emission of π^0s dominates. The LARGE MAGELLANIC CLOUD is the only other normal galaxy where γ-ray emission of this type has been detected.

During its million-year lifetime, radioactive ^{26}Al from more than 10 000 Wolf–Rayet stars and supernova explosions has been accumulated in the Galaxy's disk. Its characteristic 1.8 MeV line has been detected by HEAO-3 in 1984 and mapped by CGRO as diffuse emission along the galactic plane (figure 3). The HEAO-3 detection revealed that stars continue to enrich the Galaxy with their nucleosynthesis products. The galactic ^{26}Al map reveals, better than any other tracer, where the sites of current nucleosynthesis lie in the Milky Way.

Balloon-borne spectrometers detected in the 1970s the electron–positron annihilation line (at 0.511 MeV) from the Galactic center direction. For some time it was

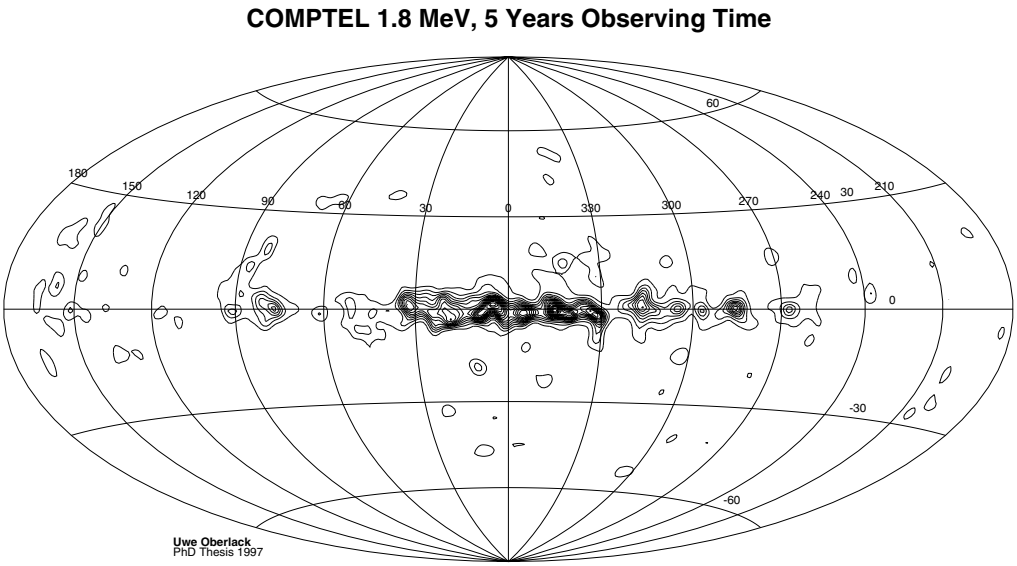

Figure 3. Map of the Galaxy in 1.8 MeV (^{26}Al line). Data from COMPTEL on CGRO.

thought that this emission was variable, but this variability was presumably due to the different properties of the instruments used. CGRO established the existence of diffuse (and steady) 0.511 MeV emission in the Milky Way, with ∼80% coming from the galactic bulge and the remaining ∼20% from the disk. Positrons produced by the β^+ decay of radionuclides, such as ^{26}Al, ^{56}Co and ^{44}Sc, are (most probably) at the origin of this galactic emission.

γ-ray bursts

Cosmic γ-ray bursts (GRBs), discovered in the late 1960s by the Vela satellites, are flashes of high-energy radiation which appear at random times from random directions, briefly dominating the γ-ray sky (from a few milliseconds to a few seconds) and then fading away. For more than a quarter of a century their nature remained a mystery: their non-thermal γ-ray emission presented no regularities at all, they did not seem to radiate in other wavelengths and it was impossible to evaluate their distances or to associate any known object with them.

The situation improved considerably in the 1990s. The BATSE instrument aboard CGRO detected about 1 burst per day for several years and established that their distribution in the sky is isotropic (figure 4). Such a distribution is naturally obtained from sources located at cosmological distances (several 10^8–10^9 light-years); in that case, their observed frequency implies about one burst per galaxy per million years, i.e. they represent events much rarer than supernovae. The Italian–Dutch x-ray satellite BeppoSAX allowed for an accurate location of GRBs, and in several cases relatively long-lived emission ('afterglow') at x-ray, optical and radio wavelengths was detected. In at least one case the afterglow optical spectra showed redshifted absorption lines due to the presence of remote intervening gas clouds, supporting the idea that the GRB is at a cosmological distance.

To be detectable at large distances, GRBs must radiate huge amounts of energy, about 10^{53} erg on average. Collisions involving neutron stars and/or black holes may produce such energies, mainly in the form of neutrinos, but the exact mechanism of the energy conversion to γ-rays is not elucidated yet. 'Fireball' models, involving material expanding at relativistic energies, seem the most promising at present.

Active galactic nuclei and blazars

The first detection of an extragalactic γ-ray source, the BRIGHT QUASAR 3C 273, was reported in 1978 by a team working with the COS-B satellite. Several other objects were subsequently detected in the low-energy γ-ray band (<1 MeV) and identified with the highly variable, moderately distant (redshift $z < 0.05$) ACTIVE GALACTIC NUCLEI (AGNs). In the 1990s, the EGRET instrument aboard CGRO detected high-energy γ-ray emission (>100 MeV) from several dozens of powerful and distant ($z > 2$) sources, a class of AGNs now known as BLAZARS; these objects radiate in their 'active' phase more energy in high-energy γ-rays (10^{45} erg s^{-1} on average) than in all other wavelengths.

The short time-scale of variability of AGNs (a few days to weeks for blazars), combined with their high γ-luminosities, suggests that accretion onto a massive black hole ($(10^6$–$10^9)M_\odot$) is the most probable power source. This idea could explain, in a unified framework, both the low-energy γ-emission of AGNs and the high-energy γ-emission of blazars. In the former case, the γ-rays are emitted from the hot inner regions of the accretion disk surrounding the black hole (as is the case with accreting stellar mass black holes in our Galaxy); in

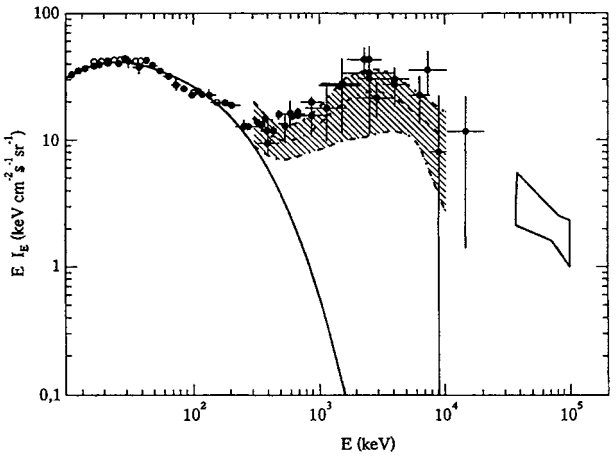

Figure 5. Diffuse extragalactic γ-ray background. Data compiled by Paul and Laurent (1998).

the latter case γ-rays are emitted by relativistic particles moving in diametrically opposite highly collimated jets (the intensity of the emission being enhanced along the direction of motion). This unified scheme seems able to explain not only the γ-ray properties of AGNs and blazars, but also their observed features in other wavelengths.

Diffuse extragalactic background

Since the early days of γ-ray astronomy, observations established the presence of a uniform, diffuse, isotropic γ-ray emission in the sky, most probably of extragalactic origin (figure 5). The most natural explanation for this diffuse γ-ray background involves the contribution of numerous extragalactic high-energy sources, unresolved by current instruments. In the low-energy range (<300 keV), the observed γ-ray background spectrum can be explained by the collective emission of Seyfert galaxies (a class of AGNs), while in the high-energy range (∼100 MeV) it is the collective emission of blazars that prevails; indeed, in both cases, the observed spectra of resolved individual sources compare favourably with the observed diffuse spectrum. Finally, the CGRO found no excess diffuse emission in the intermediate range of ∼1 MeV, contrary to all previous reports (obtained by instruments with underestimated and difficult to assess instrumental 'noise'). Despite that, this intermediate spectral region is not satisfactorily explained by the combination of Seyferts and blazars and another source seems to be required; the superposition of redshifted nuclear γ-ray lines from remote SNIa (mostly from the decay of ^{56}Co) seems the most promising candidate.

Bibliography

Most of the results of γ-ray astronomy in the 1990s can be found in the Proceedings of the CGRO and INTEGRAL symposia, held alternatively every two years.

Gamma-Ray Bursts

The serendipitous discovery of cosmic gamma-ray bursts (GRBs) was announced in 1973, based on the data of the military Vela spacecraft, whose purpose was to monitor the limited nuclear test ban treaty. However, it was not until the late 1990s that a clear idea of their origin was obtained. A GRB is a short-duration pulse of gamma radiation (<20 keV to energies up to tens of GeV). With instruments of sufficient sensitivity, about one burst per day can be observed. GRB durations range from 10 ms to 1000 s or more, but an average is about 10 s. For this short time, they may be the brightest objects in the gamma-ray sky. An example is shown in figure 1. Each burst comes from a unique, random direction; no two events have ever been detected from exactly the same direction. The distribution of burst sources on the sky is completely isotropic (figure 2). These properties, which are quite unlike those of typical gamma-ray sources (see gamma-ray astronomy) explain, in part, why progress in understanding the origin of bursts has been slow: Gamma-ray telescopes tend to have small fields of view and provide relatively coarse location information, making it impractical to monitor the entire sky and provide precise directional information with a single detector. The main detection techniques to date have been interplanetary networks and arrays of large-area detectors such as the Burst and Transient Source Experiment aboard the Compton Gamma-Ray Observatory. However, the inherent delays in the former, and the relatively coarse localizations provided by the latter, hampered efforts to detect burst sources at other wavelengths.

A breakthrough was achieved in 1997 by the Italian–Dutch BeppoSAX spacecraft, which carried both a wide-field x-ray camera and narrow-field x-ray telescopes. The wide-field camera made it possible to detect and locate bursts in the 2–10 keV energy range with a precision of several arcminutes. The spacecraft could then be slewed within hours to view the position of the burst source with the narrow-field telescopes. It was discovered that, long after the burst had disappeared in gamma-rays, a fading x-ray afterglow was present (figure 3). Rapid optical observations reveal similar afterglows at visible wavelengths, and radio observations show that slowly fading radio afterglows are also present. Deeper optical observations usually result in the detection of a faint host galaxy at the site of the burst with a typical redshift of 1 (implying distances of billions of light-years); it is often the case that the optical afterglow outshines its host galaxy for at least several days. Figure 4 shows an example of an optical afterglow and its host galaxy. These observations have established that the distance scale of cosmic GRBs is cosmological. This explains their perfectly isotropic sky distribution, which had been a controversial clue to their origin for many years. About two dozen bursts now have well-established redshift measurements (the largest being z=4.5).

If GRB sources emitted their radiation isotropically, their total energy output would be well above 1053 erg and it would be difficult to find viable sources for the energy. However, it seems more likely, both from a theoretical and from an observational viewpoint, that at least the gamma radiation is beamed into a relatively small cone, reducing the energy output by some two orders of magnitude. Two possible energy sources are collapsars (also known as hypernovae) and the merger of two compact objects in a binary system (such as two neutron stars). Observational evidence suggests that the former phenomenon is the one most likely to be responsible for the bursts whose optical counterparts and host galaxies have been studied.

In the collapsar or hypernova scenario, a massive star (approximately 30 solar masses) exhausts its nuclear fuel supply and collapses, forming a black hole surrounded by an accretion disk. Matter from the disk falls into the black hole and an intense magnetic field helps to extract energy from the system. Shells of matter are driven outwards at velocities very close to the speed of light. Collisions between these shells form shock waves which accelerate electrons to high energies and the electrons radiate the gamma-rays which constitute the GRB. As the shells continue to move outward, they eventually encounter a denser medium (either the interstellar medium or possibly a region filled with matter which was ejected from the progenitor star in earlier phases). Here they again form shock waves which accelerate electrons, and these electrons radiate the longer-lived radio, optical, and x-ray afterglows. This model is often referred to as the 'standard fireball model'.

The light curve of the optical afterglow decays as a power law with time. However, in several cases, there is clear evidence for a temporary departure from a power law (a 'bump' in the light curve). In most of these cases, a possible explanation is the emergence of a supernova-like component in the light curve, which is initially obscured by the intense optical light immediately following the burst. (In fact, in one instance, a gamma-ray burst was found to be spatially and temporally consistent with a known supernova, 1998bw.) Such a component might be expected in the hypernova scenario. In one case, however, an alternative explanation is gravitational lensing of the light by a foreground galaxy.

For all the bursts whose optical afterglows and host galaxies have been detected, the burst source lies well within the galaxy, and it often appears to be located within the galaxy's star-forming regions. The galaxies themselves appear to be normal galaxies, indistinguishable from their neighbors at similar distances; there is no indication that any are active galaxies.

For almost all the bursts with x-ray follow-up measurements, fading x-ray counterparts have been detected. However, only about 50% of the bursts display radio or optical counterparts, despite sensitive searches. The reasons for this are not well understood, but possible causes include heavily obscured sources, very high redshift sources and sources which are outside of their host galaxies. The last explanation might be appropriate for the merging compact object model; these binary systems can be ejected from their host galaxies long before they merge and, lacking a surrounding interstellar medium, might not generate the shocks needed to produce long wavelength afterglows.

Although some of the basic physics of GRBs is now understood, the field is in many respects in its infancy. Many more observations are needed to sort out the following questions (among others): 1. Can GRBs be used to trace star formation in the early universe? 2. Can GRBs be detected at redshifts corresponding to the reionization epoch? 3. What is the relation between GRBs and supernovae? 4. Why do some bursts display no radio or optical afterglows? A major GRB mission, Swift, will address these and other questions. Swift is a NASA Midex mission scheduled for launch in October 2003. It comprises three instruments: a burst alert telescope, an x-ray telescope and a UV/optical telescope. The burst alert telescope will survey a wide field for GRBs, which it will localize with several arcminute accuracy. The spacecraft will then slew to the position of the burst to observe it with its x-ray and UV/optical cameras, providing information on the long-wavelength afterglows and on the source redshift. Swift is expected to detect over 100 bursts per year and last for a minimum of 2 years.

Web update (30 April 2003)

On December 11, 2002, scientists obtained an image of an unusual type of GRB event one minute after the explosion. They captured a particularly fast-fading type of dark burst, which comprises about half of all GRBs. These dark bursts are so named because until this event, they have had no detectable optical afterglow. NASA's High Energy Transient Explorer (HETE) discovered this burst on December 11, 2002. The burst originated six billion light-years away, and HETE relayed its location to observatories worldwide in 22 seconds. The ground-based RAPTOR (RAPid Telescopes for Optical Response) optical telescope, operated by the Los Alamos National Laboratory in New Mexico, was the first on the scene,

Gamma-Ray Telescopes

Gamma-rays are the highest-energy photons in the ELECTROMAGNETIC SPECTRUM and their detection presents unique challenges. On one hand it is easy to detect γ-rays. The interaction cross-sections are large and above a few MeV the pair production interaction, the dominant γ-ray interaction with matter, is easily recognized. Gamma-ray detectors were far advanced when the concept of 'γ-ray astronomy' was first raised in Phillip Morrison's seminal paper in 1958. Indeed it was the expected ease of detection and the early promise of strong sources that led to the large concentration of effort in the field, even before the development of X-RAY ASTRONOMY. Today the number of known γ-ray sources is well under a few hundred whereas there are hundreds of thousands of x-ray sources. What went wrong?

The answer is simple: the detection of cosmic γ-rays was not as easy as expected and the early predictions of fluxes were hopelessly optimistic. Below we consider the physical phenomenon whereby γ-rays interact with matter, the basic detector configurations and the detectors which have provided the bulk of the observational results; we conclude with a description of the techniques now under development.

First we provide a few definitions and a few caveats. The term 'γ-ray' is a generic one and is used to describe photons of energy from 100 keV (10^5 eV) to >100 EeV (10^{20} eV). A range of 15 decades is more than all the rest of the known electromagnetic spectrum. A wide variety of detection techniques is therefore necessary to cover this huge range. We will concentrate on the telescopes in the somewhat restricted range from 1 MeV to 100 TeV. The lower definition comes from the knowledge that the lower energies are better covered by the techniques used to cover hard x-ray astronomy and that many authors would define the γ-ray regime as starting at 0.51 MeV (the rest mass energy of the electron). There are no credible detections of γ-rays at energies much beyond 50 TeV and the 'γ-ray telescope' techniques used beyond these energies are really the same as those used to study charged COSMIC RAYS and hence are best discussed under that heading. We are left with some eight decades which we will, somewhat arbitrarily, define as the medium-energy (ME) range from 1 to 30 MeV, the high-energy (HE) range from 30 MeV to 100 GeV and the very-high-energy (VHE) range from 100 GeV to 100 TeV. These ranges are not defined by the physics of their production but by the interaction phenomena and techniques employed in their detection. Thus Compton scattering dominates the ME range necessitating the use of satellite-borne Compton telescopes. The HE and VHE ranges use the pair production interaction but in very different ways; HE telescopes identify the electron pair in balloon- or satellite-borne detectors, whereas VHE detectors detect the electromagnetic cascade that develops in the Earth's atmosphere.

GAMMA-RAY ASTRONOMY is still an observation-dominated discipline and the observations have been driven not so much by the astrophysical expectations (which have often been wrong) as by the experimental techniques, which have permitted significant advances to be made in particular energy ranges. Hence the most fruitful observations have come at energies of 100 MeV; these were originally inspired by the prediction of the strong bump in the spectra expected from the decay of π^0s that are created in hadron interactions. This energy region was exploited primarily because the detection techniques were simpler and more sensitive. In contrast the ME region has the potential for very interesting astrophysics with the predicted existence of nuclear emission lines but the development of the field has been slow because the techniques are so difficult.

Peculiarities of γ-ray telescopes

There are several peculiarities that uniquely pertain to astronomy in the γ-ray energy regime. These factors make γ-ray astronomy particularly difficult and have resulted in the slow development of the discipline.

In every band of the electromagnetic spectrum astronomical telescopes make use of the fact that the cosmic rain of photons can be concentrated by reflection or refraction, so that the dimensions of the actual photon detector are a small fraction of the telescope aperture. How limited would have been our early knowledge of the universe if the optical astronomer had not been aided by the simple refracting telescope which so increased the sensitivity of the human eye. The radio astronomer, the infrared astronomer, even the x-ray astronomer, depends on the ability of a solid surface to reflect and, with suitable geometry, to concentrate the photon beam.

Above a few MeV there is no efficient way of reflecting γ-rays and hence the dimensions of the γ-ray detector are effectively the dimensions of the γ-ray telescope. (As we shall see in a later section this is not the case for ground-based VHE telescopes.) In practice to identify the γ-ray events from the charged particle background it is necessary to use detectors whose efficiency is often quite low. Hence at any energy the effective aperture of a space-borne γ-ray telescope is seldom greater than 1 m^2 and often only a few cm^2, even though the physical size is much larger. For instance the COMPTON GAMMA RAY OBSERVATORY (CGRO) was one of the largest and heaviest scientific satellites ever launched; however, its ME and HE telescopes had effective apertures of 1600 cm^2 and 5 cm^2 respectively. Beam concentration is particularly important when the background scales with detector area. This is the case with γ-ray detectors which must operate in an environment dominated by charged cosmic rays.

The problem of a small aperture is compounded by the fact that the flux of cosmic γ-rays is always small. At energies of 100 MeV the strongest source (the Vela pulsar) gives a flux of only 1 photon min^{-1}. With weak sources long exposures are necessary and one is still dealing with the statistics of small numbers. It is small wonder that γ-ray astronomers have been frequent pioneers in

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the development of statistical methods and that γ-ray conferences are often dominated by arguments over real statistical significance.

As it is to photons in many bands of the electromagnetic spectrum the Earth's atmosphere is opaque to all γ-rays. The radiation length is 37.1 g cm^{-2} and the total vertical thickness at sea level is 1030 g cm^{-2}. Even the highest mountain is many radiation lengths below the top of the atmosphere so that it is virtually impossible to consider the direct detection of cosmic γ-rays without the use of a space platform. Large balloons can carry the bulky detectors to near the top of the atmosphere and much of the pioneering work in the field was done in this way. However, the charged cosmic rays constitute a significant background and limit the sensitivity of such measurements.

The background can take many forms. In deep space it is the primary cosmic radiation itself, mostly protons, heavier nuclei and electrons. This background can be accentuated by secondary interactions in the spacecraft itself. Careful design and shielding can reduce this effect, as can active anti-coincidence shields. However, at low energies induced radioactivity in the detector and its surrounds can be a serious problem. In balloons the secondary cosmic radiation from the cosmic ray interactions above the detector seriously limit the sensitivity and were the initial reason for the slow development of the field. Huge balloons that carry the telescopes to within a few grams of residual atmosphere are a partial solution, but it is still impossible to trust the measurement of absolute diffuse fluxes.

Physics of γ-ray interactions

In the energy region above 1 keV there are basically three processes by which the γ-rays can interact with the matter in the detector: these are the photoelectric effect, Compton scattering and pair production. The relative cross-sections, or, more practically, the mass absorption coefficients peak in different energy ranges. The cross-section has the same functional form for all materials, although the actual values and relative strengths of the three processes may differ somewhat. As the photoelectric effect, the interaction of the γ-ray with bound electrons in atoms, is only important at low energies (<1 MeV), we shall not consider it here.

Compton scattering

This is the most complex of the three interactions, and hence detectors which depend on it are the most complicated and the most difficult to interpret. It is important primarily in the energy range from 100 keV to 30 MeV and hence γ-ray astronomy in this range has been the slowest to develop.

In Compton scattering the electron is unbound and it alone must take up the energy and momentum of the γ-ray. In practice the γ-ray may undergo one or more Compton scatterings, losing energy to the electron in each case, until eventually it may undergo a photoelectric reaction. In each scattering the electron will take up some of the energy as kinetic energy and the γ-ray will change direction.

The relationship between the incident energy of the γ-ray, E, and the resultant energy, E', where both are expressed in units of E_e, the rest mass of the electron, is given by

$$E' = E/(1 + E[1 - \cos\theta)]$$

where θ is the scattering angle of the γ-ray. The maximum energy loss comes for backward scattering at which the scattered energy is

$$E' = E/(1 + 2E).$$

For $E > 0.51$ MeV, E' is close to 0.5 (or 0.255 MeV) which is the typical energy loss per scattering, independent of E.

At low energies the cross-section is given by the Thomson cross-section

$$\sigma_c = \sigma_T = (8\pi/3)e^2/m_e c^2 = 0.665 \text{ barns}$$

and at high energies

$$\sigma_c = (3/8)E(\ln 2E + 1/2)\sigma_T.$$

Hence Compton scattering is almost independent of the incident energy so that the cross-section decreases only slowly with energy.

Pair production

In the pair production interaction, the γ-ray is completely annihilated with its energy transferred to an electron–positron pair which is created, i.e.

$$h\nu \rightarrow e^+ + e^-.$$

The interaction takes place in the electric field of a nucleus which takes up some of the momentum. Obviously the threshold for the interaction must be >1.02 MeV (i.e. $2m_e$). The interaction can also occur in the field of an electron, but the cross-section is much less and the threshold is higher. The energy of the γ-ray is taken up by the electron–positron pair as rest mass and kinetic energy. The positron will generally annihilate with an electron to produce two γ-rays, which can Compton scatter or suffer photoelectric absorption. These secondary products at moderate energies can be totally absorbed in the detector; by measuring their energy plus the rest mass of the pair, the energy of the γ-ray is estimated.

The cross-section for pair production rises rapidly and becomes dominant above energies of about 30 MeV, after which it rises slowly to an asymptotic value. This value is given by

$$\sigma_{pp} = \sigma_0 Z^2[(28/9)\log(183/Z^{1/3}) - 2/27] \text{ cm}^2/\text{atom}$$

where $\sigma_0 = (1/137)e^4/m_e^2c^4$.

The mean distance that a γ-ray travels before it undergoes pair production is given by

$$\lambda_{pp} = 1/N\sigma_{pp}$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

where N is the number of target nuclei per unit volume.

The mean free path for pair production is related to the radiation length, X_0:

$$\lambda_{pp} = (9/7)X_0.$$

A critical factor is the degree to which the electron–positron pair retain the trajectory of the γ-ray. The root mean square angle between the trajectory of the secondary electron of energy E_e and that of the primary γ-ray of energy E_γ is about 4° at $E_\gamma = 30$ MeV, 1.5° at $E_\gamma = 100$ MeV and 0.2° at $E_\gamma = 1$ GeV. The value of observations at high energies is thus apparent.

Unfortunately it is not possible to measure the electron trajectory precisely as it will inevitably undergo Coulomb scattering as it passes through the material of the detector.

Measuring the energy of the γ-ray is essentially measuring the energy of the electron–positron pair and their secondary products. This requires that the detector have sufficient mass to absorb all these products. In practice this usually calls for a calorimeter with as much absorber as the spacecraft can carry.

ME and HE telescopes

Compton telescopes

The basic detector of γ-rays in the difficult 100 keV–10 MeV energy range is the scintillation detector, which consists of a solid or liquid material, in which light is produced by charged secondary particles resulting from the photoelectric or Compton scattering γ-ray interaction, and a phototube, in which light is converted into an electrical signal. A common material is thallium-activated sodium iodide, NaI(Tl). Charged particles are rejected by surrounding the detector by another plastic scintillator detector. If the outer detector is shaped like a well with small opening then it can serve as a collimator with crude angular resolution. Many of the early detectors worked on this principle.

A more sophisticated detector is the Compton telescope in which two detectors are operated in series (figure 1). In the front detector a primary γ-ray, which Compton scatters in the forward downward direction, is selected (based on the energy registered by the first detector from the recoil electron); the γ-ray is then absorbed in another Compton scatter in the lower detector. The lower detector is surrounded by an anti-coincidence scintillator to veto charged particles coming up from below. Of necessity because of the wide range of angles that the scattering may have, the efficiency of these simple detectors is poor, typically less than 1%. However, the energy and angular resolutions are improved over the simple one-stage detector.

The upper detector should have a large cross-section for Compton scattering over the desired energy range. In the 1–10 MeV region the best material is one with low Z; hence the detector should be a relatively thin liquid or plastic scintillator so that a single Compton scattering occurs with good efficiency. The second, lower, detector should totally absorb the product of the second Compton scatter and hence should be thicker and composed of high-Z material.

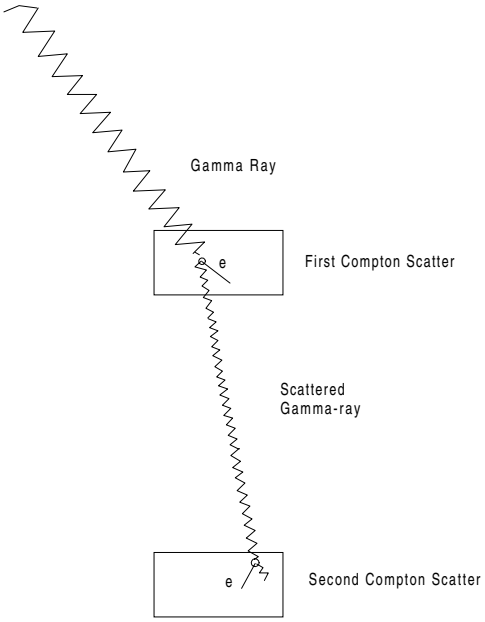

Figure 1. Schematic of double Compton scatter. In the upper scintillator the primary γ-ray Compton scatters in the downward direction; the γ-ray is then absorbed in another Compton scatter in the lower detector. In each case the energy of the recoil electron is measured and thence the energy and arrival direction of the primary are determined.

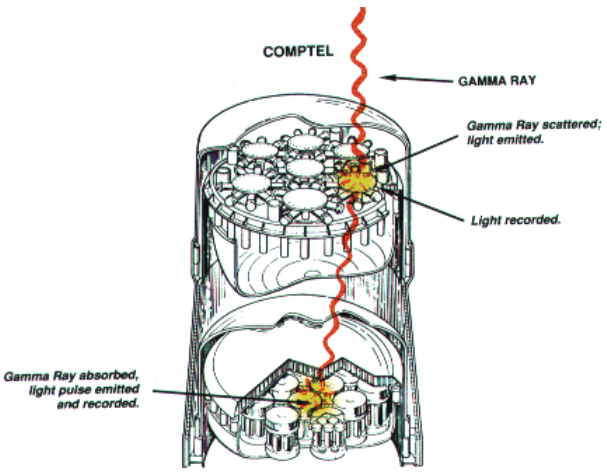

Figure 2. An example of a Compton telescope: COMPTEL. It is sensitive from 1 to 30 MeV. The angular resolution is 3–5°.

A double Compton scattering is also the basic principle used in the most sophisticated 1–30 MeV telescope flown to date, COMPTEL on the CGRO (figure 2). The primary γ-ray incident within ±40° of the telescope axis first Compton scatters in the upper detector which is a

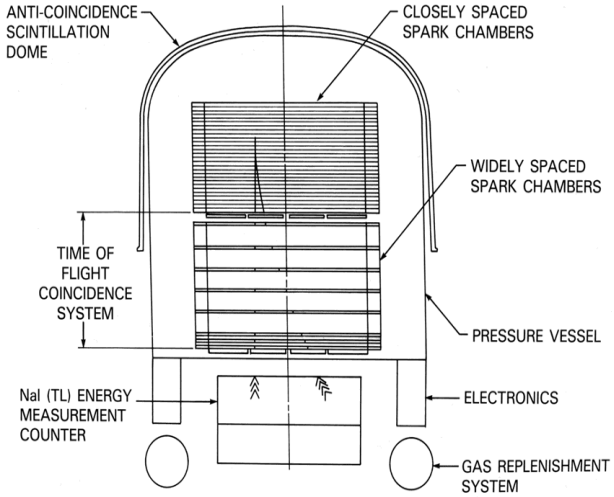

Figure 3. Example of a spark chamber telescope: EGRET. The telescope is sensitive from 30 MeV to 30 GeV. The field of view $\pm 20^\circ$ and the energy resolution is about 20%.

low-Z liquid scintillator; the second scattering takes place in the lower detector which is a high-Z NaI(Tl) scintillator. Each detector actually consists of seven modules and the separation between the two layers is 1.5 m. Hence time of flight can be used to discriminate against upward-going particles. In addition, all of the detectors are surrounded by thin plastic anti-coincidence scintillators which respond to charged particles. If the energy deposited in the upper and lower modules is measured, then the direction of the incident γ-ray can be determined to be within a narrow ring on the sky and its energy estimated to about 5–10%. A source then is apparent as the locus of intersections of a number of such rings.

Pair production telescopes

The spark chamber, long obsolete for HE physics experiments, has been the workhorse detector for γ-ray astronomy in the energy range 30 MeV–10 GeV from the early 1960s through the end of the century. The three experiments, which provided almost all the results during this period, all used the spark chamber as their principal detector. These were the USA's SAS-II (1973), Europe's COS-B (1975–82) and the joint European– USA EGRET on the Compton Gamma Ray Observatory (1991–).

Although the basic principles of the pair production telescope are simple, the detailed design is complex and accounts for the fact that the effective collection area is far smaller than the geometrical cross-section of the telescope. This is illustrated by EGRET, the pair production telescope on the CGRO. As with most pair production spark chamber telescopes, this consists of four distinct components which are shown schematically in figure 3.

(i) A spark chamber usually consists of a series of parallel metal plates in a closed container; the alternate plates are connected together electrically with one set permanently connected to ground. On an indication that a charged particle has passed through the chamber, a high voltage is applied to the second set of plates. The chamber contains a gas at a pressure such that the ionization left behind by the passage of the charged particle causes an electric spark discharge between the plates. The gas is a mixture of neon and ethane. An electron–positron pair created by a γ-ray interaction in one of the plates is then readily apparent as a pair of sets of sparks that delineate the path of the electron and positron. In practice the tracks are disjointed as the electrons suffer multiple scattering within the plates of the chamber. This limits the thickness of the plates (which should be as thick as possible to ensure that the γ-rays interact effectively, but not so thick that the electrons undergo excessive Coulomb scattering in the plate material). Multiple plates ensure that the tracks are effectively mapped. The collection area and angular resolution of the telescope are determined by the spark chamber geometry. In EGRET the spark chamber 'plates' consist of 28 wire grids interleaved with interaction plates of 0.02 radiation lengths thickness in which the γ-ray interacts. Each wire is threaded through a magnetic core memory, which is read out and reset after each event.

(ii) At least one electron must emerge from the spark chamber to ensure that it initiates a trigger that causes the application of the high-voltage pulse to the second set of plates to activate the spark chamber. A permanent high-voltage difference cannot be maintained between the plates, as the spark discharges will take place spontaneously. EGRET is triggered by a coincidence between two thin sheets of plastic scintillator with a 60 cm separation (sufficient to recognize and reject upward-going charged particles). It is the need for this trigger which limits the lower-energy threshold of the spark chamber telescope. The trigger detection system effectively defines the field of view of the telescope.

(iii) The electrons must be completely absorbed if their energy is to be measured; to achieve this there must be a calorimeter that is some radiation lengths thick. In EGRET, as in most spark chamber telescopes, this is an NaI(Tl) crystal, whose sole function is to measure the total energy deposited. At the low end of the sensitivity range the energy of the electrons can also be determined by the amount of Coulomb scattering in the plates of the spark chamber.

(iv) Finally the entire assembly is surrounded by an anti-coincidence detector which signals the arrival of a charged particle, but which has a small interaction cross-section for γ-rays. This consists of a very thin outer shell of plastic scintillator viewed by photomultipliers.

EGRET is the largest and most sensitive HE γ-ray telescope flown to date; it is the flagship instrument on

CGRO. Approximately the size of a compact car and with a total mass of 1900 kg, the telescope has an effective collection area of 1600 cm^2. The characteristics of the telescope are listed in table 1.

The telescope was designed for a 5 yr lifetime. The gas which fills the chamber gradually becomes poisoned and must be replenished. It was expected that a filling would last 1 yr. Hence only four gas canisters were attached to the instrument for replenishment at yearly intervals. In practice the unprecedented and unexpected success of CGRO meant that the mission was extended as were the replenishment intervals so that, for a considerable fraction of the 9 yr lifetime of the mission, EGRET operated at less than optimum efficiency.

VHE telescopes

Air Čerenkov telescopes

When an HE γ-ray strikes the upper atmosphere, it produces an electron–positron pair (as it does in a spark chamber). However, if the energy of the γ-ray, and hence of the electron–positron pair, is large enough, an electromagnetic cascade will result which will continue down through the atmosphere with secondary γ-ray and electron production by bremsstrahlung and pair production. The cascade will continue along the axis of the trajectory of the original γ-ray and the total energy of the secondary particles will be a good representation of its energy.

For γ-rays of energy 100 TeV and above, sufficient particles can reach ground level for the shower to be detected by arrays of particle detectors spread over areas of 0.1 km^2. As the secondary particles all move at nearly the speed of light and retain the original trajectory of the primary γ-ray, the shower front arrives as a disk which is only a meter thick. Differential timing between the detectors can then determine the arrival direction and hence the source of the γ radiation.

At lower energies the cascade will die out as the average energy of the secondary particles drops to the point that ionization losses become the major loss process (figure 4). For a primary γ-ray of energy 1 TeV, few secondary particles will reach even mountain altitude. However, as the relativistic particles traverse the atmosphere, they excite the atmosphere to radiate Čerenkov light with high efficiency. Although the fraction of energy that goes into this mode is small (less than 10^{-6} of the primary energy), it permits a very easy way to detect the cascade and thence the γ-ray. A simple light detector (mirror, plus phototube, plus fast pulse counting electronics) provides an easy way of detecting the cascade. Early telescopes consisted of ex-World War II searchlight mirrors with phototubes at their foci, coupled to fast pulse counting electronics.

The observations are best made from a dark mountain top observatory. Since the Čerenkov angle in air is about 1° and the amount of light is proportional to the number of particles in the cascade (and hence to the energy of the γ-ray), the measurement of the atmospheric Čerenkov

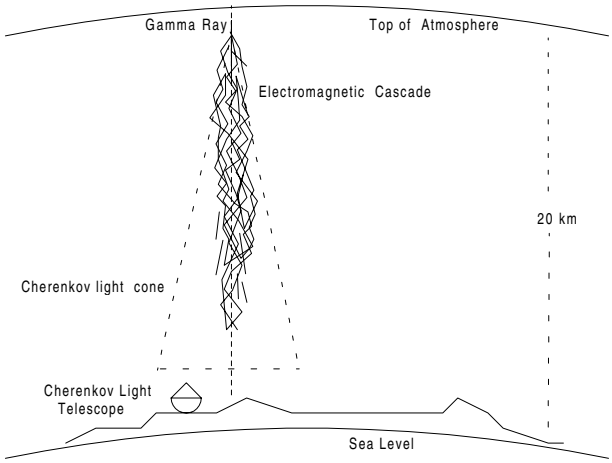

Figure 4. Schematic of atmospheric air shower detection. The γ-ray interacts with an air molecule high in the atmosphere and produces an electron–positron pair. These electrons subsequently interact and produce an electromagnetic cascade. The passage of relativistic particles through the atmosphere causes the emission of Čerenkov light which reaches ground level as a disk of diameter 200 m and thickness 1 m. The light can easily be detected by optical Čerenkov light telescopes (not to scale).

component provides a good measure of the energy and arrival direction of the γ-ray. Because the light spreads out as it traverses the atmosphere, the collection area for γ-ray detection is as large as the lateral dimensions of the light pool at detector altitude; this can be as much as 50 000 m^2.

This is one of the few astronomical techniques in which the Earth's atmosphere plays an essential positive role. However, the technique has its drawbacks. Although the atmosphere comes cheap (and the gas does not need to be replenished), the observer has no control over it; the telescope is wide open to the elements and the detector is susceptible to a troublesome background of light from Sun, Moon and stars, from the airglow, from lightning and meteors, and from a variety of man-made light sources, from satellites and airplanes to airport beacons and city lights. These limit the sensitivity for γ-ray source detection. However, the most troublesome background is that from air showers generated by charged cosmic rays of similar energy to the γ-rays under study. These air showers are cascades of particles which are superficially very similar to a pure electromagnetic cascade but contain penetrating particles (mostly muons) which reach ground level (see COSMIC RAYS: EXTENSIVE AIR SHOWERS). These showers are thousands of times more numerous and their light flashes are difficult to distinguish from those from γ-rays. Because of interstellar magnetic fields, the arrival directions of the charged cosmic rays are isotropic; hence a discrete source of γ-rays can stand out only as an anisotropy in an otherwise isotropic distribution of air showers. Unfortunately a γ-ray source would have to be very strong (a few per cent of the cosmic radiation) to be detectable in this way.

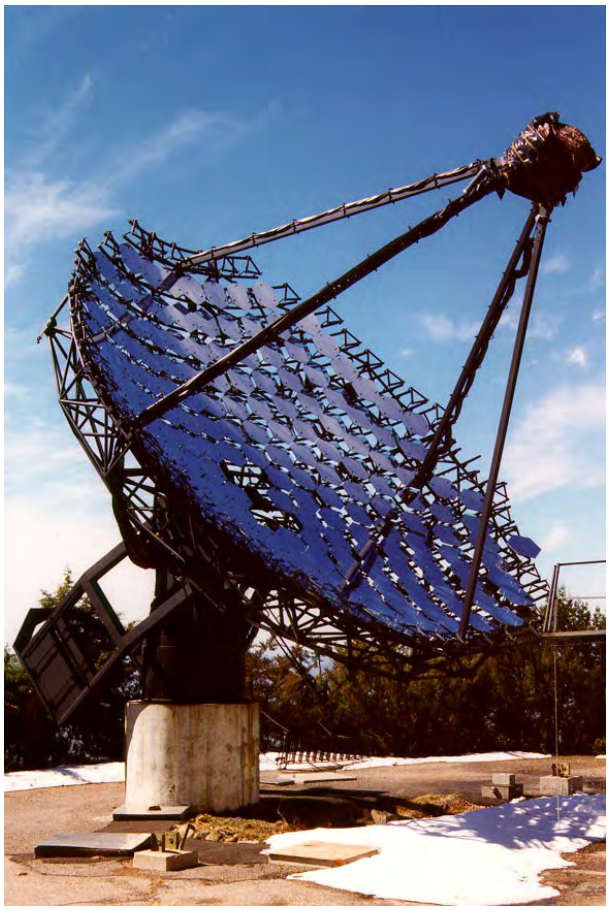

Figure 5. The Whipple 10 m γ-ray telescope. Note the '10 m' refers only to the aperture of the optical reflector; the effective collection area is >50 000 m^2 so that the γ-ray 'aperture' is 120 m.

Imaging detectors

Early attempts to discriminate the electromagnetic showers initiated by γ-rays from air showers initiated by charged particles were unsuccessful using either the ground-level arrays of particles detectors or atmospheric Čerenkov detectors. The development of the Čerenkov imaging technique gave the first effective discrimination; an array of photomultipliers in the focal plane of a large optical reflector was used to record a Čerenkov light picture of each air shower. Monte Carlo simulations of the development of air showers from photon and hadron primaries predicted that the images of the former would have somewhat smaller angular dimensions and thus could be identified. The largest optical reflector built for γ-ray astronomy is the Whipple Observatory 10 m optical reflector (built on Mount Hopkins in southern Arizona in 1968) (figure 5); in 1984 this was equipped with a photomultiplier camera with 37 pixels which was used to detect the CRAB NEBULA. This first detection led to a rapid development of the imaging technique, with significant improvements in flux sensitivity.

There are currently nine observatories around the globe using variants of this technique and the detection of some 13 sources has been claimed, both in the Galaxy and beyond. Background rejection of cosmic rays is now in excess of 99.7%, and the technique is effective from energies of 250 GeV–50 TeV. The energy resolution is typically 30–40%. A signal with significance of (5–10)σ can be detected from the Crab Nebula in just an hour of observation. Because of the very large collection area associated with the technique (>50 000 m^2), it is particularly powerful for the detection of short transients in TeV γ-ray sources (see also VERY-HIGH-ENERGY GAMMA-RAY SOURCES). In fact the shortest flare ever seen from a known γ-ray source at energies greater than 1 MeV was recorded from the blazar, Markarian 421; the duration of the TeV flare was 15–20 min. In some cases the telescope is an array of small reflectors operated in a stereo mode, e.g. the German–Spanish HEGRA experiment in the Canary Islands.

Table 1. Comparison of EGRET and GLAST.

Parameter	Units	EGRET (achieved)	GLAST (desired)
Energy range	GeV	0.02–30	0.02–300
Effective area	cm^2	1500	8000
Field of view	sr	0.5	2
Angular resolution (at 100 MeV)	deg	5.8	3.0
Energy resolution	%	10	10
Source sensitivity (>100 MeV) $\times 10^{-7}$	cm^{-2} s^{-1}	1	0.04

There are also two air shower particle detectors which have successfully detected γ-rays of a few TeV from the strongest sources. One is a large water Čerenkov detector, MILAGRO near Los Alamos, New Mexico, USA, at an elevation of 2.6 km. The other is a densely packed array of scintillation detectors in Tibet, which operates at an elevation of 4.3 km. Although these telescopes are somewhat less sensitive, they have the advantage over Čerenkov telescopes in that they can operate continuously and hence monitor a large section of the sky.

Future telescopes

INTEGRAL

The International Gamma-Ray Astrophysics Laboratory (INTEGRAL) is primarily a European mission which will be launched in 2001. It will operate in the 15 keV–10 MeV region with two prime objectives: good angular resolution (12 arcmin) and good energy resolution ($E/\delta E$) = 500). To achieve these objectives two instruments are used: the spectrometer SPI based on solid-state germanium detectors with coded aperture masks to define the field of view and the imaging IBIS which used cadmium telluride and cesium iodide detectors. These detectors are supplemented by small x-ray and optical telescopes for the monitoring of transient sources over a broad range

Dirac House, Temple Back, Bristol, BS1 6BE, UK

of wavelengths. The detector design is based on the assumption that broad lines are emitted from point-like sources and narrow lines come from extended sources as indicated by earlier missions.

GLAST

The next-generation pair production telescope will replace the spark chamber with solid-state detectors which will be more compact, more efficient and have better angular and energy resolution. However, the general principle of the telescope will be the same, with an anti-coincidence scintillator shield, an interaction region with three-dimensional imaging system and a calorimeter; only the triggering system is unnecessary, as the imaging system can be active all the time. There are no expendables and no noisy pulsed high voltage and sparks.

NASA envisages the next-generation telescope as operating in the range 20 MeV–300 GeV, with a scheduled launch date of 2005. With the somewhat unimaginative acronym, GLAST (Gamma-Ray Large Area Space Telescope), GLAST will surpass EGRET by a factor of 10–40 in most parameters. A comparison of the two missions is given in table 1.

There are two competing technologies for the central pair production detector on GLAST. One (fiber GLAST) uses crossed planes of silicon fibers coupled to multi-anode photomultipliers, separated by thin layers of high-Z converter plates. The calorimeter uses the same kind of detector but with thicker plates. The fibers are 1.3 m long and the whole detector is 1.8 m high; they have a square cross-section of side <1 mm. This technology has already been used in cosmic ray particle experiments and is thus favored by space scientists. The other technology (silicon GLAST) uses the silicon strip technology that has been used in HE particle accelerator experiments for a number of years; it has not so far been used in space science applications. Again the layers of ionizing-particle-sensitive detectors are alternated with thin layers of lead converter. The calorimeter will be made of bars of cesium iodide, with individual read-outs to give spatial resolution.

Both technologies seem to address equally well the physical demands of GLAST, so it will be a difficult choice to select just one of them. Remarkably both technologies can achieve the dramatic improvement over EGRET, outlined in table 1, with an instrument that will only be twice as heavy.

Next-generation VHE telescopes

The success of the atmospheric Čerenkov imaging technique has led to plans for next-generation VHE telescopes (NGVHETs) of increased collection area and complexity. One of the most ambitious of these is the Very Energetic Radiation Imaging Telescope Array System (VERITAS), first proposed to the Smithsonian Institution in 1996. An international collaboration has been formed to build this array of 10 m aperture Čerenkov telescopes in southern Arizona.

Similar NGVHETs are now under construction in the southern hemisphere: the High Energy Stereoscopic System (HESS) is a European collaboration based in Heidelberg, Germany, which plans to build an array of four 12 m telescopes in Namibia and the Collaboration of Australian and Nippon for a Gamma-Ray Observatory in the Outback-IV (CANGAROO-III) is an Australian–Japanese collaboration which will add three more 10 m telescopes to their existing 10 m telescope in Woomera, Australia.

VERITAS will consist of six telescopes located at the corners of a hexagon of side 80 m with a seventh at the center. The telescopes will be similar to the design of the Whipple 10 m reflector, which is the most sensitive telescope of its kind. By employing largely existing technology in the first instance and stereoscopic imaging, VERITAS will achieve the following:

- effective area >0.1 km^2 at 1 TeV;
- effective energy threshold <100 GeV with significant sensitivity at 50 GeV;
- energy resolution 10–15% for events in the range 0.2–10 TeV;
- angular resolution $<0.05^\circ$ for individual photons and source location to better than 0.005°.

Other designs are also under consideration. In the northern hemisphere a European collaboration centered in Munich, Germany, is building an advanced technology 17 m telescope called MAGIC. This will effectively bridge the energy gap between space- and ground-based γ-ray telescopes. There are also three groups using large solar arrays in an attempt to significantly lower the threshold of the technique. Although their optics are crude, such arrays can have very large mirror areas (>1000 m^2) and attain energy thresholds below 50 GeV. Two such experiments, STACEE in the USA and CELESTE in France, have already reported the detection of a signal from the Crab Nebula.

Gamow, George (1904–68)

Physicist, born in Odessa, Russia, researched on radioactivity and atomic fission, emigrated to the USA. Worked with EDWARD TELLER on beta decay, worked out the theory of stellar nuclear reactions in terms of the tunneling of a colliding nucleus through another nucleus's potential barrier. Even though there is only a small probability that a nucleon in the Sun would tunnel through the electrostatic repulsion barrier of another (say once every 10 000 million milllion million collisions), collisions in the solar core are so frequent that enough nuclei do get close enough to fuse and release solar energy. Gamow developed a Big Bang cosmology in which a primordial matter (ylem) existed at the origin of the universe. He supported the LEMAÎTRE Big Bang model, predicting that its consequence was a residual cosmic fireball of background radiation with a temperature of 10 kelvin (PENZIAS and WILSON later discovered this radiation at 3 kelvin, surprisingly close to Gamow's prediction). He was the prime mover for a theory for the origin of the elements in the Big Bang in which neutrons were sequentially added to hydrogen to build up the periodic table of elements one by one. This was the alpha–beta–*gamma* theory, named in part for the sequence and in part for the authors, ALPHER, BETHE and Gamow himself. Outside astronomy, he correctly theorized that the DNA structure forms a code that directs protein synthesis. He was a successful popularizer of science, inventing a cartoon character, Mr Tompkins, who traveled through a world of scientific adventure.

Ganymede

Ganymede, one of Jupiter's icy moons and one of the Galilean satellites, is the largest planetary satellite in the solar system (see figure 1). This moon, which is larger than the planet Mercury (Ganymede's radius is 2638 km, Mercury's radius is 2439 km), generates its own magnetic field and has large polar caps composed of thin frosts which reach an average latitude of 40 degrees. On a global scale the surface of Ganymede can be subdivided into two basic terrains: dark terrain and bright terrain (see figure 2).

Dark terrains, which make up approximately one-quarter of Ganymede's surface area, are older, more heavily cratered regions that are generally crosscut by areas of the younger bright terrain. The low ALBEDO of the dark terrain is thought to be due to mixtures of rocky material with water ice on the surface. The origin of the dark material is unknown, but it is believed to have resulted in part from the non-ice components of the many meteors and comets that have hit Ganymede over geologic time. Although dark terrain was originally characterized using global VOYAGER images, moderate to high-resolution Galileo images show that dark terrain is made up of discrete regions with a range of albedos (e.g. bright hummocks interspersed with smooth dark patches; see GALILEO MISSION TO JUPITER). The relatively higher-albedo regions within dark terrain are brightened by both tectonic and impact processes. Dark material also appears to have moved down slopes, exposing bright icy walls, and collecting in valleys and depressions.

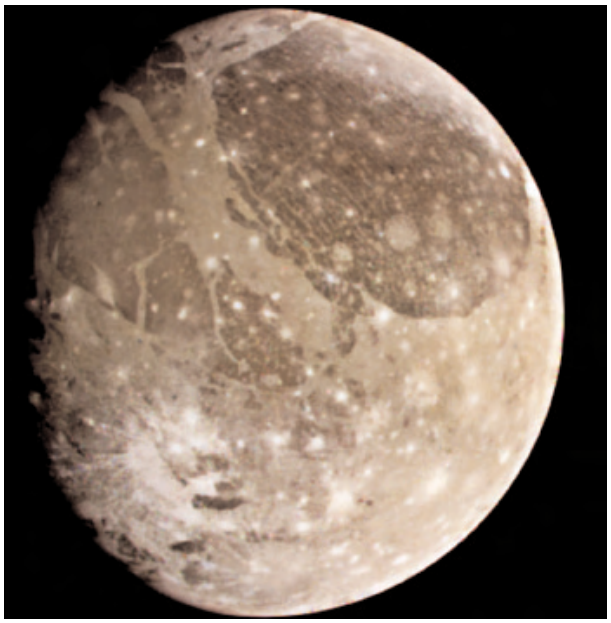

Figure 1. View of Ganymede from the Galileo spacecraft during its first encounter with the satellite. North is to the top of the picture and the Sun illuminates the surface from the right. The dark areas are the older, more heavily cratered regions and the light areas are younger, tectonically deformed regions. The brownish-gray color is due to mixtures of rocky materials and ice. Bright spots are geologically recent impact craters and their ejecta. The finest details that can be discerned in this picture are about 13.4 kilometers across.

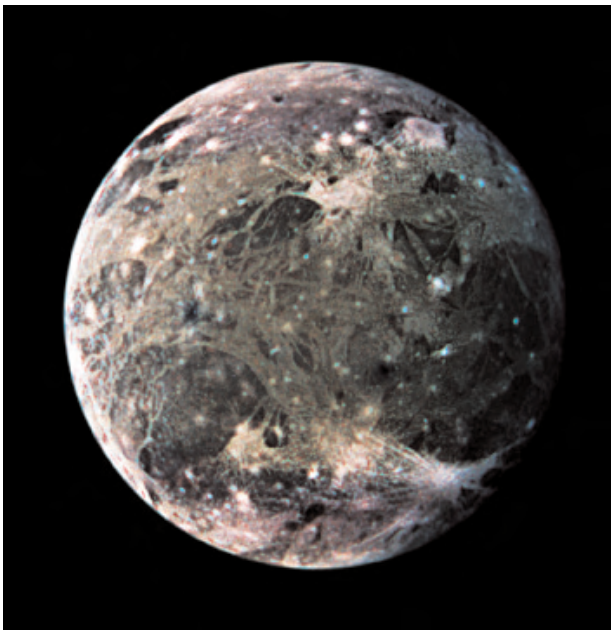

Figure 2. Global view of Ganymede's trailing side, enhanced to reveal frosty polar caps in addition to the two predominant terrains on Ganymede—bright, grooved terrain and older, dark furrowed areas. Many craters with diameters up to several dozen kilometers are visible. The violet hues at the poles may be the result of small particles of frost which would scatter more light at shorter wavelengths (the violet end of the spectrum). Ganymede's magnetic field, which was detected by the magnetometer on NASA's Galileo spacecraft in 1996, may be partly responsible for the appearance of the polar terrain.

Voyager and Galileo images show that this heavily cratered terrain, which is almost as old as the solar system itself, was fractured by tectonic activity as well as by large impact craters. Concentric furrow systems, similar to multiring structures on neighboring CALLISTO, are interpreted to have been formed when large asteroids or meteors impacted Ganymede early in its history.

Bright terrain, based on Voyager images, is divided into grooved and smooth subunits. Prior to the Galileo mission the smooth bright terrain was interpreted to have been emplaced by ice vulcanism. However, Galileo data not only reveal a paucity of volcanic features associated with bright terrain, but high-resolution data also show that many of these 'smooth' regions are in fact grooved or striated by tectonic activity.

Two wavelengths of troughs and grooves have been identified on Ganymede using Voyager and Galileo data. The average spacing between parallel grooves, based on

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

low-resolution Voyager data, is about 8.5 kilometers. However, high-resolution Galileo images reveal that smaller grooves, with an average spacing of about 1 kilometer or less, are superimposed on the longer-wavelength ridges and troughs. This two-wavelength style of deformation is interpreted to have formed by brittle deformation of an upper layer due to extension and thinning (producing the ridges/troughs with ~1 km spacing) combined with upwarping of regions by underlying warm and buoyant ductile ice (producing the longer wavelength deformation).

TECTONIC activity is now recognized as the dominant mechanism that has operated on Ganymede's surface. Tectonic resurfacing is thought to be responsible for transforming dark terrain into bright terrain. In one scenario, for example, a region that began as dark terrain is cut by numerous parallel to subparallel faults; the fault-blocks tilt with continued extension, and dark material slides down into the grooves and furrows, exposing bright, icy slopes and resulting in the formation of bright grooved terrain. While tectonic resurfacing appears to be the dominant process that forms grooved terrain, icy vulcanism cannot be completely ruled out. A depression and associated lobate material seen in Sippar Sulcus (an area of grooved terrain) are interpreted to be a volcanic caldera and water-ice volcanic flow. Additional ice-vulcanism may have occurred on Ganymede, but if it had, it has been subsequently masked by tectonic features and impact craters.

Ganymede is known as an icy satellite because its relatively low mean density (1926.8 kg m^{-3}) requires that it is made of about equal amounts, by mass, of water ice and rock-metal (actually, about 60% rock and 40% ice). Ganymede's mean density and normalized axial moment of inertia ($C/MR^2 = 0.3105 \pm 0.0028$, C is the axial moment of inertia, M is the satellite's mass and R is the moon's radius), known from radio Doppler measurements by the Galileo spacecraft, require that it be differentiated into a metallic core surrounded by a silicate mantle. The deep metal-rock interior of Ganymede is covered by a thick (800 km) ice-liquid water shell. Ganymede thus has a three-layer internal structure consisting of an inner metal core (radius 400–1300 km) depending on the composition and hence the density of the metal with the smallest radius corresponding to a pure iron core and the largest radius to an Fe–FeS core), a middle rock shell and an outer water (ice-liquid) shell.

Ganymede's magnetic field was first detected by the Galileo spacecraft. The magnetic field is large enough to carve out its own magnetosphere within the Jovian magnetosphere. The source of Ganymede's magnetic field is probably dynamo action within a still liquid part of Ganymede's metallic core. This is the same process, i.e. the geodynamo, that produces the Earth's magnetic field. The existence of a large Ganymedean magnetic field supports the inference from the gravity (Doppler) measurements by the Galileo spacecraft that Ganymede has a metallic core. The internal differentiation of Ganymede into its three-layer structure supports the inference of tectonism as the predominant surface modification process since differentiation is indicative of sufficient internal energy for endogenic activity.

Subsolidus convection in the ice-dominated outer layer of Ganymede plays a major role in controlling the evolution and present internal state of the satellite. Convection through the ice layer transfers Ganymede's internal heat to its surface. The source of this heat is mainly the present radioactive heat generation in the silicate component of the satellite. Secular cooling, i.e. the gradual cooling of Ganymede from an initially hot state established early in its history by accretion, differentiation and radioactivity, also contributes to the present heat loss from the satellite. Tidal dissipation in Ganymede is an additional potential heat source, since Ganymede is in an orbital resonance with EUROPA and Io (see IO: VOLCANISM AND GEOPHYSICS). While tidal heating is demonstrably important in Io, as evidenced by the satellite's sustained and ubiquitous volcanic activity, there is no evidence that tidal heating is important in Ganymede at present. However, tidal dissipation could have been significant in Ganymede in the past as the satellite evolved through other resonances in its orbital history. Perhaps this heat source played a role in differentiating Ganymede. Ganymede cannot have cooled so thoroughly over geologic time as to have completely frozen its metallic core since the satellite's present magnetic field requires dynamo action in a still liquid part of the core.

Web Update (31 July 2002)

New observations of Jupiter's satellites have been made during the Cassini spacecraft's flyby by Cassini, Galileo, the Hubble Space Telescope, the Chandra x-ray Observatory and Earth-based radio and optical telescopes. The Galileo spacecraft has been in orbit around Jupiter since December 1995 while Cassini observed Jupiter from October 1 2000 to March 31 2001. Cassini made its closest approach on December 30, 2000, at a distance of about 9.7 million kilometers (6 million miles). Observational results include data on interactions of the Galilean moons with Jupiter's magnetic field. Persistent, faint, far ultraviolet emission from the magnetic footprints on Jupiter's upper atmosphere from Ganymede has been observed. From these data it is inferred that Ganymede has persistent interactions with Jupiter's magnetic field despite its thin atmosphere.

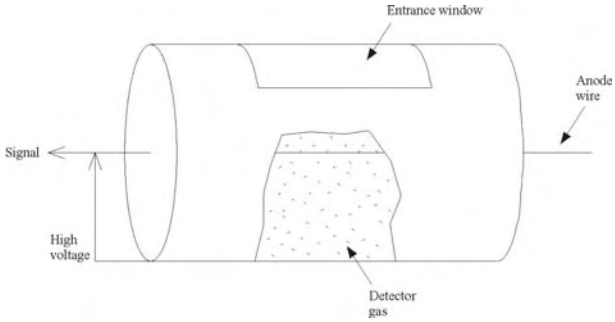

Figure 1. Schematic of a simple single-wire cylindrical proportional counter.

Gas Detectors

Gas detectors have been one of the principal methods of detecting cosmic X-RAYS since the early 1960s. They function by detecting the charge liberated when a photon interacts with the filling gas via the photoelectric process. Their principal performance advantage is that they can offer different combinations of high temporal and spatial resolutions, large area and bandwidth, good background rejection efficiency and high throughput. In addition, their basic design is well established, being a development of the Geiger counter. Only recently has the use of these devices in many areas of X-RAY ASTRONOMY and high-energy physics been replaced by CHARGE COUPLED DEVICES (CCDs), which can offer significantly better spectral resolution. Here the method of operation, the principal types and how different detector configurations are used to optimize different parameters such as energy and spatial resolutions and collecting area are discussed.

Method of operation

In its simplest form, shown in figure 1, a gas detector consists of an enclosed volume sealed with an x-ray transmitting entrance window, an anode at a typical potential of +2 kV and associated electronics. In front of the detector there is normally a grazing incidence x-ray optic, a coded mask or a mechanical collimator to focus, modulate or restrict the field of view of the incident x-rays, respectively. When an x-ray photon with an energy of ∼0.1–50 keV enters the detector it may ionize (i.e. remove one or more electrons from) one of the atoms contained in the detector volume. Under the influence of the electric field, the free electrons are then accelerated towards the anode where they cause further ionizations by colliding with other atoms. This produces an avalanche of electrons close to the anode which is detected as a pulse of charge by the associated electronics.

The number of initial electrons produced is proportional to the energy of the incident x-ray and depends on the characteristics of the filling gas, which often consists primarily of a noble gas such as Ar or Xe. Typically, a mean energy, W, of 20–25 eV is needed to liberate each electron. This means that a 6 keV x-ray liberates ∼300 electrons. If the creation of each electron–ion pair was an independent event, then Poisson statistics would apply, and the standard deviation would be the square root of the number of electron–ion pairs. However, this is not the case and this process usually gives better energy resolution than predicted in this way. The Fano factor, F, is used to quantify this difference and the FWHM energy resolution of the initial signal can be expressed as $\Delta E/E = 2.35(F/N)^{0.5}$, where N is the number of electron–ion pairs produced. F typically has values in the range 0.2–0.3 for gas-filled detectors.

Types of gas detectors

There are two principal ways of detecting the charge produced by the interaction of an x-ray with the detector gas. In a proportional counter the charge that arrives at the anode is measured directly by the associated electronics. With a suitable choice of the anode voltage the amount of charge read out is proportional to the energy of the incident x-ray—hence the name. The overall energy resolution of a proportional counter consists of two components. The first is derived from the statistics of the initial ion–electron pair production (see above) and the second from the charge multiplication process. The overall FWHM energy resolution at energy E can be expressed as:

$$\Delta E/E = 2.35[W(F + A)/E]^{0.5}$$

where $A \approx 0.6$ is the relative variance of the multiplication process. This component is the larger of the two and therefore dominates the overall energy resolution. This results in a typical energy resolution ($\Delta E/E$) of 20% at 6 keV. Examples of this type of detectors include the large area Proportional Counter Array on the ROSSI X-RAY TIMING EXPLORER satellite and the imaging Position Sensitive Proportional Counter (PSPC) on the ROSAT satellite.

In a gas scintillation proportional counter (GSPC) the primary charge cloud normally drifts into a region where the electric field strength is such that the electrons gain, on average, enough energy to excite the gas atoms to higher energy levels, but not enough to ionize them. No avalanche occurs and instead the UV light produced by secondary interactions is converted to an electrical signal by a photomultiplier tube (PMT). A schematic of a GSPC is shown in figure 2. The intensity of the UV pulse is proportional to the input x-ray energy. GSPCs provide an energy resolution of ∼10% at 6 keV, a factor ∼2 better than standard proportional counters, but at the expense of extra complexity and poorer background rejection efficiency. In addition, because of the low electric field strength in the drift region, some of the electrons produced by x-rays that interact close to the entrance window will not undergo amplification, limiting the sensitivity of these devices at energies $\lesssim$1 keV. An example of this type of detector is the Gas Imaging Spectrometer on the ASCA satellite. The Low-Energy Concentrator Spectrometer (LECS) on the BEPPOSAX satellite dispenses with separate 'drift' and 'scintillation' regions in order to extend the low-energy response down

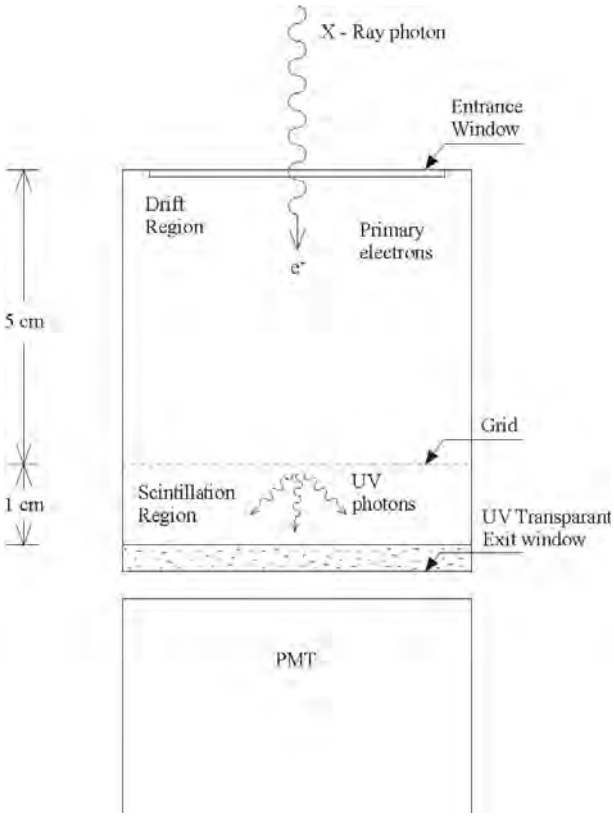

Figure 2. Schematic of a conventional GSPC with separate drift and scintillation regions.

to 0.1 keV, but at the expense of making the higher-energy ($\gtrsim$4 keV) signals no longer directly proportional to energy.

Space operation

As well as being sensitive to x-rays, gas detectors are sensitive to the energetic particles that pervade space. Many such particles have high enough energies that they can pass directly through the detector and the satellite. In doing so they deposit a line of charge in the counter gas, which is then detected in the same way as an x-ray. In an unshielded detector, the counting rate from such particles may be many times that from the target cosmic x-ray source. Improvements in gas detector design have resulted in ways of discriminating between particle and x-ray induced events. With proportional counters there are three main techniques.

1. Events that have energies between lower and upper boundaries are selected.
2. A second anode, called a guard counter, is placed in a region of the detector unreachable by x-rays. If an event is detected simultaneously on both wires then it is almost certainly produced by a charged particle. More complex arrangements of anode and guard wires divide the detector gas into many separate regions; simultaneous event detection in more than one region results in the event being rejected.
3. Since an x-ray photon is stopped by the detector gas in a very small region it yields a short pulse. A charged particle produces a long trail of charge, which will normally arrive at the anode over a much longer interval. The different timescales of these types of events can be measured and only short events accepted.

In the case of GSPCs energy and rise time thresholds are also used, supplemented, in the case of imaging systems, by analyzing the spatial distribution of light observed by the PMT.

Imaging detectors

Both proportional counters and gas scintillation proportional counters can be designed to measure the location in the detector where an x-ray was detected, and hence its likely location on the sky if a suitable x-ray optic or coded mask is used. The spatial resolution of the best imaging proportional counters is very good (the PSPC has a spatial resolution of around 0.3 mm at 1 keV), which has only been bettered by CCD and MICROCHANNEL PLATE DETECTORS. The PSPC contains two sets of thin cathode wires located at right-angles to each other interleaved with a set of anode wires. The wires are grouped together to minimize the number of pre-amplifiers required. The interaction site of an x-ray can then be recovered by measuring the relative strengths of the signals induced on the cathodes using the so-called 'center of gravity' technique. Simpler arrangements include interconnecting the sensing wires with resistors allowing only two signal processing chains per dimension.

The spatial resolution of imaging GSPCs is not as good as with proportional counters and is typically around 1 mm. In imaging GSPCs the PMT normally contains a small number of separate anodes which are read out and operated like an Anger camera. In the case of the LECS, the anodes are arranged in a square 3 × 3 configuration and measuring the distribution of light in each direction gives a measure of the centroid of the x-ray position.

Gas in Galaxies

The interstellar medium (ISM) can be thought of as the galactic atmosphere which fills the space between stars. When clouds within the ISM collapse, stars are born. When the stars die, they return their matter to the surrounding gas. Therefore the ISM plays a vital role in galactic evolution.

The medium includes starlight, gas, dust, planets, comets, asteroids, fast-moving charged particles (cosmic rays) and magnetic fields. The gas can be further divided into hot, warm and cold components, each of which appears to exist over a range of densities, and therefore pressures. Remarkably, the diverse gas components, cosmic rays, magnetic fields and starlight all have very roughly the same energy density of about 1 eV cm^{-3}. All the major constituents (or phases) of the ISM appear to be identified now, although complete multi-phase studies are extremely difficult beyond a few thousand parsecs from the Sun. The ISM is a highly complex environment which does not lend itself to simple analysis. However, this has not stopped astrophysicists from producing basic models of the ISM in order to make sense of the great wealth of data coming in from ground-based telescopes and satellites.

The study of the ISM began around 1927 with the publication of Edward Emerson Barnard's photographic atlas of the Milky Way. The atlas shows dark clouds silhouetted against the background starlight. At about the same time, spectra by John Plaskett and Otto Struve established the existence of clouds containing ionized calcium. By number of nuclei, about 90% of INTERSTELLAR MATTER is hydrogen, 10% is helium. All of the elements heavier than helium constitute about 0.1% of the interstellar nuclei, or about 2% by mass. Roughly half of the heavier elements are in the gas phase. But most of the refractory elements (Si, Ca, Fe) are depleted from the gas phase, and are locked up in small dust grains mixed in with the gas. Clouds only account for about half the mass and 2% of the interstellar volume. A far more pervasive 'intercloud' component was not identified until the discovery of PULSARS and the invention of ULTRAVIOLET/X-RAY ASTRONOMY in the mid to late 1960s.

The ISM's properties generally depend on the type of galaxy, and its distribution shows clear radial trends for a given galaxy. In DISK GALAXIES, the gas piles up into spiral arms (figure 1); this is where most of the young stars and SUPERNOVAE are to be found.

The ISM in galaxies is constantly evolving. Stellar winds and supernova explosions enrich the gas with metals over the course of billions of years. In the context of the widely accepted cosmological model of hierarchical GALAXY FORMATION, this may be compensated by the accretion of primordial gas in the outer parts of galaxies. Stars are the principal source of energy for the ISM. Starlight photons produce photoelectric emission from dust grains; these photoelectrons help to heat the neutral gas. Ultraviolet photons from the youngest stars ionize atoms and dissociate molecules. The main source of kinetic energy is the supernovae: these drive shock waves into the surrounding ISM and are largely responsible for its complexity.

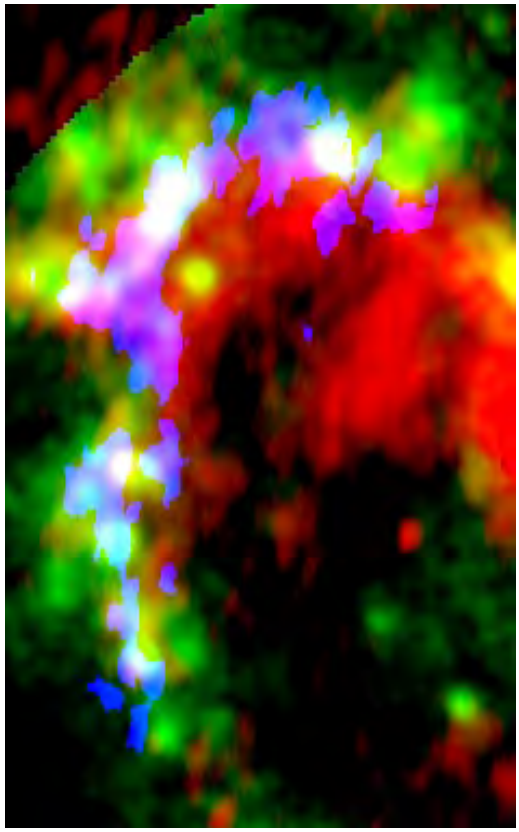

Figure 1. A color composite of the northern spiral arm in M83. The molecular gas is shown in blue, the 20 cm radio continuum in red and the ionized gas in green (courtesy of R Rand, University of New Mexico). Note that the cold gas, warm gas and dust pile up into spiral arms. Young stars form within the cold gas and then warm up the gas and dust through photoionization. Eventually, the young stars evolve to become supernovae which interact violently with the gas and dust (see figure 2). **This figure is reproduced as Color Plate 13.**

Atomic and molecular clouds

Half of the neutral atomic hydrogen and all of the molecular hydrogen in the ISM are concentrated into relatively high-density and low-temperature regions called 'clouds'. The properties of the atomic hydrogen (H I) clouds have been determined primarily from radio observations of the hyperfine ground state transitions of hydrogen at 1420 MHz (21 cm); interstellar absorption lines of trace elements such as Ca^+ also continue to play a key role in the study of these clouds. For the most common clouds, where the 21 cm radiation escapes freely, the brightness of the emission provides a direct measurement of the H I column density $N_{\rm H} = \int n_{\rm H}\,{\rm d}s$ where $n_{\rm H}$ is the atomic hydrogen density. When an H I cloud lies in front of a bright source of radio continuum emission,

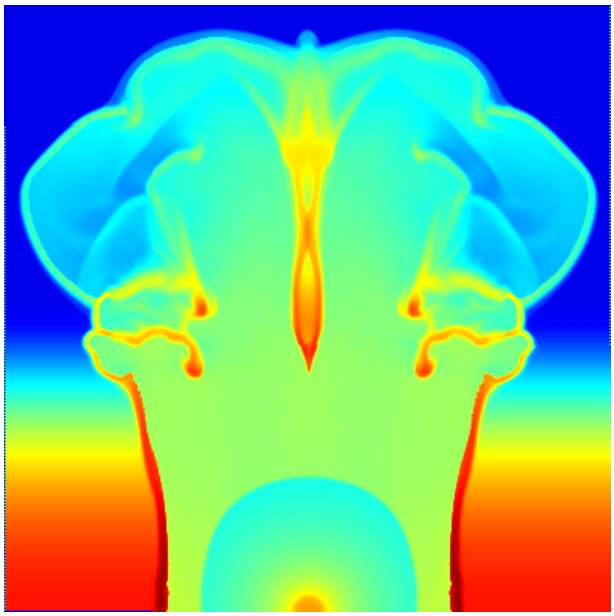

Figure 2. A simulation of the breakout from a galactic disk of a superbubble driven by multiple supernovae. The densities of gas in the disk and superbubble are shown in cross-section, with only the upper half of the disk shown. Red is high-density gas, while blue is low-density gas, with other colors of the rainbow intermediate. Each side of the image is approximately 800 pc long. (Courtesy of M-M Mac Low, American Museum of Natural History.) **This figure is reproduced as Color Plate 14.**

the decrease in the brightness of the background source at 21 cm is proportional to $N_{\rm H} = \int (n_{\rm H}/T_{\rm H})\,{\rm d}s$, where $T_{\rm H}$ is the temperature of the H I cloud. Thus, observations of H I clouds at 21 cm in emission and absorption provide direct information about cloud temperatures and column densities. Table 1 summarizes basic properties of the cold and warm neutral media. Maps of the sky show that H I clouds have complex shapes resembling thin extended sheets or filaments with embedded small clumps.

Molecular hydrogen is confined to the interiors of the densest and most massive clouds, the dark clouds, where starlight capable of dissociating molecules cannot penetrate. These clouds constitute the active star-forming component of the ISM. Because H_2 has no electric dipole moment, radiative transitions of H_2 are greatly suppressed. Therefore, most of the structural information about molecular clouds in the ISM is obtained through observations of the rotational transitions of the trace molecule CO at 115 GHz (2.6 mm). In addition, a wide variety of other molecules, including complex hydrocarbon chains, have been detected within the H_2 clouds. Molecular clouds are small (40 pc), dense (200 cm^{-3}), with structure on scales of less than 0.1 pc (see table 1 and also INTERSTELLAR MOLECULAR CLOUDS). Some of the small condensations can have densities as high as 10^5 cm^{-3}. In disk galaxies like our own, the cold neutral gas and molecular gas are confined to a disk which is much thinner than the stellar disk.

The intercloud medium

Astrophysicists have long wondered as to what confines gas clouds within the Galaxy. In 1956, Spitzer speculated that a rarefied ($\sim 10^{-3}$ cm^{-3}) hot gas ($\sim 10^6$ K), extending a kiloparsec or more above the Galactic plane, would confine the diffuse gas clouds observed far above the plane and would prevent their expansion and dissipation. Confirmation of the predicted corona came 17 yr later with the advent of space astronomy (table 1). Present-day satellites allow for the direct detection of diffuse x-ray emission and ultraviolet–x-ray spectral lines from the highly ionized trace elements within the hot gas (see the review by Spitzer 1990). The hot gas is thought to arise from the action of supernovae as we discuss below (see figure 4).

The existence of widespread hot gas in the disk of the Galaxy comes from observations of O^{5+} ions at ultraviolet wavelengths and the direct detection of soft x-ray emission. A clear demonstration of coronal halo gas far from the disk has been harder to come by. A wide range of ions is observed (Si^{3+}, C^{3+}, N^{4+}) towards the halo. Current models suggest that ultraviolet light from disk stars can only account for some of the ionization. The N V absorption lines appear to require collisional heating from a pervasive hot corona (Sembach and Savage 1992).

From a theoretical standpoint, the expectation is that hot young stars and supernovae punch holes or blow bubbles (figure 2) in the surrounding gas, and the diffuse hot component escapes into the halo through buoyancy. In fact, there are spectacular examples of bubbles seen at 21 cm in the Galactic ISM (see figure 3). However, there are many outstanding problems with these models, not least complications imposed by the magnetic field. Since the gas is thermally unstable, it is equally probable that the gas undergoes a 'cooling flow' or 'fountain flow' back towards the disk.

Filling the space between clouds are two additional components of the intercloud medium. By mass, most of the intercloud medium is in the form of a 'warm neutral' or a 'warm ionized' medium. These phases extend far beyond the thin disk of cold gas (table 1). The existence of the warm ionized medium was firmly established by 1973 from three independent observations: (i) low-frequency radio observations by Hoyle and Ellis, (ii) time delays in radio pulses from pulsars (see below) and (iii) through direct observation of H^+ recombination emission by wide-field Fabry–Perot interferometers. The gas has a density of roughly 0.1 cm^{-3} and a temperature near 10^4 K. The dominant source of ionization appears to be dilute ionizing flux from young stars in the disk, although some models suggest that the cooling radiation in old SUPERNOVA REMNANTS can be important. The deepest optical spectra to date show that the ionized gas extends to at least 5 kpc into the halo in some cases, and extends even further in radius than the H I disk.

Roughly half of the interstellar H I appears to be located in the 'warm neutral' component of the intercloud medium. This intercloud H I was first identified in 1965

Table 1. The component properties of the interstellar medium.

Component	Temperature (K)	Midplane density (cm^{-3})	Filling fraction (%)	Average height (pc)
Clouds				
H_2	15	200	0.1	75
H I	120	25	2	100
Intercloud				
Warm H I	8000	0.3[a]	35[a]	500
Warm H II	8000	0.15	20	1000
Hot H II	$\sim 10^6$	0.002	43[a]	3000[a]

[a] Value uncertain by at least a factor of 2.

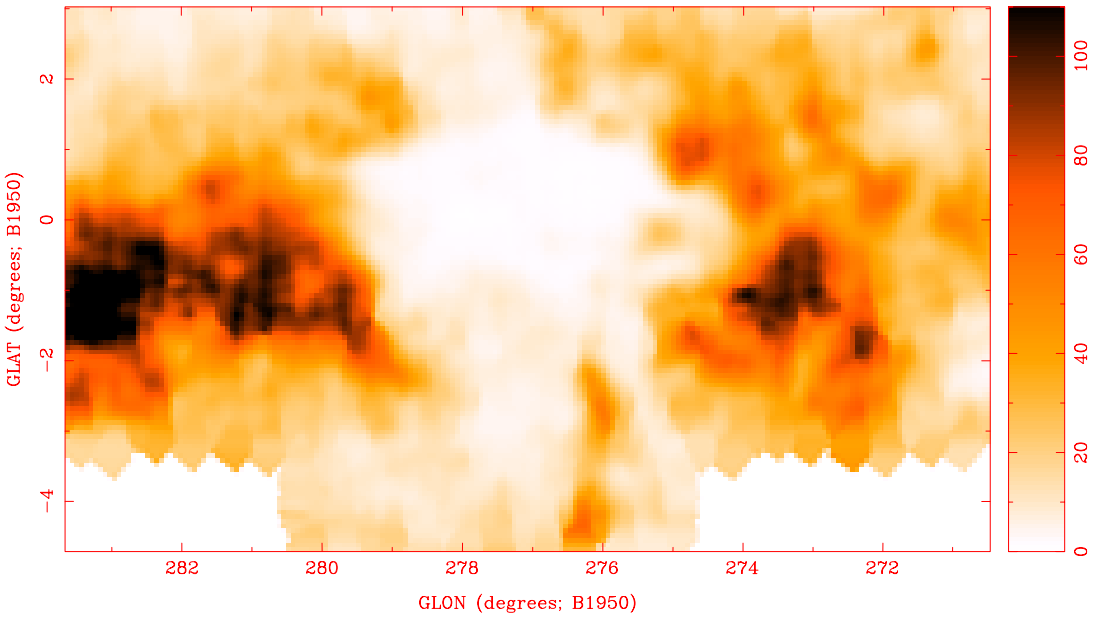

Figure 3. An image of a large Galactic H I supershell (white region at center). The empty supershell has a central brightness temperature of about 3 K; the shell edges have a brightness temperature around 60 K (black). The shell also shows narrow channels which appear to extend to the Galactic halo, forming a 'chimney' above and below the plane. The shell lies at a distance of about 6.5 kpc, has a diameter of roughly 600 pc and extends more than 1.1 kpc above the Galactic plane. The data were obtained at the Parkes Radio Telescope as part of the Southern Galactic Plane Survey. (Courtesy of N M McLure-Griffiths and J R Dickey, University of Minnesota.) **This figure is reproduced as Color Plate 15.**

as the source of the ubiquitous, relatively broad (velocity dispersion ~9 km s^{-1}) 21 cm emission features that had no corresponding absorption when viewed against bright background radio sources. The large velocity dispersions and the absence of absorption imply temperatures of 5000–10 000 K. Observations of the Ly α absorption line of H I toward bright stars show that this gas has a mean extent from the midplane of 500 pc, i.e. much thicker than the cold neutral disk. If the warm neutral medium is in pressure equilibrium with the cold component, then it would be clumped into regions occupying 35% of the intercloud volume with a density of 0.3 cm^{-3} at the midplane (table 1), although these numbers are highly uncertain.

The solar neighborhood

We now consider the interplanetary medium (heliosphere) within the solar system as distinct from the local interstellar medium. The Sun moves with a velocity of about 20 km s^{-1} relative to the local ISM. The solar wind produces a bow shock ahead of the Sun. This discontinuity (heliopause) defines the extent of the heliosphere in the upstream direction. It is expected that the Pioneer 11 or Voyager deep space probes will eventually confirm the existence of this boundary. The neutral interstellar gas is largely unaffected by the heliopause, so that the local neutral medium presumably streams relatively freely through the solar system. In contrast, ions and charged dust grains are probably deflected by the advancing heliosphere. COSMIC RAYS are relativistic particles and therefore penetrate the heliosphere.

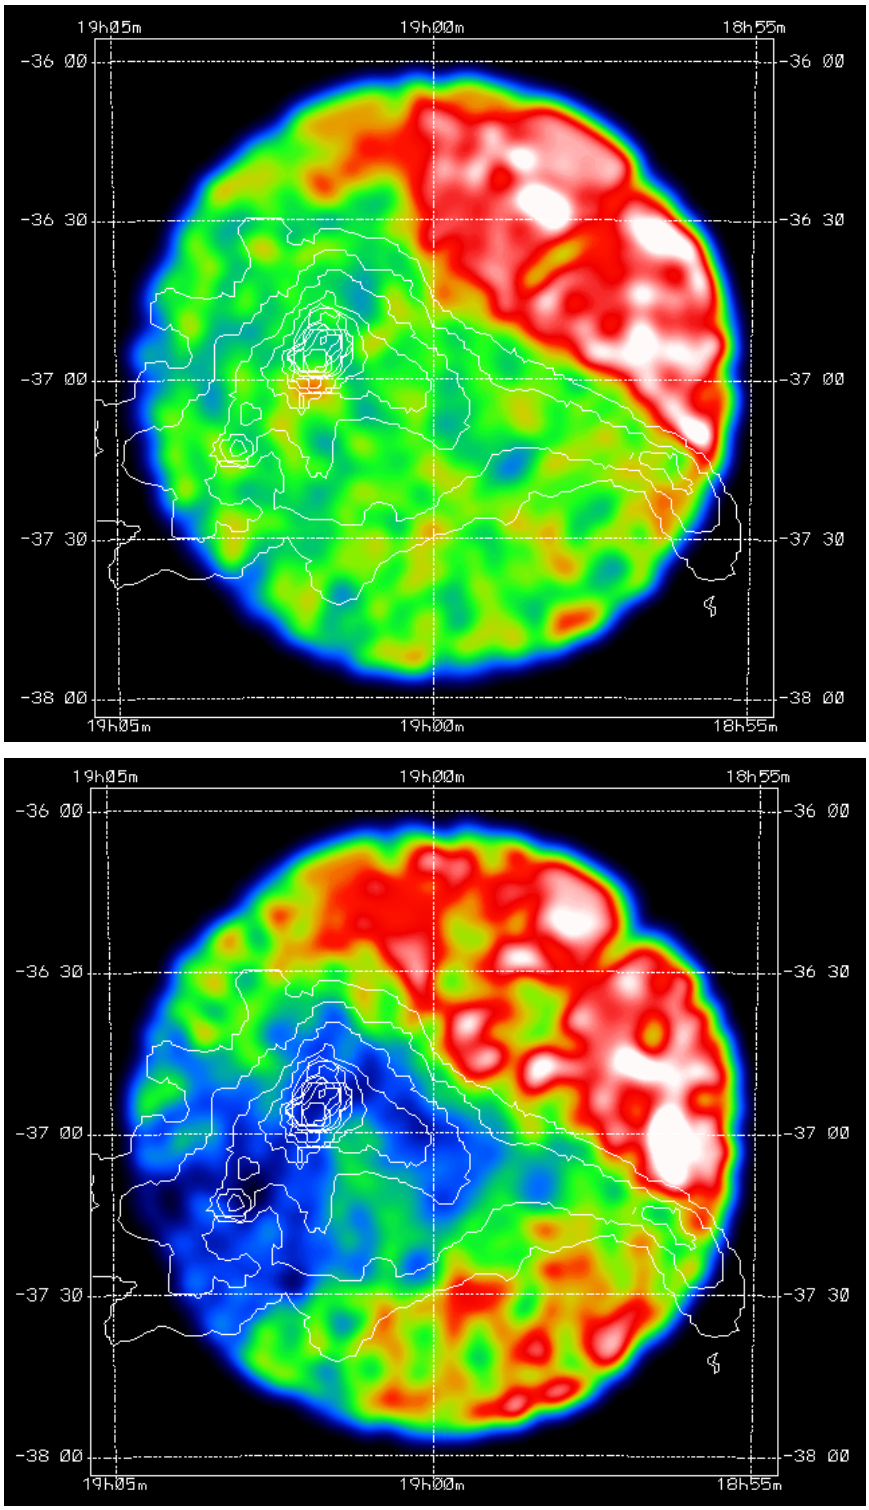

Figure 4. ROSAT false-color images of the Corona Australis dark molecular cloud. The contours show the 100 μm emission from dust in this cloud measured by the IRAS infrared satellite. The self-scaled images are for two different energy bands: (a) 100 eV and 300 eV (C band) and (b) 500–1100 eV (M band). These soft (low-energy) x-rays are absorbed by interstellar dust and gas. Because the M band x-rays are more penetrating than the C band x-rays, they are absorbed more strongly in the core of the cloud than in the periphery, while the C band x-rays from beyond the cloud are completely absorbed over the entire cloud. These images demonstrate that much of the x-ray flux originates from beyond the cloud. (Courtesy of D N Burrows, Penn State University.) **This figure is reproduced as Color Plate 16.**

The most local gas we can associate with the local ISM has the properties of the warm neutral medium (see also SOLAR WIND: INTERACTION WITH LOCAL INTERSTELLAR MEDIUM). The solar radiation is backscattered by the local medium. Studies which exploit the resonance lines of hydrogen and helium show that the gas has a temperature of 8000 K, a hydrogen density of 0.25 cm^{-3} and a helium density of 0.02 cm^{-3}. Absorption line measurements toward nearby stars indicate that this warm gas is only a few parsecs in extent with hotter 10^6 K gas occupying most of the volume within 100 pc of the Sun.

Theories of the ISM

The two-phase model

Field, Goldsmith and Habing (FGH) (Field *et al* 1969) developed the first quasi-static theory of a multiphase ISM. The FGH model contained two stable phases, the 'cold' neutral phase at a temperature of ∼100 K and a 'warm' phase at $\sim 10^4$ K where about 10% of the gas is ionized. The model uses cosmic ray heating to balance the cooling of these two phases. The cooling is dominated by fine-structure excitations from C^+ in the cool gas, and collisional excitations (Lyα) in the warm gas. The model predicts an ISM where the majority of the volume is occupied by the warm ($\sim 10^4$ K) intercloud medium while the majority of the mass is contained within the dense cold clouds.

However, the FGH model indicated that the ISM should be stratified perpendicularly to the Galactic disk, which was known to violate the observed properties of the ISM. They therefore appealed to the collective explosive effects of H II regions and supernovae, which impart sufficient turbulent motions to destroy any gravitationally induced stratification. The FGH model allows the cold clouds to have a large range of sizes. The smallest clouds are destroyed by thermal conduction within the warm layer, while the largest are gravitationally unstable and prone to collapse. Otherwise, there is no limit on the size or shape of the expected neutral structures.

FGH also raised the possible existence of another stable phase at a temperature of $\sim 10^6$ K, dominated by bremsstrahlung cooling. However, without observations of the soft x-ray background or high-ionization UV spectra, there was no need to invoke the actual existence of this medium.

In the FGH model, supernova explosions were required to destroy the gravitationally induced vertical stratification of the ISM. This inspired theoretical models of the expansion and thermal evolution of supernova remnants (SNRs), and it was then that the full importance of supernovae came to be realized. Supernovae generate blast waves with speeds of 10 000 km s^{-1} which shock the ambient material, producing gas at $\sim 10^6$ K which then slowly cools through bremsstrahlung emission *and* line emission from highly ionized ions. The remnant structure is a hot bubble surrounded by a thin, dense shell of cool $\sim 10^3$ K gas. This situation proves to be quite stable; the hot bubble cannot expand through the shell expanding ahead of it. After a million years, the radius of the hot bubble is roughly 80 pc. At this point, the interior pressure of the bubble reaches the ambient pressure of the ISM. This static situation remains until the hot bubble cools and contracts after four million years or so.

Cox and Smith (1974) were the first to recognize the importance of this evolutionary sequence for the dynamical and thermal balance of the ISM. If an expanding SNR happens to intersect the static hot cavity of another remnant, the expanding remnant 'breaks out' through the old, hot remnant. Because of the low density within the static bubble, the expanding shock wave propagates preferentially into it, reheating the matter inside. Depending on the rate of Galactic SNe, the ISM could therefore evolve towards an interconnected tunnel network filled predominantly by hot gas.

To estimate the importance of such a tunnel network, a porosity parameter was introduced such that

$$q = r\tau V_{\rm sn} \tag{1}$$

where r is the average SN rate per unit volume, τ is the lifetime of an isolated bubble and $V_{\rm sn}$ is the final volume of the average SN-generated bubble. For $q \ll 1$, q is the proportion of the total interstellar volume that would be filled with hot bubbles. For an SN frequency of 1 per 80 yr, they found $q \sim 0.1$. This implies that 10% of interstellar space should be filled by unconnected, hot, SN-generated bubbles. Therefore, the probability of any new SN occurring within a preexisting cavity was 0.1, but the probability that any new SNR would expand into and reheat another older remnant was 0.55. The consequences of the overlap and phase structure of the ISM were radical.

This chain of reasoning rests heavily on supernovae occurring randomly throughout the Galactic volume. The simple conclusion prompted many to believe in the 'porosity imperative', that is the need for a hot 10^6 K phase to occupy the majority of the interstellar volume. The cold and warm ($\sim 10^4$ K) phases were relegated to the walls between the pervasive bubbles. Large filamentary structures in the ISM seem to support this, except that the overall pervasiveness and smoothness of the ISM are in conflict with this picture.

The three-phase model

This paved the way for a true theoretical tour de force, the McKee–Ostriker (MO) model of the supernova-dominated, three-phase ISM. In their model, supernovae produce the 'hot ionized medium' (HIM), the $\sim 10^6$ K component of the ISM in their bubble interiors, as well as enhancing the formation of the 'cold neutral' (CNM), 'warm neutral' (WNM) and 'warm ionized' (WIM) media along the compressed edges of remnants. There are still only two fundamental phases (CNM, HIM) in the MO theory. The WNM and WIM are restricted to the interface regions of the neutral clouds, and the WIM is in direct contact with the HIM and photoionized by thermal emission from it.

The model attempts to balance the thermal and mass exchange between the different phases. The energy input

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

from supernovae is offset by radiation cooling from the four media. The mass lost by cloud evaporation into the HIM is balanced by dense shell formation of swept-up interstellar material. The model is known to be incorrect in many details. There are numerous observations of local, dense clouds that are highly overpressured with respect to their environment. The model does not treat the influence of magnetic fields which are known to thread throughout the ISM and are likely to suppress thermal evaporation. The magnetic fields are of the right strength to play an important role in equilibrating the pressure balance. However, in the absence of a better working model, the MO theory remains the dominant conceptual framework. In fact, it remains unclear whether thermal pressure balance between the phases is an essential feature of the MO picture.

Pressure equilibrium should exist between the cosmic rays, the magnetic field and the kinetic interstellar component. However, the latter need not be the thermal pressure of the gas. Random, turbulent 'bulk' motions of the gas have a high enough energy density to provide the required effective pressure. The minimum interstellar pressure, $P = nT$, is probably about $\sim$25 000 cm^{-3} K and may even be higher.

The influence of supernovae

After a burst of STAR FORMATION has taken place, the first supernovae appear after about 10 million years. These type II supernovae arise from collapsing massive stars which have exhausted most of their nuclear fuel. Type II supernovae are distributed like the young stars in a disk galaxy, i.e. concentrated along spiral arms. A billion years after the initial starburst, the type I supernovae appear. Type Ia supernovae are thought to be due to accretion of matter by a white dwarf in a binary pair. These are to be found among the older STELLAR POPULATIONS and therefore have an exponential distribution with radius like the underlying disk.

The increase in type Ia supernovae towards the Galactic centre implies that here the ISM becomes supernova dominated, resulting in a two-phase ISM with only an HIM and a CNM. The warm phases are disrupted as diffuse clouds are shocked and heated to high temperatures. The molecular clouds survive the assault of supernovae and remain essntially intact, having only their outer warm layers stripped away. The scale height of the oldest stellar populations is higher ($\sim$300 pc) than for the atomic hydrogen ($\sim$100 pc), such that half of all type Ia supernovae explode above the gas and therefore deposit much of their energy directly to the halo. This picture produces a volume filling fraction of about 25% for the HIM, and presumably explains the H I holes seen in external galaxies.

The correlated distribution of type II supernovae has an important consequence. The time interval between successive supernovae is less than the bubble lifetime. This can result in a large-scale wind of energy into the Galactic halo. Heiles (1987) derives a two-dimensional porosity parameter

$$q_{2D} = 8.3\sigma s N^{-1} \tag{2}$$

where σ is the supernova rate in kpc^{-2} Myr^{-1}, s ($\sim$2) is a correlation factor and N ($\sim$40) is the number of type II supernovae that occur in a single association. However, this leads to a volume filling factor of more than 95% along the spiral arms, and about 80% outside of the arms, contrary to observation. Furthermore, the type II energy flow is expected to break out and produce a mass flow rate of $\sim 20 M_\odot$ per year, which would deplete the total gas content of the disk in 10^9 yr. How are we to reconcile this?

The role of pulsars

Discovered in 1967, pulsars are the rapidly rotating cores left behind by exploding type II supernovae. More than a thousand have now been observed in our Galaxy, in halo globular clusters, and in the LMC and SMC. Radio observations of these rapidly pulsating stars provide information on the plasma densities and magnetic field strengths of the intervening interstellar medium over baselines of tens of kiloparsecs.

The electrodynamic properties of a plasma are functions of the frequency of the electromagnetic wave that traverses the plasma. The group velocity of a wave in a plasma is

$$v_g = c\left(1 - \frac{\omega_p^2}{\omega^2}\right)^{1/2} \tag{3}$$

where ω is the angular frequency and ω_p is the plasma frequency defined by $\omega_p^2 = 4\pi n e^2/m$, for which n, e and m are the number density, charge and mass of the free electrons.

Because the group velocity of a wave depends on its frequency, the Fourier components of a pulse will traverse a total distance d through a plasma in a time t_ω given by

$$t_\omega = \int_0^d \frac{ds}{v_g} \tag{4}$$

where s defines a small increment of distance through the plasma. Plasma frequencies in interstellar space are typically very low so we can expand equation (3) and substitute into equation (5) such that the time taken for the Fourier component of a pulse to traverse a plasma is

$$t_\omega \approx \frac{d}{c} + (2c\omega)^{-1}\int_0^d \omega_p^2\,\mathrm{d}s. \tag{5}$$

The first term is the time taken to traverse a distance d *in vacuo* and the second term is the plasma correction.

Studies of the arrival times of the various Fourier components indicate that the highest frequencies arrive ahead of the low-frequency components. What is actually measured is the derivative

$$\frac{\mathrm{d}t_\omega}{\mathrm{d}\omega} = -\frac{4\pi e^2}{cm\omega^3} D_m. \tag{6}$$

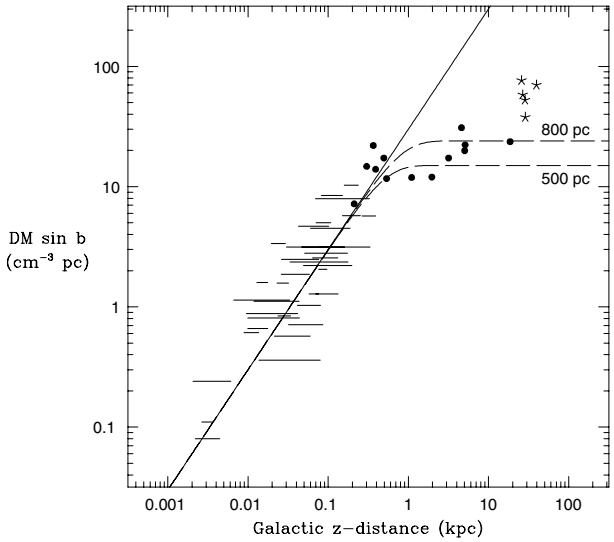

Figure 5. Dispersion measures from pulsars, $D_{\rm m} \sin b$ where b is galactic latitude, versus z-distance above the Galactic plane. The horizontal lines show the distance uncertainty for different pulsars. The black circles and stars refer to pulsars in globular clusters and the Magellanic clouds respectively. The sloping line corresponds to a model electron distribution which is uniform in density 0.03 cm^{-3}, and the two dashed lines are for models in which the electron layer has the same density at $z = 0$ but falls off with increasing z as $\mathrm{sech}^2(z/h)$ where h is 500 pc and 800 pc. (Courtesy of R N Manchester, Australia Telescope National Facility and J Taylor, Princeton University.)

The dispersion measure, defined as $D_{\rm m} = \int_0^d n_{\rm e}\,{\rm d}s$, is a measure of the total column of free electrons along the path to the pulsar in units of pc cm^{-3}. A column of 10^{20} electrons results in a $D_{\rm m}$ value of 30 pc cm^{-3} and a delay of 12 s for a signal at 100 MHz relative to infinite frequency. Dispersion measures were first obtained by the pulsar discovery team. Since then, we have come to learn (figure 5) from pulsars in distant globular clusters and the Magellanic Clouds that the warm atmosphere in the Galaxy extends to about a kiloparsec above the Galactic plane.

The radio signals reveal other important properties about the diffuse gas. In the presence of a magnetic field along the path to the pulsar, $B_\parallel$, the plane of polarization of the propagating wave will rotate by an angle χ equal to the phase delay between the ordinary and extraordinary components of the electric field. The so-called Faraday rotation angle is given by

$$\chi = \frac{\pi}{c\omega^2}\int_0^d \omega_{\rm p}^2\omega_{\rm B}\,{\rm d}s \qquad (7)$$

for which $\omega_{\rm B}$ is the cyclotron frequency. We define a quantity called the rotation measure,

$$R_{\rm m} = 0.81\int_0^d n_{\rm e}B_\parallel\,{\rm d}s \qquad (8)$$

in the traditional units of rad m^{-2}, and where $B_\parallel$ is in units of microgauss (μG). The ratio of $R_{\rm m}$ to $D_{\rm m}$ is the average galactic magnetic field strength along the path,

$$\langle B_\parallel\rangle = 1.232\frac{R_{\rm m}}{D_{\rm m}}. \qquad (9)$$

The influence of magnetic fields

Radio observations towards 500 pulsars show that there is a random and ordered magnetic field dispersed throughout the Galaxy. The ordered component has a field strength of 1–2 μG, while the random component is 5–6 μG with a cell size of about 50 pc.

The random field has a dramatic effect on the evolution of supernovae. While it can be neglected in the early stages of the explosion, as the remnant expands, the trapped magnetic field in the thin, cool shell resists the expansion, and this results in a much thicker shell with much lower compression. Now, after a million years, the hot bubble has an inner edge at 60 pc and an outer edge of 90 pc. Over the next four million years, the combined thermal and magnetic pressure of the thick shell forces the hot bubble to decrease in size. After $\sim 5\times10^6$ yr, the bubble radius is only 10 pc or so. Supernova bubbles can still overlap, but generally at a time when they are significantly weaker disturbances. This suggests that, consistent with the observations, the HIM produced by type II supernovae should be much smaller than predicted by Heiles.

Dependence on galaxy type

Surveys of several hundred galaxies show a systematic trend in the fraction of molecular gas to neutral gas for galaxies along the 'Hubble sequence' (see figure 6). This relationship is not fully understood although possible answers include the effect of the large-scale gravitational field in the formation or disruption of molecular clouds. For example, the stronger gravitational field in the bulge-dominated (early) galaxies may encourage fragmentation of the gas as a first step to forming dense clouds through collapse. It appears that there is also an enhanced fraction of molecules to neutral atoms in merging galaxies and cluster galaxies. In the latter case (e.g. Virgo), it is thought that the diffuse hydrogen has been swept away by the intracluster gas as the galaxy moves through the cluster.

Unanswered questions

On the subject of the ISM, there are vastly more questions than answers. There are few topics in astrophysics which are so well served by the new and planned generation of space-borne and ground-based observatories. These highly technological and expensive facilities provide the necessary impetus to encourage progress from theorists and computational analysts alike.

Although the principal components of the ISM have been identified and many of their properties measured, there is very little understanding of how they fit together into a dynamic system. This lack of progress has begun to stifle progress in other astrophysical fields. What are the feedback mechanisms that determine the stellar and interstellar properties of a galaxy? What regulates the star

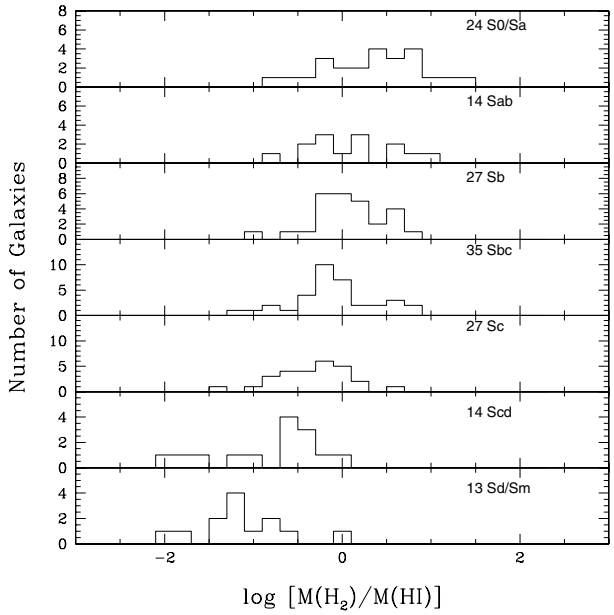

Figure 6. The ratio of molecular to atomic hydrogen for different 'Hubble types' of spiral galaxies. The histograms are presented in order of declining bulge to disk ratios, with the S0–Sa galaxies having the largest bulges. The increasing fraction of dense molecular clouds towards earlier Hubble types may reflect a higher cloud formation rate in the presence of a stronger gravitational field. (Courtesy of J S Young, University of Massachusetts.)

formation rate? Why do the many components of the ISM have very roughly the same energy density? What are the volume filling fraction and topology of the various gas phases? What is the large-scale and fine-scale topology of the magnetic field for each of the gas phases? How do the properties of the ISM change with cosmic time as more and more of the gas becomes locked up in stars?

To quote from Spitzer (1990), 'Understanding the processes that occur as the hot interstellar gas evolves in our Galaxy is an ambitious goal that we are far from achieving'. The dynamics of a compressible gas bombarded by photons and cosmic rays is a highly complex problem. Progress has been made through idealized models. In these models, one commonly recognizes three phases. Initially, the supernova ejects a rapidly expanding envelope whose interaction heats the ambient gas to high temperatures. Second, the hot gas expands and compresses or destroys clouds in its wake. Finally, the hot gas may escape or fall back down to the galactic plane. The problem is that, in practice, these three stages overlap so much that their mutual interactions are crucial. Since we can expect major gains in the computational power of supercomputers, we can look forward to the development of more realistic models in the decades ahead.

Gas Tail, Cometary

The part of a comet consisting of ions and electrons formed from gas molecules expelled from the comet during a close approach to the Sun; also known as an *ion tail* or *plasma tail*. The molecules are ionized by ultraviolet light from the Sun and drawn away from the head of the comet by the solar wind. Not all comets develop a gas tail (or a dust tail), but both types of tail always point away from the Sun. Gas tails are straight, but may appear kinked or discontinuous as a result of a disconnection event—a consequence of a change in the polarity of the magnetic field entrained in the solar wind. They are predominantly blue, the characteristic color of emission by ionized carbon monoxide (CO^+) at 420 nm. Gas tails begin to form typically at 2 AU from the Sun and can extend to 10^8 km.

See also: cometary atmospheres, disconnection event.

Compare: dust tail, cometary.

Gaseous Nebulae

Orion treads the nightly sky, his jeweled sword hanging from his belt, its centerpiece a small bright cloud, the ORION NEBULA. Though under ideal conditions visible to the naked eye, the nebula was discovered telescopically by the French scientist Nicolas de Pieresc in 1610 at the same time that Galileo was probing the heavens. The Orion Nebula was but one of what would become a huge number of unresolved 'nebulae'. Some nebulae yielded to better instruments and were revealed as star clusters. In our own time, EDWIN HUBBLE began to resolve yet others as galaxies, M31 still being known as the Great Nebula in Andromeda.

Still other nebulae could not be so resolved because they were not made of stars. Turning his primitive spectroscope in 1864 to one of Herschel's 'planetary nebulae', SIR WILLIAM HUGGINS found it to radiate emission lines characteristic of a hot gas. Though some astronomers had contended that they had indeed seen the Orion Nebula break into myriad stars, Huggins found that it too displayed the characteristic three emission lines: hydrogen at 4861 Å and the mysterious green 'nebulium' lines at 4959 Å and 5007 Å that, in 1928, were identified by I S Bowen as 'forbidden lines' of doubly ionized oxygen. The Orion Nebula—and large numbers of similar objects—must also be made of hot ionized gas.

Three main kinds of 'emission nebulae'—those that radiate emission lines—inhabit the Galaxy. The PLANETARY NEBULAE, found everywhere from the galactic disk to the halo, are small shells of gas around, and illuminated by, hot dying intermediate-mass stars. SUPERNOVA REMNANTS are the heated remains of high-mass exploding stars. To distinguish between them, the Orion Nebula and its kind are known as 'gaseous nebulae' (in spite of the others being gaseous as well), as 'diffuse nebulae' from their fuzzy appearances, and as 'H II regions' because they are largely made of ionized hydrogen (figure 1).

The diffuse nebulae are distinguished by their relation to new stars and star formation. Vastly larger than planetary nebulae, they are strictly confined to the inner plane of the Galaxy where we find the giant molecular clouds (GMCs), and specifically are either inside or contiguous to the molecular clouds themselves, where they are commonly related to young T Tauri stars and to the bipolar outflows that make Herbig–Haro objects. The nebulae are local portions of the molecular clouds that have been ionized by new hot massive stars that the molecular clouds have recently spawned. More than any other galactic feature, the diffuse nebulae lead our eye to the Galaxy's newest birthing grounds.

The diffuse nebulae are closely associated with a fourth kind of galactic object, 'REFLECTION NEBULAE' that glow in a similar fashion but whose spectra are the same as those of the surrounding stars. Though they too are gas clouds, their gas is neutral and largely unilluminated, the visual radiance coming from the scattering of starlight by embedded dust grains, returning us again to the molecular clouds, which are cold because of the dust they contain.

Figure 1. No diffuse nebula can be 'typical', but the Rosette Nebula gives a fine sense of their general natures, a huge cloud of ionized gas illuminated by hot stars within. Set in the foreground are numerous dust clouds including some classic 'elephant trunks' that show the intimate relation between interstellar gas and dust (National Optical Astronomy Observatories).

Reflection nebulae are illuminated by stars too cool to ionize the gas. Turn up the stellar heat and they glow like Orion.

A tour

Several diffuse nebulae are fine showpieces that decorate the Milky Way. Though the brighter nebulae, like Orion, look rather greenish to the eye (as a result of the forbidden oxygen lines), photography reveals most as red, the color caused by the bright red H_α emission line at 6563 Å. Reflection nebulae are quickly revealed by their blue colors, as blue starlight is scattered much more efficiently than red.

Orion was featured as M42 in Charles Messier's famed 1780s list that warned comet hunters of celestial mimics. Just to the north, also in Orion's Sword, lies small M43, part of the same complex. To the east in dim Monoceros is the Rosette Nebula, which surrounds the open cluster NGC 2237, a circular galactic flower well over a degree wide. Then go north along the Milky Way into Perseus, where glows the California Nebula, faint but three degrees long. Swing near the North Pole into Cygnus and there next to bright Deneb is the immense North America Nebula, three degrees across and visible in binoculars.

Plunging south we hit the motherlode in and around Sagittarius, where diffuse nebulae abound. Here, admire the naked-eye Lagoon Nebula, which nearly harbors the Winter Solstice. Above it is the smaller Trifid Nebula, a red patch with a blue reflection border. A bit to the north flies the Eagle Nebula in Serpens, between them the Omega. Farther south the wonders yet improve, the rich southern Milky Way capped by the Carina Nebula, a massive complex over 2.5 degrees across.

Between these treasures are hundreds more, some small and compact, some great glowing clouds so faint

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

they are difficult to see. Many are known by their NGC numbers. Others are included in the 'Sharpless' catalogue of 1959, which contains 313 objects identified on the red plates of the Palomar Sky Survey (which highlight H_α radiation). Prefixed 'S', nearly all are true diffuse nebulae, with Orion called S281, and the North America S 117. Diffuse nebulae are also powerful radio emitters. The 'Westerhout' list of 1958, compiled from a long-wave radio survey of the Milky Way, includes over 50 gaseous nebulae (and several supernova remnants). Though it overlaps with the brighter Sharpless nebulae, it has the distinct advantage of including nebulae that are optically obscured by interstellar dust, radio waves traveling the Galaxy unimpeded. Indeed, W49, one of the largest diffuse nebulae in the Galaxy, is invisible optically, hidden behind the thick dust in the Great Rift. Numerous other catalogs simply designate the nebulae by galactic coordinates (G).

Other galaxies with active star formation are also filled with diffuse nebulae, some—'giant H II regions'—vastly larger than our own classic objects. The LARGE MAGELLANIC CLOUD, outlined by vast numbers of glowing red nebulae, contains the magnificent Tarantula Nebula, so big and bright that even at a distance of 52 kpc it acquired a naked-eye star name, 30 Doradus. It is similar in scale to NGC 604, which lies within a spiral arm of the Triangulum Galaxy M33. Indeed, a mere glance at the distribution of diffuse nebulae in an external galaxy shows clearly that they lie strictly along the spiral arms, and in fact help identify the arms. Since diffuse nebulae are closely identified with new stars, their locations show that the spiral arms are the galaxies' star-formation factories (figure 2).

Factoring in the distances of the known diffuse nebulae reveals an immense range in size and structure. The centerpiece Orion Nebula, considered small, is about 5 pc across and contains about 100 solar masses of gas. At the low end are compact diffuse nebulae whose diameters are measured in tenths of a parsec, while at the high end the giant diffuse nebulae 30 Doradus and NGC 604 are 400 pc across and contain thousands of solar masses lit by whole clusters of hot stars. If placed at the Orion Nebula, they would overfill the entire constellation.

The nebulae range in structure from ionized bubbles set within dark molecular clouds, through blisters on the clouds' surfaces that are heated from the outside, to extended thin sheets of ionized matter that have undefined boundaries, pervade the Galaxy, are uncataloged, and with no specific integrity push the limit of the definition of 'diffuse nebula'. This ionized background belongs more to discussions of the general interstellar medium.

The illuminating stars

Like the planetary nebulae, diffuse nebulae, predominantly made of hydrogen, are ionized by stellar radiation shortward of the hydrogen Lyman limit at 912 Å. For a star to radiate this Lyman continuum, it must be hotter than about 25 000 K, which corresponds to spectral class B1, a limit found empirically by Edwin Hubble in the 1920s.

Figure 2. The spiral arms of the galaxy M101 are outlined by great numbers of giant diffuse nebulae that dwarf the Orion Nebula, are lit by clusters of O stars, and reveal the locations of active star formation (National Optical Astronomy Observatories).

Earlier (hotter) spectral classes ionize their surroundings, while later (cooler) ones do not, their radiation producing blue reflection nebulae when the starlight is scattered from the dust embedded in the gas. Thus the diffuse nebulae are the realm of the O stars (B0 included here with them).

O stars are massive. At 25 000 K, a zero-age main sequence star has a mass around 10 $M_\odot$, the minimum mass that can ionize a diffuse nebula. Because typical B1 stars are evolved from higher masses, the average bottom-end mass is more like 12 $M_\odot$. Orion's ionizing 'Trapezium' quartet consists of B0.5, B0, O7, and O6 stars. Because mass and luminosity climb so quickly with earlier spectral class, the O6 star (with about 20 $M_\odot$) dominates, it alone effectively producing the nebula. Herschel 36, the O7 luminary of the Lagoon nebula, does the same. At the high end are 120 $M_\odot$ O3 stars whose radiation dwarfs that of the mere Trapezium. Exceedingly rare in our Galaxy, O3 stars abound in the immense cluster R136 that ionizes 30 Doradus, over 50 packed into a volume only 2 pc across.

O stars do not live very long, beginning to evolve through the main sequence band as soon as they are born. A new O7 star at 20 $M_\odot$ has but 10 million years to ionize its surroundings and make a diffuse nebula before it cools below class B1, where it makes a reflection nebula. At

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

40 $M_\odot$ we are down to 5 million years and at 120 $M_\odot$ to 3 million. At typical stellar velocities, the stars can move only a few tens of parsecs before they evolve and cool below the limit. Most O stars are thus quite attached to the nebulae that mark their places.

Above about 12 $M_\odot$, core hydrogen fusion ceases before the stellar surface cools below the limit. Diffuse nebulae can therefore be illuminated by evolved O and B stars, O giants, and even supergiants. At the extreme, the most massive stars can lose their envelopes through powerful winds and convert themselves to WOLF–RAYET STARS, which abound within the illuminating clusters of extragalactic giant H II regions. The winds of such evolving stars can have dramatic structural effects on their surroundings.

At the low limit near 10 $M_\odot$, the stars may evolve to oxygen–neon white dwarfs. Much above the limit, however, stars seem fated only to explode as Type II (core-collapse) SUPERNOVAE. The diffuse nebulae therefore mark the spots of future exploding stars, though by that time most will have left their surroundings. Supernovae within large diffuse nebula complexes can blow huge bubbles that shape the interstellar medium for new generations of stars to illuminate as diffuse nebulae.

Distances, dimensions, and distribution

Even with HIPPARCOS, diffuse nebulae are too distant for parallax measurements of their exciting stars, Orion being about 400 pc away. The distances to optically visible nebulae thus rely primarily on spectroscopic distances. These contain significant errors, as the main sequence becomes vertical with earlier spectral class, O7 stars for example having a range in luminosity that spans more than an order of magnitude. One must therefore have some idea of the evolutionary state of the star to pin down its luminosity. Much more accurate are distances from main sequence fitting of embedded clusters, the distance of the Lagoon Nebula coming from the open cluster NGC 6530 rather than from Herschel 36 alone, and that of the Rosette derived from NGC 2237.

Distances are also obtainable from nebular radial velocities found from Doppler shifts of the emission lines. Diffuse nebulae are the most extreme of disk Population I, allowing the assumption of circular motion around the galactic center. Adoption of a rotation curve for the Galaxy gives radial velocity as a function of distance along any line of sight, from which a distance can readily be found. This technique is the only one available for nebulae hidden optically by interstellar dust, for which radio emission lines are used. Unfortunately, along lines of sight toward the inner Galaxy, between longitudes 270° and 90°, two distances on either side of the point nearest the galactic center have the same velocities, so there is often an ambiguity. If distances are available from spectroscopic parallaxes, the nebulae can be used to derive the rotation curve of the Galaxy, a technique used to establish the flatness of the curve to great distances from the galactic center where dust obscuration is low. As with the planetary nebulae, a good recourse is to study the diffuse nebulae in other galaxies whose distances we already know, first among them being the MAGELLANIC CLOUDS, in which the nebulae can be readily resolved.

From a compilation of all information, astronomers loosely classify nebulae—H II REGIONS—into several groups. Smallest are the 'ultracompact H II regions' under 0.1 pc, which are found around the newest stars embedded in GMCs. Among them is the 'BN/KL complex' that lies hidden within the dusty cloud in back of the Orion Nebula and visible only through its radio radiation and the infrared that arises from dust heated by its embedded stars. They are often spatially associated with molecular masers whose sources lie within the enclosing molecular clouds. At the next scale are the 'compact H II regions' with dimensions in the realms of tenths of a parsec. The Orion Nebula, with a dense core about 0.5 pc across, could qualify, though its extended halo, ten times larger, places it more into the next category in the hierarchy: the 'classical' H II regions. Above these are 'large' structures like the North America Nebula, and at the top the 'extragalactic giant H II regions' like 30 Doradus and NGC 604, which abound in the arms of open spiral galaxies such as M101. Once the dimensions of the largest of the diffuse nebulae are measured, we can use them as distance indicators for yet more distant galaxies, a technique that has met with some limited success.

Diffuse nebulae and their associated stars are the most extreme of Population I, more so even than the GMCs, as they indicate where new star formation is actually taking place. The thickness (full width at half maximum) of the distribution in the Galaxy is only about 100 pc. Radially, diffuse nebulae track molecular hydrogen (and the GMCs) rather well, both peaking around 5 kpc from the galactic center, the galactic surface density there being over 10 times that found in the solar neighborhood (figure 3).

Spectra

The spectra of gaseous nebulae are similar to those of low excitation planetary nebulae and are formed by the same processes. The Zanstra mechanism, first applied to the planetary nebulae, produces the hydrogen emission lines, including the prominent optical Balmer lines and easily observed infrared Paschen and Brackett lines. Ignoring helium and the other elements, each Lyman continuum photon from the central star causes one hydrogen ionization, which results in one recapture of an electron by a proton, which in turn results in one Balmer photon. Ionization and recombination are responsible for the helium lines as well, and for a variety of oxygen, nitrogen, carbon, and neon emissions. The freed electrons thermally equilibrate by collision, and before they recombine can collisionally excite low-lying metastable states of lighter ions, particularly those of nitrogen, oxygen, and neon, to produce the forbidden 'nebulium' lines, all of these emissions, recombination and forbidden, extending from the ultraviolet through the infrared and even into the radio.

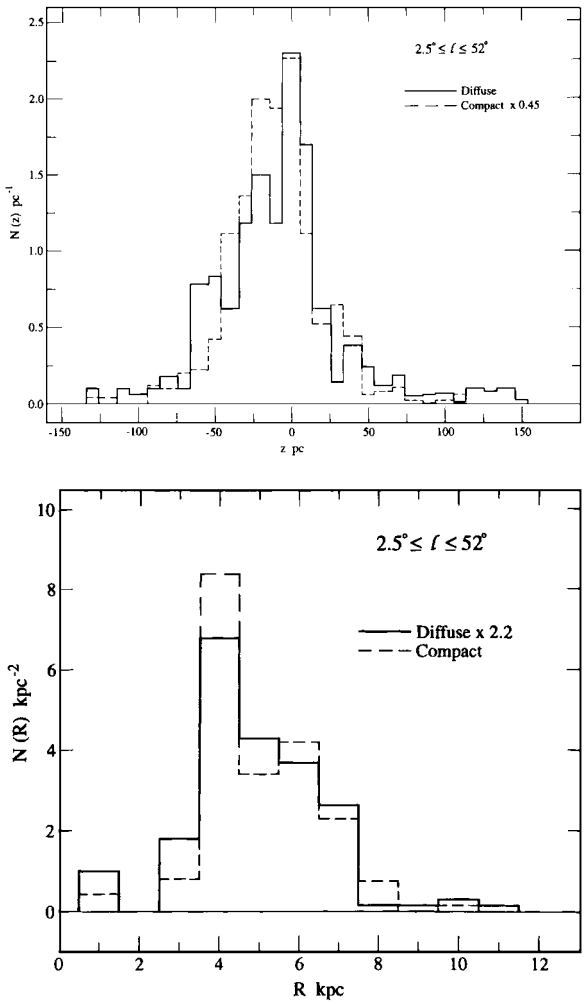

Figure 3. Diffuse nebulae of all kinds are tightly concentrated to the galactic plane (top), where z is the distance perpendicular to the plane. The number peaks about midway between the galactic center and the Sun (bottom), R the distance from the galactic center (from Lockman F J, Pisano D J and Howard G J 1996 *Astrophys. J.* **472** 173).

Spectra of diffuse nebulae differ from the average planetary nebula because their exciting stars can be no hotter than delivered by the main sequence, about 50 000 K for a zero-age O3 star, whereas 50 000 K is only modest for an evolved planetary nucleus. As a result, diffuse nebulae do not generally exhibit lines of ionized helium (He II), which arise from recombination from the doubly ionized state. Since most exciting stars are cooler, helium may not even be fully singly ionized within a nebula. Lower star temperatures also produce relatively weak double ionized oxygen lines, as O^+ may be the dominant ionization state. The exciting stars also commonly have absorption edges in the ultraviolet that allow even less ionizing ultraviolet radiation to emerge, yielding yet lower effective ionizing temperatures.

The great masses of the diffuse nebulae make the radio continuum and line spectra prominent. There are three principal sources of nebular continuum. An electron in hydrogen's second orbit can emit a pair of photons instead of Ly-α, the only constraint being that the energies of the two add to that of Ly-α. Such two-quantum emission provides most of the optical continuum emission (for both diffuse and planetary nebulae). Continuous emission is also produced by recaptures of free electrons onto bound states, producing jumps in continuum strength at the Balmer and Paschen limits at 3646 Å and 8202 Å and providing a general background. In the diffuse nebulae, these two continuum sources are added to by a stellar continuum scattered by internal dust.

Continuous emission is also radiated by free electrons that make close passes to protons but without recombination. The interaction changes one hyperbolic orbit to another, lost energy radiated as 'free–free' emission ('bremsstrahlung') that is particularly important at radio energies. The characteristic spectrum of free–free radiation readily allows the identification of diffuse nebulae as 'thermal' emitters (radiating as a result of thermally heated gas), as opposed to the non-thermal radiation of supernova remnants.

Though in principle there is no limit to the orbits of the hydrogen atom, the maximum principal quantum numbers are limited to under 1000 by interactions with neighboring atoms. Electron recombinations to high orbits n and the transitions to $n-1$ ($n\alpha$), $n-2$ ($n\beta$), etc., emit radio lines that are superimposed on the radio continuum, huge numbers of them being observed. At high quantum numbers, helium and other elements behave much like one-electron atoms. As a result, helium radio lines are observed to the high-frequency sides of their hydrogen counterparts. At slightly higher frequencies yet are similar emissions for 'carbon', a mixture of high-order lines from heavier atoms.

Because radio emissions are unimpeded by dust, they allow the discovery of nebulae that are hidden behind and within the thick dust of galactic GMCs, the emission lines also allowing measures of radial velocity and distance. Somewhat less obscured nebulae (as well as those optically visible) are also studied in the infrared through their hydrogen Brackett emissions and from the lines of a variety of other species.

While not hidden, optically visible diffuse nebulae are still dimmed and reddened by the dust (the problem affecting the planetary nebulae as well). The most noticeable effect is the steepening of the Balmer decrement, which describes the progressive weakening of higher-order lines within the series. After adopting an extinction curve (extinction versus wavelength), a coefficient C equal to the logarithmic extinction at H_β is found by forcing the Balmer line intensities to fit theory. C is readily converted to $E(B-V)$ color excess. Application of C to the extinction curve then allows the correction of the reddened line intensities. Theoretical forbidden-line ratios that span a large wavelength base serve as well. A major problem is that the diffuse nebulae are surrounded by a great deal

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of circumstellar dust that may—and usually does—have a non-standard extinction curve as a result of grains that have been modified in the local GMC environment, which contributes errors to the corrected relative line intensities.

Physical parameters

The determination of the physical parameters of diffuse nebulae from optical observations involves much the same techniques as for planetary nebulae. Electron temperatures are easily derived from forbidden-line ratios, particularly of the 4363 Å and 5007 Å lines of [O III] and of the 5754 Å and 6584 Å lines of [N II]. Temperature fluctuations within the filamentary gas can cause serious distortion of the result, as the forbidden lines from the higher metastable states are preferentially produced at higher temperature, a problem difficult to account for. For both optically visible and obscured nebulae, electron temperatures are also derivable from the ratios of the fluxes in radio recombination lines to the flux densities in the neighboring continua. Account must be taken of natural masering in the radio lines and of the nebular geometry, as the observed radio flux is the average of that produced over a wide range of conditions, accurate results requiring a nebular model. Emission lines are also Doppler broadened as a result of 'turbulence' (a vague concept at best) and by thermal effects, the linewidth therefore giving an upper limit to electron temperature. The two effects can be deconvolved by observing emissions from ions of differing atomic weight. Line widths of hydrogen lines are all that is available for large numbers of distant, weakly radiating sources.

Electron temperatures depend on the balance between the heating rate, which depends on the temperature and ultraviolet spectrum of the central star, and the cooling rate, which effectively depends on the oxygen-to-hydrogen ratio (as the forbidden lines are collisionally excited by free electrons). They start notably lower than for planetary nebulae and range upward from around 4500 K for weak sources toward the center of the Galaxy through around 9000 K for Orion and up to 20 000 K for some extragalactic objects with low O/H. Since metallicity drops with distance from the galactic center, the electron temperature rises from its central low of 4500 K up to 10 000 K or so 2 kpc outside the solar orbit, the gradient about 400 K kpc^{-1}.

Densities fall equally well to optical and infrared forbidden lines, particularly to the close doublets of [O II] at 3727 Å and 3729 Å and [S II] at 6717 Å and 6731 Å. These ratios give densities within radiating sheets and filaments, which may occupy only a small portion of the nebular volume. Since the recombination rate depends on the product of the electron and proton densities, which are about equal, the fluxes in the recombination lines and continuum yield a mean electron density. Electron densities range from over 10^6 cm^{-3} for ultracompact H II regions to 5000 cm^{-3} or so for the filaments in the central regions of Orion to under 100 cm^{-3} for the huge, spread-out giant H II regions.

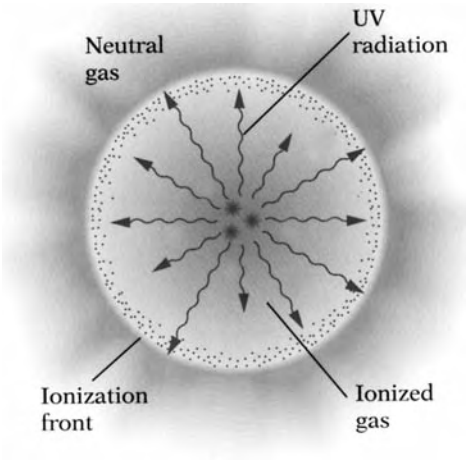

Figure 4. In the classic Strömgren sphere, hot stars ionize a bubble within a cold neutral molecular medium, the gas fully ionized out to a sharp edge (art from Kaler J B 1997 *Cosmic Clouds* Scientific American Library (NewYork: Freeman).

The mass of a diffuse nebula appears simple to find just by multiplying the electron density found from forbidden lines (essentially the proton density) by the mass of the proton and the volume of the nebula. Nebulae are highly filamentary, however, and the electron density is that of the radiating filaments. To find the mean density requires that we know the volume occupied by the filaments relative to the volume of the nebula, or the 'filling factor', which is generally set around 0.1, but is highly uncertain. The volume of the nebula is also uncertain, as the distance may not be well known and the three-dimensional structure may not be obvious; what may appear to be a rough sphere may be a sheet, or a blister on the edge of a GMC, or vice versa. The range of nebular masses is enormous, as they depend on the density and extent of the local molecular cloud (the amount of matter available to be ionized), the temperature and radius of the star (which controls the number of ionizing photons), the age of the star (how much matter it has had a chance to ionize), and on the number of sufficiently hot stars within the diffuse nebula. Masses go from under a thousandth that of the Sun for young ultracompact H II regions through 50–100 $M_\odot$ for modest objects like Orion to millions of solar masses for the giant diffuse nebulae like 30 Doradus and NGC 604 that are lit by clusters of O3 stars. The terms 'diffuse nebula' or 'H II region' define not one kind of object but a great many.

Chemical compositions stem directly from the theories of recombination and of the collisional excitation of the forbidden lines in both the optical and infrared, helium abundances for obscured nebulae also found from the radio recombination lines of high-order states. Major problems involve the incomplete ionization of helium, which gives a lower limit to the helium abundance, and severe filamentation, which can distort electron temperatures and densities. Detailed models of the

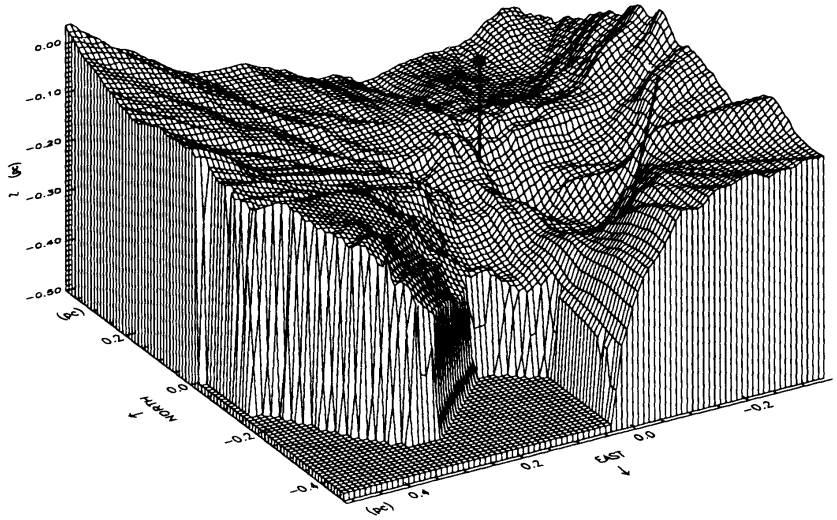

Figure 5. A three-dimensional model of the Orion Nebula shows its ionization front working its way into a dark molecular cloud, the ionizing radiation coming mostly from $\theta 1$ Orionis C, marked by the dark circle. The dark line to the right indicates the curved surface that makes the well known 'bright bar' (from Wen Z and O'Dell C R 1995 *Astrophys. J.* **438** 784).

nebulae can account for these difficulties as well as for incompleteness in the ions observed.

The resulting compositions are similar to those found in the Sun and in Population I in general. Indeed, more than any other kind of body, the nebulae define the composition of Population I. O/H, a general indicator of metallicity, averages from around double that found in the Sun in the inner Galaxy to about a third solar at distances half again the solar galactocentric distance. The N/H ratio drops in a similar way, though there are indications that it flattens out twice as far from the center as the Sun, the N/O ratio thus being anomalously high. Diffuse nebulae in other disk galaxies show similar, though controversial, relations.

Orion and other diffuse nebulae effectively at the solar circle have O/H ratios significantly lower (about 30%) than the Sun, not expected since O/H should have been built up in the interstellar medium to greater than solar in the five billion years since the Sun was born. One explanation posits that the metallicity of the Galaxy has declined as a result of infusion of low-metal gas through collisions with other systems.

Structures

A basic structure for a diffuse nebulae was defined by BENGT STRÖMGREN in 1939. His 'Strömgren sphere' is a bubble formed within a neutral cloud (a GMC) by a hot, ionizing star. The idea builds on the Zanstra mechanism, in which the number of ionizing photons radiated per second equals the number of recombinations that take place in the nebula per second. A diffuse nebula is illuminated by N stars (N_*) of (assumed similar) temperatures T_*. If the stars are black bodies, the rate of Lyman photon production depends on N_*, the integral of the Planck function from the Lyman limit to infinity (which approaches a T_*^4 proportionality for a very hot star), and the square of the stellar radius, R_*^2. The total recombination rate in a homogeneous medium depends on the product of the electron and proton density—effectively the electron density squared (N_e^2)—multiplied by a rate coefficient computed from recombination theory times the nebular volume, which depends on the nebular radius cubed ($R_{\rm neb}^3$). Equating the two yields

$$R_{\rm neb} = (\text{constant}) \times T_* R_*^{2/3} N_{\rm e}^{-2/3} N_*^{1/3} f(T_*).$$

The (constant) contains a combination of numerical and atomic constants and the recombination coefficient (which is slowly dependent on electron temperature), and $f(T_*)$ is the $\frac{1}{3}$ power of an integral of a function of $h\nu/kT$ taken from the Lyman limit to infinity (figure 4).

The photons within the Strömgren sphere fully ionize the nebula (ionizing those protons that have just captured electrons to create the neutral state) out to the radius $R_{\rm neb}$, at which point the gas suddenly becomes neutral. Photons with energies lower than the Lyman limit will pass through the Strömgren sphere unhindered, will ionize atoms with low ionization potentials, and will photodissociate molecules, producing a 'partially dissociated region' (a PDR) that is a layered transition to the fully neutral molecular gas in the GMC.

As appealing as it is, the Strömgren sphere is not a very realistic model for optically visible nebulae. By definition, the sphere must be inside a dusty GMC, and by their very visibility, the classic nebulae are not inside GMCs, as they otherwise would not be visible. The concept works better for obscured nebulae that are detectable only through their radio and infrared radiation.

Strömgren spheres, indeed diffuse nebulae in general, are dynamic. The heated gas in the Strömgren

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

sphere produces a pressure at the boundary—the 'ionization front'—that expands the ionized zone into the surrounding GMC, shocking the gas in front of it, the nebula expanding, the electron density dropping as the pressures in the two zones go toward equilibration. If the nebula becomes large enough, it can break through the outer boundary of the GMC, the high pressure gas erupting in an ionized fountain that would readily be optically visible. If O stars form near the edge of the GMC, they can also erode the molecular layers separating them from open space. A nebula might then appear as a blister on the molecular cloud's surface, the stars in front of it, the nebula behind.

Though the Orion Nebula appears more or less spherical to the eye, its luminosity relative to its density and its internal velocities as measured by Doppler shifts clearly show that it is not an expanding Strömgren sphere, but in fact is such a blister that has dense ionized gas behind the star and a much lower density plasma in front of it. The star (mostly $\theta 1$ Orionis C) is eating its way into the dense dark cloud at the same time that the hidden KL object is eating its way out. The curvature of the blister relative to the line of sight gives the nebula considerable two-dimensional structure, the obvious 'bright bar' feature, for example, an ionization front seen more or less edge on, a PDR behind it. These structures make the planetary nebulae, for all their complexity, look simple (figure 5). The immense power of the ionizing O6 star is readily seen in the photoerosion of remnant disks that surround lower-mass stars seen in relief against the nebula. Superimposed on such complex nebular structures are the ever-present foreground dust clouds that take on a multiplicity of shapes that range from tiny black circular patches to elongated 'elephant trunks' in which stars are still being formed.

Gaseous (diffuse) nebulae thus allow a look into both local and global stellar evolution and into the evolution of the Galaxy as a whole. We use them to find how massive stars are born and how the Galaxy changes its chemical composition with time. Similar studies of other galaxies allow the comparison of their evolution with ours, yielding insights back into the development of our own. Equally important, they provide us with grand sights, shimmering within the Milky Way, allowing us to see the grandeur of star birth before our very eyes.

Gaspra

An asteroid discovered by Grigorii Neujmin in 1916, designated (951) Gaspra. In October 1991 it became the first asteroid to be imaged from close by when the Galileo probe passed it at a distance of about 16 000 km on its way to Jupiter. Images showed a highly angular body measuring 18 × 11 × 9 km, pitted with small craters but with few large craters, so either Gaspra has a strong, metal-rich surface or it is a young object. Galileo also detected a significant interaction with the local interplanetary magnetic field, suggesting that there is remnant magnetism. Gaspra orbits the Sun at a mean distance of 2.21 AU (331 million km), near the inner edge of the main asteroid belt, in a period of 3.28 years; the orbital inclination is 4° and the eccentricity 0.17. It is an S-type asteroid, with a reflection spectrum similar to that of ordinary chondrite and stony-iron meteorites.

Gauge Bosons

Particles that transmit the fundamental forces. Photons convey the electromagnetic force between charged particles, intermediate vector bosons (the W and Z particles) transmit the weak nuclear force, which governs the radioactive decay of atomic nuclei, and gluons carry the strong nuclear interaction (or 'color force') between the quarks that comprise hadrons and mesons. The existence of an equivalent force carrier for gravitation, the graviton, remains unproven.

The term 'gauge', meaning 'measure', is used essentially for historical reasons, while the term 'boson' applies to any particle or atomic nucleus that has an integral spin and which, therefore, obeys Bose–Einstein statistics (the statistics that govern the behavior of systems in which an unlimited number of particles can occupy the same quantum state); bosons are not constrained by the Pauli exclusion principle.

Gauge bosons have integral values of spin (expressed in units of the Planck constant, h, divided by 2π). The photon has zero mass and charge. W particles have masses (expressed in energy terms) of 83 GeV (88 times that of the proton), the W^+ having a charge of +1 (in units of the charge on the electron) and the W^-, a charge of -1. The electrically neutral Z particles have masses of 93 GeV (nearly a hundred times that of the proton). Gluons have zero mass and charge but carry another property, analogous in some respects to electrical charge, which is called 'color'. Because the lifetime of a force-carrying particle is inversely proportional to the amount of energy that is required to make it, the range over which a gauge boson can transmit a force is inversely proportional to its mass. Because the photon and hypothesized graviton have zero mass, they can transmit the electromagnetic and gravitational forces over infinite distances. Because the heavy W and Z particles have lifetimes of about 10^{-25} s the range of the weak interaction is restricted to about 10^{-17} m. Although gluons have zero mass, and might therefore be expected to have infinite range, their 'color' properties confine their range of influence to within the diameter of the proton. The strong nuclear force between the protons and neutrons in an atomic nucleus is conveyed by pions (particles that are composed of quark–antiquark pairs).

Gauss, Carl Friedrich (1777–1855)

Scientist, born in Brunswick (now in Germany), worked in mathematics and physics including number theory, analysis, differential geometry, geodesy, magnetism, astronomy and optics. A child prodigy, at an early age Gauss independently discovered BODE's law, the binomial theorem and the prime number theorem, as well as the method of the construction of a regular 17-gon by ruler and compasses. In 1801, Ceres, a minor planet discovered by G PIAZZI, was lost behind the Sun. Several predictions of its position on reappearance were made from the rather few discovery observations, including a prediction by Gauss which differed greatly from the others. When Ceres was recovered by ZACH on its reappearance it was almost exactly where Gauss had predicted. Although he did not disclose his methods at the time, Gauss had used his least squares approximation method. A *Gaussian distribution* is the name of the normal distribution of residuals in statistical data, solved by the least squares method, which Gauss refined in 1828. Gauss became director of the Göttingen observatory and published a book, *Theoria Motus Corporum Coelestium in Sectionibus Conicis Solem Ambientium*. This was a treatise on the motion of celestial bodies, in which he showed how to estimate and then to refine the estimation of a planet's orbit, following this with further work on mechanics. He carried out a geodesic survey of Hanover, inventing a surveying instrument, the heliotrope, that worked by reflecting the Sun's rays. With Weber he investigated terrestrial magnetism, making magnetic surveys. To mark Gauss' theoretical treatment of magnetism, a unit of magnetism, the *gauss*, was named after him (superseded by the SI unit, the tesla).

Geminga

A gamma-ray source in the constellation of Gemini, its name deriving from 'Gemini gamma-ray source'. Located at a distance of about 300 light-years, Geminga is a pulsar with a period of 0.237 s and, as such, is one of the nearest known neutron stars. Its optical counterpart is a low-luminosity star of apparent magnitude 25 with an annual proper motion (angular motion across the sky) of about 0.2 arcsec. Because its luminosity outside of the gamma-ray region is so low, the nature of this source remained a mystery until the discovery of pulsed emission, by the ROSAT satellite in 1992, showed that it is a pulsar.

Gemini

(the Twins; abbrev. Gem, gen. Geminorum; area 514 sq. deg.) A northern zodiacal constellation which lies between Auriga and Canis Minor, and culminates at midnight in early January. It represents Castor and Pollux, the twin sons of Leda, Queen of Sparta, in Greek mythology, whose brotherly love was rewarded by a place among the stars. Its brightest stars were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest*.

The two brightest stars in Gemini, α Geminorum (Castor), (combined) magnitude 1.6, and β Geminorum (Pollux), magnitude 1.2, are about 4.5° apart and easily recognizable. The former is a multiple system, consisting of a pair of bluish-white (A1 and A2) components, magnitudes 1.9 and 3.0, separation 3.1″, period about 467 years, and a third, red (M1) component (the variable star YY Geminorum), magnitude 8.9–9.6, separation 73″, each of which has an unseen companion, periods 9.21, 2.93 and 0.81 days, making this a sextuple system. There are 11 other stars of magnitude 4.0 or brighter, including ζ Geminorum, a bright Cepheid variable (range 3.6–4.2, period 10.15 days). Other interesting variables include the Mira-type star R Geminorum (range 6.0–14.0, period about 370 days) and the dwarf nova U Geminorum (range 8.2–14.9, mean period about 105 days).

Other interesting objects include M35 (NGC 2168), an open cluster of a couple of hundred stars fainter than eighth magnitude, and NGC 2392 (the Eskimo Nebula or Clown Face Nebula), a ninth-magnitude planetary nebula.

The Geminid meteor shower appears to radiate from a point just to the west of Castor.

Gemini Observatory

The twin 8 m Gemini telescopes represent a new generation ground-based observatory incorporating many innovative technologies that will provide astronomers in the seven-country Gemini partnership with some of the best optical/infrared observations ever obtained from Earth or space.

The Gemini Observatory began as an effort by the United States National Science Foundation to build a new generation large astronomical telescope for the entire US astronomical community. However, it was quickly realized that a partnership with the United Kingdom and Canada (who had similar observatory plans) could produce twin 8 m telescopes more economically while providing the same amount of total telescope time for US astronomers. Chile, Argentina, Brazil and Australia later joined the partnership. Each partner is allotted observing time for their astronomical communities in proportion to their financial contribution.

In order to provide complete sky coverage of both the northern and southern skies, one of the Gemini telescopes is located on Hawaii's Mauna Kea (Gemini North) and the other on central Chile's Cerro Pachón (Gemini South). Both telescopes are expected to be fully operational by mid-2001 employing a staff of approximately 100. The Gemini telescopes utilize many new technologies, engineering innovations and operational philosophies that will allow them to excel in the study of stellar nurseries, galactic evolution and distant high-redshift galaxies.

Gemini North's first adaptive optics images, during commissioning in 1999, revealed the remarkable potential of the telescopes. Over integrations of several minutes, star images of 0.08 arcsec FWHM were obtained in the infrared.

Geminids

One of the year's most prolific meteor showers, taking place in December. The radiant lies in the constellation Gemini. Uniquely, the parent body of the Geminids is not a comet but the asteroid (3200) Phaethon, discovered in 1983. The perihelion distance of Phaethon is a mere 0.14 AU. It may be that the Geminid meteor stream consists of particles that crumble away from the asteroid's surface under the intense heat of its perihelion passage. An asteroidal source is consistent with the Geminid meteoroids' high density of around 2 g cm^{-3}, about an order of magnitude higher than other meteoroids, which are cometary dust particles. These dense particles tend to produce quite slow, bright meteors of long duration.

Gemma Frisius, Reiner [Regner, Regnier] (1508–55)

Born in Dokkum, Friesland, Netherlands, became professor of medicine and mathematics at the University of Louvain. In 1530 wrote *De Principiis Astronomiae Cosmographicae* in which he describes, for the first time, how the longitude of a place may be found using a clock ('it must be a very finely made clock which does not vary with change of air') to determine the difference in local and absolute times. He described the theory of trigonometric surveying as a method of accurately locating places.

General Relativity and Gravitation

The General Theory of Relativity (GR), created by Albert Einstein between 1907 and 1915, is a theory both of gravitation and of spacetime structure. It is based on the assumption that matter, via its energy-momentum, interacts with the metric of spacetime, which is considered (in contrast to Newtonian physics and SPECIAL RELATIVITY) as a dynamical field having degrees of freedom of its own (GRAVITATIONAL RADIATION). In brief, 'matter tells spacetime how to curve, and spacetime tells matter how to move' (J A Wheeler). GR is a generalization of Newton's theory of gravitation and of Special Relativity, which are both approximations to GR under appropriate conditions (see below). More generally, GR provides a common, coherent basis for classical (as opposed to quantum), macroscopic physics. Its relation to quantum physics is not yet well understood (QUANTUM GRAVITY). While this poses an important problem of principle, it does not present a practical difficulty to astrophysics, since the atomic and subatomic scales, on which quantum laws operate, are very small compared to macroscopic scales, where gravity dominates.

According to present fundamental physics, the only one among the four basic interactions which acts between all kinds of matter is the gravitational interaction. Since it always acts as an attraction and thus cannot be shielded, and because its range is unbounded, it dominates the behavior of matter on large scales in spite of its extreme weakness. Therefore, gravity plays a significant role in nearly all parts of astronomy and astrophysics. (In the atomic and subatomic domain gravity is unmeasurably weak and totally negligible, as is highlighted by the 'fact' that the gravitational force between a proton and an electron is weaker than the Coulomb force by the factor 5×10^{-38}.)

Relativistic gravity is important in the following areas of research: high-precision astrometry (REFERENCE FRAMES AND TIME SCALES IN GR, SPACE AND TIME REFERENCES: CONCEPTS), compact objects such as NEUTRON STARS and BLACK HOLES and systems thereof (binary PULSARS, low-mass X-RAY BINARY STARS), active galactic nuclei and quasars, supernovae and gravitational collapse, identification of dark stars and planets (MICROLENSING), cosmology (COSMOLOGY: STANDARD MODEL, DARK MATTER, COSMOLOGICAL CONSTANT, distribution of luminous and DARK MATTER via weak GRAVITATIONAL LENSING). In the near future a new window onto the universe is expected to open when GRAVITATIONAL WAVES become observable.

Though GR covers a larger range of phenomena than Newton's theory, the latter provides a satisfactory description whenever the system under study is (nearly) isolated, the relevant velocities are small compared to the speed of light, $\frac{v}{c} \ll 1$, and bodies are not too compact, $\frac{2GM}{Rc^2} \ll 1$. Moreover, Newton's theory is used to describe the basic facts of gravity; it often serves as a point of departure for approximations in GR, and its shortcomings motivate the introduction of GR and help to understand and highlight GR's achievements. For these reasons, the Newtonian theory of spacetime and gravity is reviewed before GR is considered.

Newton's theory of gravity

Can be summarized as follows.

1(a) On spacetime, the set of events 'here-now', there exists an absolute time, measurable by means of arbitrarily moving, undisturbed clocks. Distances between bodies at one instant of time satisfy the laws of Euclidean geometry. Hence, motions of bodies can be referred to rigid frames of reference associated with coordinates (t, x^a) specifying times t and positions $(x^a) = \vec{x}$.

1(b) There exist preferred reference frames, inertial frames, with respect to which the motions of N bodies which form a nearly isolated system (like the solar system or a double star), are given by Newton's gravitational equations of motion

$$\ddot{\vec{x}}_{\rm A} = \sum_{B \neq A} \frac{M_{\rm B}}{r_{\rm AB}^2} \vec{e}_{\rm AB} \qquad (1)$$

which form the basis of classical celestial mechanics. The positive constants $M_{\rm A}$ are called the gravitational masses of the bodies, $r_{\rm AB}$ denotes the distance between the simultaneous positions of the bodies A and B, $\vec{e}_{\rm AB}$ indicates the unit vector pointing from $\vec{x}_{\rm A}$ to $\vec{x}_{\rm B}$, and dots signify time differentiation. Equation (1) characterizes an inertial frame as a rigid frame with respect to which the equations of motion do not contain velocity dependent (Coriolis acceleration) terms and relative to which the center of mass of such a system moves uniformly in a straight line.

1(c) If a body, or a part of a body, is subjected not only to gravity, its motion relative to an inertial frame is governed by the equation

$$m(\ddot{\vec{x}} - \vec{g}(t, \vec{x})) = \vec{F}. \qquad (2)$$

Here, the positive constant m is the inertial mass of the body, $\vec{g}$ denotes the acceleration the particle would have if subjected to gravity only, and $\vec{F}$ is the non-gravitational force acting on the particle. The product $m\vec{g}$ is traditionally called the gravitational force, although it is not needed to describe purely gravitational motions, see equation (1). In contrast to other forces, the gravitational force depends on the particle solely through the latter's inertial mass.

1(d) Measurements indicate that the ratio gravitational mass/inertial mass for laboratory-size bodies has a universal value. This ratio,

$$\frac{M}{m} = G = 6.673(10) \times 10^{-8}\ {\rm cm}^3\ {\rm g}^{-1}\ {\rm s}^{-1} \qquad (3)$$

though far less precisely known than most other physical constants, is assumed to have a universal

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

value, the constant of gravitation. Accordingly, M and m are considered as different measures of one physical quantity, 'mass'. Note, however, that the gravitational mass of the Sun defined in accordance with equation (1) is known about two orders of magnitude more accurately than G: $M_\odot = 1.32704(2) \times 10^{26}$ cm^3 s^{-2}.

1(e) If matter is described as continuously distributed, with (inertial) mass density ρ, velocity $\vec{v}$ and pressure p, the effect of gravity on motion is expressed, in generalization of (2), as

$$\rho\left(\frac{\partial\vec{v}}{\partial t} + \vec{v}\cdot\vec{\nabla}\vec{v} - \vec{g}(t,\vec{x})\right) = -\vec{\nabla}p \qquad (4)$$

and the gravitational acceleration $\vec{g}$ can be obtained from the gravitational potential

$$\phi(t,\vec{x}) = -\int \frac{G\rho(t,\vec{x}')}{|\vec{x}-\vec{x}'|}\,\mathrm{d}^3x', \qquad (5)$$

by taking its gradient,

$$\vec{g} = -\vec{\nabla}\phi. \qquad (6)$$

Equations (5) and (6) generalize the expression for the acceleration of equation (1). For a spatially bounded mass distribution, the law (5) can be replaced by Poisson's equation

$$\Delta\phi = 4\pi G\rho \qquad (7)$$

together with the boundary condition

$$\lim_{|\vec{x}|\to\infty}\phi(t,\vec{x}) = 0. \qquad (8)$$

1(f) The laws (1) and (2) for particles, or (4)–(8) for spatially bounded matter distributions, determine the motions of all matter elements uniquely if its positions and velocities at one time are specified. Without the boundary condition (8), the laws (6) and (7) do not determine $\vec{g}$, and thus do not determine the motion; Newton's theory applies only to systems which can be treated as isolated, but not to the apparently spatially unbounded cosmic matter distribution.

All laws stated above take the same forms in all inertial frames, they are invariant under Galilean transformations which express symmetries of Newtonian spacetime.

Shortcomings of the Newtonian theory

Which led, first, to the special relativity theory (SR) and, later, to GR, include the following facts and considerations.

2(a) The assumptions about time and space listed above under 1(a) are incompatible with electrodynamical and optical phenomena involving moving bodies, with well established facts about moving clocks and with many other experimental results. Those facts for which gravity can be neglected or, more precisely, where the temporal and spatial scales on which the gravitational acceleration changes, are negligible compared to the relevant scales, are well accounted for by Special Relativity. According to SR, there is no universal, absolute time. Rather, each inertial frame has its own measure of time and also of distance, and the coordinates of inertial frames are related not by Galilean, but by Poincaré transformations. The metric of spacetime determines, for each pair of events $(t_1,\vec{x}_1)$ and $(t_2,\vec{x}_2)$, whether there exists an inertial frame with respect to which the events: (a) are simultaneous; or (b) happen at the same point of space; or (c) whether the events can be connected by a light signal. Formally, the metric is given, in any inertial frame, by the interval

$$\Delta s^2 = -c^2(t_2-t_1)^2 + (\vec{x}_2-\vec{x}_1)^2 \qquad (9)$$

and the alternatives just listed correspond to

(a) $\Delta s^2 > 0$
(b) $\Delta s^2 < 0$
(c) $\Delta s^2 = 0$.

According to SR, no interaction or signal can be transmitted faster than with the speed of light in vacuum, c.

2(b) In Newtonian theory, inertial frames can only be identified globally for isolated systems. 'Real' inertial frames associated with spatially separated, nearly isolated systems such as galaxies, are relatively accelerated and cannot be fitted into a single, 'truly inertial' frame of reference. Also, freely falling test particles which can be observed locally, exhibit relative accelerations in any real, inhomogeneous gravitational field; 'free' particles exactly obeying the law of inertia do not exist since all particles 'feel' gravity in the same way, see equation (2) with $\vec{F} = 0$.

2(c) As stated in 1(f), Newtonian theory does not provide predictive dynamical laws for spatially unbounded matter distributions.

2(d) Newtonian celestial mechanics is unable to account for the 'anomalous' advance of the perihelion of Mercury's orbit, noticed first by Leverrier in 1859.

General Relativity Theory overcame these shortcomings and predicted additional phenomena.

Basic concepts and laws of General Relativity

3(a) In order to preserve locally the approximate validity of SR, it is assumed that, for any event E of spacetime, there exists a coordinate system (t, x^a) such that the statements made in connection with equation (9) are valid for spacetime points P which are 'close to E', in the sense that

$$\Delta s^2 = -c^2\Delta t^2 + \Delta\vec{x}^2 + 0(4). \qquad (10)$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

(The symbol 0(4) indicates that additional terms are at least as small as fourth powers of the leading ones, e.g., $c^2\Delta t^2 \cdot \Delta\vec{x}^2$, and thus are negligible for small displacements $\Delta t, \Delta\vec{x}$ connecting E to P.) Such coordinate systems are called locally inertial at E. They may be vizualized/realized as connected with a small, non-rotating, freely falling cabin, like a space shuttle. Two such coordinate systems, referring to different 'central' events E_1 and E_2, represent approximately inertial systems near E_1 and E_2, respectively, but in contrast to Newtonian or SR inertial systems they are nonlinearly related, and thus exhibit relative accelerations between those reference frames. The basic assumption, symbolized in equation (10), at the same time preserves SR as a local approximation and weakens the concept of an inertial frame as suggested by the considerations in 2(b). Mathematically this assumption means that spacetime carries a Lorentz metric whose components in a general coordinate system, $g_{\alpha\beta}(x^\gamma)$, are functions of those coordinates ($\alpha, \beta = 0, 1, 2, 3$). The fact that these functions in general cannot be reduced to constants in a finite coordinate domain means geometrically that spacetime is curved.

3(b) The most direct physical interpretation of the metric is that it determines the times shown by undisturbed clocks or natural time carriers like atoms. The motion, or 'history', of a clock is represented by a time-like curve (figure 1), and the proper time τ it measures is given by the 'arc length'

$$\tau = \int |g_{\alpha\beta}\, \mathrm{d}x^\alpha\, \mathrm{d}x^\beta|^{1/2} \tag{11}$$

along that world line. This statement is the GR-substitute for Newtons's axiom about absolute time.

3(c) According to Einstein's equivalence principle all local, non-gravitational laws of physics take the same mathematical form at the origin of a local inertial coordinate system. This principle restricts the relativity principle on which SR is based since it implies that the laws of SR hold only approximately in small domains; at the same time it generalizes its approximate validity to arbitrary gravitational fields. The principle is used to generalize laws from Special Relativity to General Relativity. Applied to the law of inertia of SR, it leads to the statement that the spacetime curve, or world line, of a freely falling particle is a straightest curve, or (timelike) geodesic, in spacetime. Applied to Maxwell's laws of electromagnetism it provides the corresponding laws in curved spacetime, i.e., in an arbitrary gravitational field. In the geometrical optics approximation this implies that light rays (≡ photon world lines) are null geodesics, i.e., geodesics everywhere tangent to the local light cones (figure 1). Analogously, one obtains the equations of motion for fluids or gases in gravitational fields. While in these and similar cases of classical physics Einstein's equivalence principle works perfectly, it proved to be complicated to generalize quantum field theory to curved spacetimes. For reasons given in the introduction this is, however, so far of no practical importance to astrophysics.

The mathematical forms of the general-relativistic laws for particles and fields show that in GR the metric $g_{\alpha\beta}$ of spacetime also plays the role of the gravitational potential which has ten components that replace the one Newtonian potential ϕ.

3(d) The third, and most important, ingredient of General Relativity is Einstein's gravitational field equation. It relates the metric field of spacetime to the distribution and motion of matter and energy. More precisely, the metric tensor $g_{\alpha\beta}$ and its first and second derivatives determine the so-called curvature tensor (which measures the tidal field) and a tensor derived from it, called the Einstein tensor $G^{\alpha\beta}$. Moreover, the energy density, energy current density and stresses of matter and fields are combined into a ten-component quantity $T^{\alpha\beta}$, the stress-energy-momentum tensor. These fields are required to satisfy the (tensor) equation

$$G^{\alpha\beta} = \frac{8\pi G}{c^4} T^{\alpha\beta}. \tag{12}$$

This system of nonlinear partial differential equations replaces Poisson's equation (7) and does for gravity what Maxwell's equations do for electromagnetism.

3(e) In contrast to SR, the topology of spacetime is not given once and for all. Rather, the problem of finding a spacetime model involves to determine a four-dimensional manifold and, on it, physical fields satisfying equation (12). This aspect of GR is particularly relevant for the study of black holes and cosmology.

3(f) The unification of special relativity and Newtonian gravitation theory brought about by Einstein's GR has solved an old conceptual problem emphasized especially by Ernst Mach. In Newtonian theory (and in special relativity), the structure of spacetime as exhibited in the set of inertial frames, acts on matter, but it cannot be observed independently of the motion of matter, and it is not influenced by matter. It is, in other words, an absolute, unobservable cause. To assume such a cause contradicts the scientific mode of thinking ('widerspricht dem wissenschaftlichen Verstande') according to Mach, and Einstein consented. According to GR, the metric of spacetime is not given once and for all, but is a dynamical field interacting with matter, acting and being acted upon; in this respect GR overcomes Mach's objection. The dynamical nature of the metric is the most important insight of principle of GR.

Since the metric depends on the circumstances, one cannot introduce coordinates with a definite physical

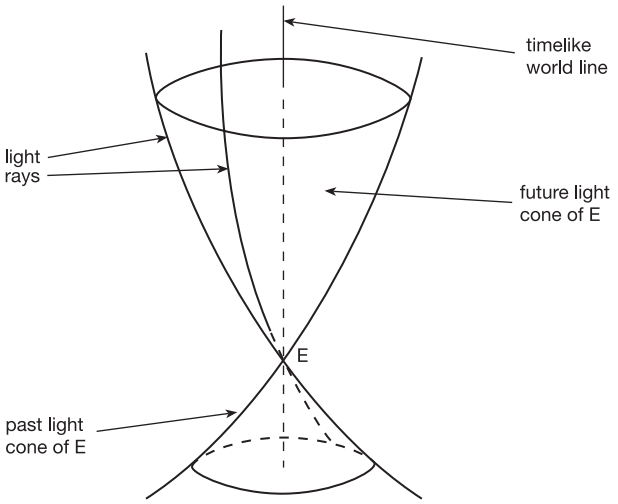

Figure 1. The future and past light cones of event E, generated by light rays, and a timelike world line which could represent a clock's motion.

meaning independently of the physical situation. Therefore, coordinates only serve to 'name' and distinguish spacetime points and to express their 'nearness' in a qualitative (topological) sense. For the same reason, the laws of the theory have to be formulated so as to hold in arbitrary coordinate systems; they have to be generally covariant. This requirement, together with the principle of equivalence, guided Einstein on his way towards GR.

Some consequences of GR

Causality

The mathematical analysis of the field equation (12) has shown that the metric (≡ gravitational field) propagates like a wave. Its value in the vicinity of an event A can influence the field at a later event B only if B is contained in the interior of or on the future light cone of A, i.e. the field propagates not faster than light. To determine the field at B, it suffices to know the field on a 'spacelike', three-dimensional subspace S of spacetime earlier than B, on that part C of S which is contained in the past light cone of B. This is illustrated, with one space dimension suppressed, in figure 2. These statements also hold for the combined gravitational and matter fields. They generalize corresponding laws of special relativity (e.g. for electromagnetic fields), and contrast sharply with the instantaneous action-at-a-distance of Newtonian forces.

Violation of local energy-momentum conservation

The field equation (12) implies that the energy tensor satisfies an equation which generalizes the laws of local conservation of energy and momentum from SR to GR, in accordance with the equivalence principle,

$$\nabla_\beta T^{\alpha\beta} = 0. \qquad (13)$$

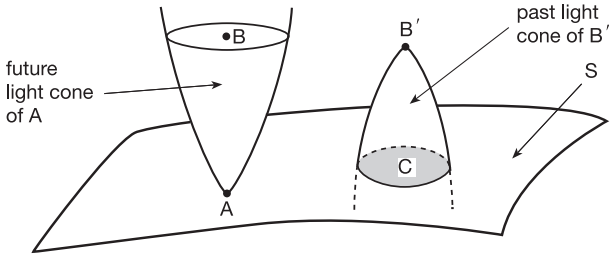

Figure 2. An event B in the interior of the future light cone of A and the region C of S which causally determines what happens at B′.

Special cases of this equation provide GR–generalizations of the equations of motion (1), (2) and (4) of Newtonian theory. The derivative operator ∇ depends on the metric and expresses that the localizable energy and momentum of matter and of non-gravitational fields are not strictly conserved, due to the action of gravity. For an isolated system, however, a global conservation law holds which includes a contribution from the gravitational field, see section Isolated systems, global energy-momentum below.

Equations of motion and gravitational waves

A fundamental task for any theory of gravitation is the prediction of the motions of bodies such as planets and stars. Approximation methods based on the gravitational field equation (12) and its consequence (13) have been developed to solve that problem. Solutions which represent the gravitational fields of well-separated, nearly spherical, slowly moving ($v \ll c$) and weakly stressed ($p \ll \rho c^2$) bodies forming an isolated system reproduce, in lowest order, the results of Newtonian dynamics and provide higher 'Post–Newtonian' order, general-relativistic corrections, see section Tests of the field equation below. These methods have been successful in describing effects in the solar system like the perihelion advance, and even the effect of the emission of gravitational waves on the motions of the binary pulsar are in agreement with the theory. We do not yet understand in detail what happens if, under the damping action of gravitational radiation, two neutron stars and/or black holes forming a binary system approach each other and then merge to form a single compact object. Such a process is expected to produce a strong gravitational wave signal, gravitational waves.

At large distances from the source, gravitational waves have properties similar to electromagnetic waves; they propagate with the fundamental speed c, are transverse, and have two independent states of polarization. However, while the patterns of two basic states of linear polarization of an electromagnetic wave form an angle of 90° as indicated symbolically by | and —, in the gravitational case they form an angle of 45° only as indicated by + and ×. This corresponds, in quantum language, to the fact that photons have spin 1 (in units of $\hbar$), while gravitons are expected to have spin 2.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

Gravitomagnetism
It follows from equations (12) and (13) that, in addition to Newtonian-type gravitational forces depending on the mass distribution only, there exist 'gravitomagnetic' forces depending on the flow of mass, analogous to magnetic forces, which depend on the motions of the charges. Such forces are taken into account in post–Newtonian approximations, but have not yet been measured in isolation, see Tests of the field equation below.

Isolated systems, global energy-momentum
The spacetime of an isolated system in GR is required to be such that its light cones behave, at large distances from matter sources, asymptotically like those of the spacetime of special relativity. It is then possible to define a conserved total energy momentum of such a system and to show that the total energy is positive, except if there is no true gravitational field, i.e., no curvature (Yau, Witten). It is also possible to give an exact expression for parts of the total energy-momentum which are radiated out of the system between two future light cones (Bondi, Sachs).

Horizons and black holes
The causal structure of a curved spacetime, indicated in the section Causality above, sometimes has the consequence that part of spacetime can never be seen by some observers. If a spherical star collapses, that particular future light cone of the center of the star which passes the star's surface at the instant when the ratio mass/radius of the star reaches the 'Schwarzschild limit' $c^2/2G$, will never reach an outside observer (figure 3). This so-called event horizon separates those events, which can be seen from outside, from those which are hidden from sight. That part of spacetime which is thus hidden is called a black hole; the horizon is its surface. Although according to (classical) GR no radiation and no particles can be emitted from a black hole, it does have a mass and attracts other bodies accordingly. For additional information on black holes see also QUANTUM GRAVITY, where singularities of gravitational fields are also briefly discussed.

Cosmology
General Relativity allows to treat spatially unbounded matter distributions and thus provides a basis for cosmology. The basic reason for this is that the solutions to equations (12) and (13) are determined, like those of Maxwell's equations, by initial data whose influence on the evolving metric and matter propagates at most with the fundamental speed c, as explained in the section Causality. Therefore, the field at some spacetime point never depends on a spatially infinite amount of matter, as it would according to the old equations (5) or (7). (Boundary conditions can be imposed in General Relativity only on initial data specifying a solution of the field equation (12), not on the field which evolves from these data.)

To allow for a static and spatially closed world model, Einstein in 1917 supplemented his field equation (12) of 1915 by a cosmological term $-\Lambda g^{\alpha\beta}$ on the right-hand side. This contribution has later been interpreted as the expectation value of the energy-momentum of the field fluctuations of the quantum vacuum. The appropriateness of this interpretation depends on a better understanding of the quantum vacuum and its relation to gravity. So far, this interpretation has not led to a computation of the value of the COSMOLOGICAL CONSTANT Λ.

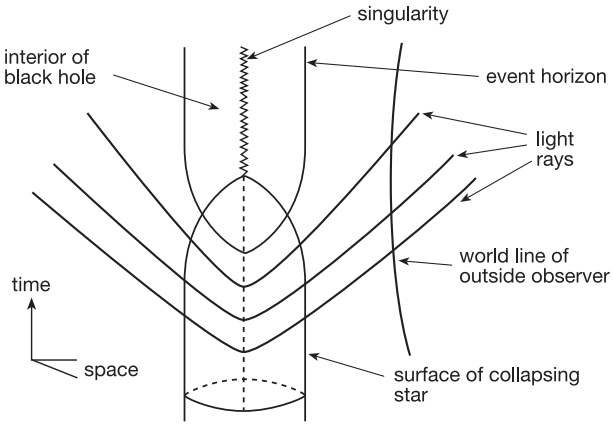

Figure 3. Collapsing star with event horizon, outside observer and light rays from the center of the star. The singularity is hidden behind the event horizon.

Experimental and observational tests of general relativity

Experiments and measurements supporting GR can be classified into those which test the Einstein equivalence principle and those which probe the gravitational field equation.

Tests of the Einstein equivalence principle
Tests of the first kind probe the approximate local validity of Special Relativity, i.e. the existence of local inertial frames or, equivalently, the possibility to assign a unique Lorentz metric (see 3(a) and (b)) to spacetime. From the viewpoint of GR these experiments serve to identify, relative to some arbitrary reference frame, a local inertial frame. Free fall experiments and Foucault pendulum experiments carried out in a terrestrial laboratory, for example, measure the acceleration and the angular velocity of the laboratory relative to a local inertial frame. Optical experiments and quantum interference experiments with neutron waves accomplish the same, and the concordance of the results establishes, up to experimental uncertainties, the uniqueness of the spacetime metric. The experimental fact that local inertial frames are accelerated relative to each other shows that spacetime is curved.

Tests of the field equation
Approximation methods to solve the field equation (12) show that, for a nearly isolated system of slowly, not too dense bodies, the metric differs from that of the flat spacetime of special relativity only in the time component;

Dirac House, Temple Back, Bristol, BS1 6BE, UK

the latter is determined by the Newtonian potential ϕ according to

$$-g_{00} = 1 + 2\frac{\phi}{c^2}. \tag{14}$$

This formula specifies how the gravitational potential affects clock rates and determines frequency shifts of electromagnetic waves; it has been tested for the Earth's gravitational field to within a measurement uncertainty of 2×10^{-4} (Vessot–Levine, gravity probe A). This formula is not specific to GR; it has to hold in any 'metric' theory of gravity to ensure the approximate validity of Newtonian theory. Tests which can distinguish between Einstein's theory, equation (12), and alternative theories of gravity require more accurate approximations to the metric. To obtain the light deflection, the metric

$$\mathrm{d}s^2 = -\left(1 + 2\frac{\phi}{c^2}\right)c^2\,\mathrm{d}t^2 + \left(1 - 2\frac{\phi}{c^2}\right)\mathrm{d}\vec{x}^2 \tag{15}$$

which exhibits space curvature, is sufficient. The validity of this approximate metric has also been confirmed by the retardation of electromagnetic waves in gravitational fields (fourth test, Shapiro effect) and by the geodetic precession (de Sitter effect) of the angular momentum of the Earth–Moon system. Additional terms are needed to measure the Schiff precession (mixed $\mathrm{d}t\,\mathrm{d}x^a$–terms, to be tested in the gravity probe B experiment in 2000), as well as the Lense–Thirring precession of the line of nodes of satellites orbiting the Earth, due to the Earth's angular momentum. This effect appears to be observable through the orbits of the satellites Lageos I and III (Ciufolini). The famous perihelion motion of Mercury's orbit requires the additional term $+2\phi^2/c^4$ in the g_{00} term of (15). The tests here summarized have verified Einstein's field equation up to relative measurement uncertainties of a few parts in 10^3. For more details, see GR: SOLAR SYSTEM EXPERIMENTS. Of still higher order of approximation is the effect of gravitational radiation reaction on the orbits of bodies; it has been verified in the case of binary pulsars (see GR TESTS: BINARY PULSARS). The major challenge of experimental gravity is the direct measurement of gravitational radiation which is expected to open a new window onto the universe.

General Relativity Tests: Binary Pulsars

PULSARS are rapidly spinning NEUTRON STARS emitting a beam of radio waves, like lighthouses. Experiment tells us that they are very stable clocks when isolated. A pulsar in a binary system is thus a moving clock, the best tool that one could dream of to test a relativistic theory. Indeed, many orbital data can be extracted from the analysis of the pulse arrival times, then compared with the predictions of the theory. Currently, general relativity passes all the available tests with flying colors.

Binary-pulsar data analysis

As the pulsar moves outwards or towards the observer, during its orbit, the Doppler effect modifies the pulse frequency like that of a fire-truck siren, and the time between two maxima of this frequency is thus a measure of the orbital period P_b.

More precisely, one can fit the pulse arrival times to a general formula taking into account any possible timing effect and depending on several phenomenological parameters. Five of them describe the approximate Keplerian orbit of the pulsar: the orbital period P_b, the epoch of periastron passage T_0, the eccentricity e, the longitude of periastron ω and the projected semimajor axis $xc \equiv a_1 \sin i$ (where a_1 is the semimajor axis of the pulsar orbit and i the inclination angle of the orbit with respect to the plane of the sky). The possible relativistic corrections to this Keplerian orbit are described by eight 'post-Keplerian' parameters:

(i) the Einstein timing parameter γ_T, which combines the second-order Doppler effect ($\propto v_1^2/2c^2$, where v_1 is the pulsar's velocity) together with the redshift due to the companion ($\propto Gm_2/r_{12}c^2$, where m_2 is the companion's mass and r_{12} the pulsar–companion distance);
(ii) the rate of periastron advance $\dot{\omega}$, i.e. the analogue of Mercury's perihelion shift for the present binary system (a relativistic effect of order v^2/c^2);
(iii) the rate of change of orbital period $\dot{P}_b$, caused by gravitational radiation damping, i.e. resulting from the fact that the system loses energy as it emits gravitational waves (an effect of order v^5/c^5 in general relativity);
(iv) the 'range' r and
(v) the 'shape' s of the Shapiro time delay, r being a global factor for this effect ($=Gm_2/c^3$ in general relativity), while s can be interpreted as the sine, $s = \sin i$, of the inclination angle;
(vi) three other parameters which have not yet been accurately measured in any system.

A similar analysis of the pulse structure also gives access to 11 extra post-Keplerian parameters, although they have not yet been determined precisely enough to be used to test relativistic gravity. (For further details, see also SOFTWARE: RADIO PULSAR SOFTWARE.)

The interest of such a phenomenological analysis of binary-pulsar data is that it is theory independent. Once the parameters have been obtained by a least-squares fit, they can be compared with the predictions of a given theory, which may be derived independently. In fact, the eight post-Keplerian timing parameters can be predicted in a relativistic theory of gravity only if one knows the two masses of the pulsar (m_1) and its companion (m_2), which are not directly measured. Moreover, the 11 pulse-structure parameters depend also on two unknown angles defining the pulsar spin axis. Therefore, if all the post-Keplerian parameters could be measured precisely enough, each binary pulsar would give $8 + 11 - 2 - 2 = 15$ tests of gravity. As shown below, only a few of them are currently available, in different binary-pulsar systems, but they are extremely constraining anyway. Moreover, even if one cannot determine enough post-Keplerian parameters to obtain a clean test, statistical arguments can still be used to constrain the possible theories of gravity.

The two most precise tests

PSR B1913 + 16

The Hulse–Taylor binary pulsar, PSR B1913 + 16, has been continuously observed since its discovery in 1974. This is a rapid ($P_b \approx 8$ h) and eccentric ($e \approx 0.6$) system, and three post-Keplerian parameters have been determined with great accuracy: γ_T, $\dot{\omega}$ and $\dot{P}_b$. The measure of $\dot{P}_b$ is in itself a great experimental achievement, as it confirms the existence of gravitational radiation. It is impressive to note that this quantity, of order -2×10^{-12}, is presently known with a relative precision of 0.35%.

All three observed parameters are nevertheless necessary to provide an actual test of gravity. In a given theory, they can be predicted as functions of the two unknown masses of the pulsar and its companion, and one obtains thus $3 - 2 = 1$ test. The equations $\gamma_T^{th}(m_1, m_2) = \gamma_T^{obs}$, $\dot{\omega}^{th}(m_1, m_2) = \dot{\omega}^{obs}$, $\dot{P}_b^{th}(m_1, m_2) = \dot{P}_b^{obs}$ define three curves in the two-dimensional plane of the masses (m_1, m_2). In fact they define three strips if one takes into account the experimental uncertainties. If these strips meet in a small region, there exists a pair of masses (m_1, m_2) which is consistent with all three observables, and the theory is thus consistent with the binary-pulsar data. If they do not meet, the theory is ruled out. Figure 1 displays these strips in the case of general relativity, which passes the test with flying colors. Note that, once the test is passed, it also gives a very accurate measure of the two masses (within the considered theory). A convenient way to illustrate the precision of this test is to use the values of the masses corresponding to the intersection of the very thin γ_T and $\dot{\omega}$ strips and to compute the prediction of general relativity for $\dot{P}_b$. One finds that it is consistent with the observed value at the 0.3% level (i.e. within 1σ error bars).

It should be noted that alternative theories of gravity may pass this test even if they are significantly different from general relativity. In this case, the three curves are very deformed with respect to figure 1, but they still meet

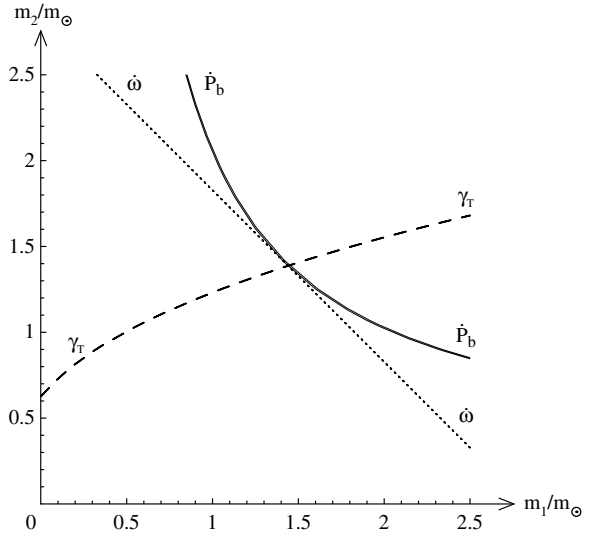

Figure 1. General relativity passes the $(\gamma_T$–$\dot{\omega}$–$\dot{P}_b)_{1913+16}$ test. The masses are given in units of the solar mass $m_\odot$, and the widths of the lines are larger than 1σ standard deviations.

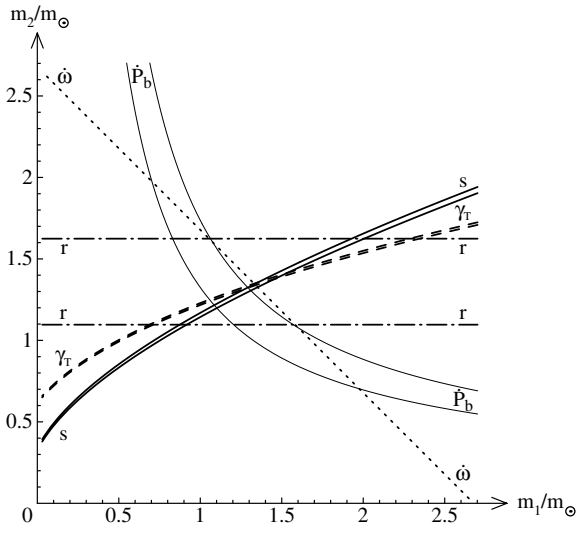

Figure 2. General relativity passes the $(\gamma_T$–$\dot{\omega}$–s–$r)_{1534+12}$ tests. The widths of the strips correspond to 1σ standard deviations. In particular, the region between the two lines labeled r is consistent with the observed value of this parameter.

in one point (corresponding usually to values of m_1 and m_2 which are different from those obtained in general relativity). However, some fine tuning is necessary to construct such alternative theories passing the test.

On the other hand, this binary-pulsar test is extremely constraining if one considers only the most natural and best-motivated alternatives to general relativity: 'scalar–tensor' theories, in which the gravitational interaction is mediated not only by a spin-2 graviton, as in Einstein's theory, but also by one or several spin-0 scalar fields carrying positive energy. Indeed, a neutron star has a small radius R, and its gravitational binding energy is proportional to $Gm/Rc^2 \approx 0.2$ (whereas the same ratio is of order 10^{-6} for the Sun). Because of nonperturbative strong-field effects, scalar–tensor theories can predict large deviations from general relativity in systems involving such compact bodies, even if they are very close to it in the weak-field conditions of the solar system. It has been shown that the PSR B1913 + 16 test rules out a wide class of these theories, including a subclass which is strictly indistinguishable from general relativity in solar system experiments. Binary-pulsar tests are thus qualitatively different from weak-field experiments.

To illustrate this difference, it is convenient to work within a generic class of scalar–tensor theories depending only on the two 'parametrized post-Newtonian' parameters β and γ (see GENERAL RELATIVITY: SOLAR SYSTEM EXPERIMENTS; the parameter γ should not be confused with the timing observable γ_T discussed above). Solar system experiments tell us that $\beta - 1$ and $\gamma - 1$ are both consistent with zero, whereas the PSR B1913 + 16 test imposes a bound on their ratio: $(\beta - 1)/(\gamma - 1) < 1.1$.

PSR B1534 + 12

The binary pulsar PSR B1534+12 is also a rapid ($P_b \approx 10$ h) and eccentric ($e \approx 0.3$) system. It has been observed only since 1991, but it is much closer to the Earth than PSR B1913 + 16, and its pulses are both stronger and narrower. It has thus been possible to measure rapidly the post-Keplerian parameters γ_T and $\dot{\omega}$ with good precision. Moreover, the orbit is nearly edge on relative to the line of sight ($i \approx 80^\circ$), and the Shapiro time delay parameters r and s have also been determined (r with a lower precision). As shown in figure 2, the strips corresponding to these four quantities are nicely consistent within general relativity.

The time derivative of the orbital period $\dot{P}_b$ is also measured at present, but it is spoiled by a poorly known Doppler contribution due to the acceleration of the system towards the center of the Galaxy. The corresponding strip is consistent with the other four observables at the 1.3σ level, but it can be brought in even better agreement if the Earth–pulsar distance is slightly larger than its estimate from dispersion measures.

Out of these $5-2 = 3$ tests, only the one corresponding to the three parameters γ_T, $\dot{\omega}$ and s is very precise. Contrary to the PSR B1913 + 16 test, it does not use the $\dot{P}_b$ observable, and therefore does not depend on the radiative structure of the theory. These two binary pulsars give thus two complementary tests of relativistic gravity. For instance, if one considers a fine-tuned theory passing one of these tests while being very different from general relativity, it usually does not pass the second one.

On the other hand, in the most natural class of scalar–tensor theories, the PSR B1534 + 12 test has also the capability of probing models which are perturbatively equivalent to general relativity in weak-field conditions.

At present, this test is slightly less constraining than the PSR B1913 + 16 one.

'Null' tests of general relativity

For many binary pulsars, it has not yet been possible to measure enough post-Keplerian parameters, and the masses of the pulsar and its companion cannot be determined as in figures 1 and 2. However, a particular combination of them and the inclination angle i, called the 'mass function', is related through Kepler's third law to the observables P_b and x:

$$\frac{(m_2 \sin i)^3}{(m_1 + m_2)^2} = \left(\frac{2\pi}{P_b}\right)^2 \frac{(xc)^3}{G}.$$

Moreover, all the neutron star masses that have been determined precisely happen to be close to $1.35 m_\odot$, with a small statistical spread. Since a pulsar is a neutron star, one can use a statistical argument on its mass m_1 and on the inclination angle i to predict a probable value for the companion's mass m_2. Usually, this information suffices to determine whether the companion may be itself a neutron star or not. When it is very probably a white dwarf, the asymmetry of the system can be used to test quite precisely some predictions of gravity theories. Actually, general relativity does not predict special effects for such asymmetric systems, and this is why they can be called 'null' tests. However, they happen to be very constraining for alternative theories of gravity.

Dipolar gravitational waves

General relativity predicts that the gravitational waves emitted by a binary system start at the quadrupolar order. If v denotes the average orbital velocity of the bodies, this means the radiated energy is of order $O(v^5/c^5)$. On the contrary, alternative theories of gravity generically predict also the emission of dipolar gravitational waves, of order $O(v^3/c^3)$. This emission almost vanishes if the two bodies are similar, but it can become much larger than the general relativistic quadrupole in asymmetric systems. Several NEUTRON STAR–WHITE DWARF binaries, such as PSR B0655 + 64, happen to have a very small observed value of $\dot{P}_b$, consistent with general relativity ($\sim -10^{-14}$) but not with a typical dipolar radiation ($\sim -10^{-11}$). This is one of the most constraining tests for alternative theories of gravity, even if one chooses the masses of the pulsar and its companion to obtain the most conservative bounds. For the most natural scalar–tensor theories of gravity, this test is almost as constraining as the PSR B1913 + 16 one discussed above.

Gravitational Stark effect

General relativity predicts that different self-gravitating bodies fall with the same acceleration in an external gravitational field (see GENERAL RELATIVITY AND GRAVITATION). On the contrary, alternative theories generically predict a violation of this 'strong equivalence principle': the acceleration of a neutron star towards the center of the Galaxy differs from that of a white dwarf. This causes a polarization of the orbit of a neutron star–white dwarf system towards the Galaxy center, analogous to the Stark effect in electromagnetism. (In the case of the Earth–Moon system in the gravitational field of the Sun, this is called the Nordtvedt effect; see GENERAL RELATIVITY: SOLAR SYSTEM EXPERIMENTS.) More precisely, the eccentricity vector $\boldsymbol{e}$ of the orbit is the sum of a fixed vector $\boldsymbol{e}_F$ directed towards the Galaxy center (proportional to the difference of the accelerations of the bodies) and of a rotating vector $\boldsymbol{e}_R(t)$ corresponding to the usual relativistic periastron advance at angular velocity $\dot{\omega}_R$. Several asymmetric systems of this kind (such as PSRs 1713 + 0747, 2229 + 2643, 1455 − 3330) happen to have a very small eccentricity. The only explanation would be that the rotating vector $\boldsymbol{e}_R(t)$ is precisely canceling the fixed contribution $\boldsymbol{e}_F$ at the time of our observation: $\boldsymbol{e}_F + \boldsymbol{e}_R(t) \approx \boldsymbol{0}$. However, this is very improbable if the system is old enough, and one can use a statistical argument to constrain the space of theories. Moreover, by considering several such systems, the probability that they have simultaneously a small eccentricity is the product of the already small individual probabilities. If m_g denotes the gravitational mass of a neutron star and m_i its inertial mass, this statistical analysis gives the bound $|1 - m_g/m_i| < 10^{-2}$. This rules out a wide class of alternative theories of gravity. For the most natural scalar–tensor theories, this test is, however, less constraining than the ones discussed above, because it is less sensitive to strong-field effects: if such a theory is close to general relativity in the solar system, it also predicts that $m_g \approx m_i$ for neutron stars.

Local Lorentz invariance and conservation laws

Theories of gravity which do not respect the symmetries of general relativity can also be tested very precisely with binary pulsars. If local Lorentz invariance of gravitational physics is not respected, there exists a preferred frame in the universe, and a binary system undergoes extra forces if it is moving with respect to this frame. This causes again a polarization of the orbit in a particular direction, as in the previous section, and statistical arguments can again be used to constrain the theories. In the 'parametrized post-Newtonian' formalism, the various possible symmetry violations of general relativity have been parametrized by a set of real numbers. At present, PSRs 1012 + 5307 and 2317 + 1439 give the tightest bounds on one of them: $|\alpha_1| < 1.2 \times 10^{-4}$. The statistical analysis of several systems also gives a very impressive bound on another post-Newtonian parameter: $|\alpha_3| < 1.5 \times 10^{-19}$. This is one of the most precise null experiments of physics. The remaining parameters are currently better constrained by solar-system experiments or isolated pulsar observations.

If the gravitational constant G varies with time, the orbital evolution of a binary system is modified, and one can prove that $\dot{P}_b/P_b$ has an extra contribution proportional to $-\dot{G}/G$. Binary-pulsar data can thus be used to constrain also the time derivative of G, but solar system experiments give currently tighter bounds.

General Relativity: Solar System Experiments

Modern gravitational theories such as general relativity produce, among their outputs, dynamical equations for clock rates, for the speed of light propagation and for the motion of bodies, with each of these equations containing relativistic modifications of their Newtonian versions. Such dynamical equations are the chief ingredients for modeling the key solar system experiments which essentially 'map out' the gravitational interaction. The GENERAL THEORY OF RELATIVITY predicts novel phenomena not present in Newtonian gravity and which also differ in detail from what emerges from plausible alternative relativistic theories of gravity. The experimental mapping of the gravitational interaction strengthens verification of general relativity as one theory within a broad class of possible gravitational theories and from that verification places stringent constraints on the existence of any additional long-range force fields in physical law which might supplement the tensor interaction of general relativity. (See also GENERAL RELATIVITY AND GRAVITATION.)

Equivalence principle

Einstein's first revolutionary innovation in gravitational physics was based on the Equivalence Principle which he formulated in 1907, a decade before construction of his specific general relativity theory. Generalizing from the apparent fact that differently composed bodies fall at identical rates in a gravitational field, Einstein hypothesized that gravitational phenomena were, when tidal effects could be neglected, locally equivalent in all respects to phenomena experienced in an accelerated frame of reference. From this equivalence he concluded that clock rates should be reduced near gravitating matter when compared with rates of more distantly located clocks. Applying universally to all clocks located at heights z and $z+h$ in a gravitational field $g(z)$, the fractional rate shift between them is (to lowest order in $1/c^2$) expected to be

$$\frac{f(z+h)-f(z)}{f(z)} \simeq \frac{g(z)h}{c^2} \tag{1}$$

or, for large clock separations, the rate shift is better stated in terms of the cumulative difference between Newtonian gravitational potentials of the clocks:

$$\frac{f(\vec{r}_i)-f(\vec{r}_j)}{f(\vec{r}_i)} \simeq \frac{U(\vec{r}_i)-U(\vec{r}_j)}{c^2}. \tag{2}$$

This frequency shift was subsequently shown, however, to simply follow from energy conservation considerations, so its observation does not so much confirm general relativity theory specifically as support a broader, often called *metric*, class of gravitational theories. In 1977 a hydrogen maser clock was put on a suborbital rocket flight, and its rate was compared with an Earth-located clock by means of one- and two-way phase-coherent radio links, and the shift given by equation (2) was confirmed with precision of almost 1 part in 10^4.

Using his Equivalence Principle, Einstein also predicted that light would be deflected by the component of gravitational acceleration perpendicular to the light trajectory

$$\frac{\mathrm{d}\hat{c}}{\mathrm{d}s} = \frac{\vec{g}-\vec{g}\cdot\hat{c}\hat{c}}{c^2} \tag{3}$$

with $\hat{c}$ being the light ray's unit propagation vector. However, this was a less dramatic prediction; a century earlier Laplace and others had reached such a conclusion based on a finite velocity, corpuscular model of light. The real novelty concerning this phenomenon later emerged from Einstein's complete theory of 1916 which he based on a tensor field of gravitational interaction; it predicts twice as large a rate of deflection. Solar system experiments which have specifically focused on measuring the effects of gravity on propagation of light yield some of the most precise tests of the general relativity theory available today, since they have been able to measure the dynamics of light rays which passed close to the Sun where the solar system's strongest gravitational fields reside.

Theories consistent with the traditional form of the Equivalence Principle can be constructed using a combination of tensor and scalar fields of interaction. In these constructions, the static-limit source for the tensor field is proportional to matter's total energy density T_0^0 (which is the normally dominant component of matter's entire *stress–energy tensor* T_μ^ν), while the source for the scalar field is proportional to the trace of that tensor T. The body integral of these two sources can be shown to be identical for a general source body which is in stationary internal equilibrium, is free of significant external force disturbances and has negligible internal gravitational binding energy:

$$\int T_0^0\,\mathrm{d}V = \int T\,\mathrm{d}V \equiv Mc^2 \qquad \text{with } T \equiv \sum_\mu T_\mu^\mu. \tag{4}$$

Such conditions are rather closely fulfilled by the sources in the solar system. In such scalar–tensor theories, therefore, the observational differences between the hybrid scalar–tensor interaction and the pure tensor interaction of general relativity are suppressed until the solar system's very weak relativistic corrections to the static limit are relevant.

Dynamical equations for light and bodies

There is a rich collection of perturbations in the orbits of solar system bodies which theory suggests may result when Newtonian theory is generally modified but which are not, in fact, observed in experiment. These often overlooked *null experimental results* are nevertheless important in establishing several properties of gravity, e.g. (1) that local gravitational physics is Lorentz invariant so that the speed of the solar system through the cosmos cannot be detected from the dynamics within that system, (2) that conservation laws of energy, momentum and

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

angular momentum are fulfilled in the solar system's total motion and (3) that the Newtonian-level interaction is spatially isotropic.

Accepting those foundations and then considering the class of theoretical possibilities consistent with these empirical findings, some general dynamical equations for light propagation and for motion of bodies are formed which represent the broad class of theoretical alternatives. These equations, which are then used to model some remaining key confrontations of general relativity and its alternatives with experiment, take forms as follows (expressed here to order $1/c^2$ which is sufficient for solar system applications): the coordinate speed of light near the Sun or other body (mass M and distance R) is slowed, as measured from afar, owing to the body's proximity

$$c(\vec{R}) = c_\infty \left(1 - (1+\gamma)\frac{GM}{c^2 R} + \cdots\right). \qquad (5)$$

γ is a dimensionless, theory-dependent parameter (equal to 1 in general relativity) which was first introduced by Eddington to represent general theoretical possibilities for the static, spherically symmetric tensor field exterior to a source, and which was later found by Will and Nordtvedt to have more wide-ranging significance for the general structure of the gravitational field. Here it scales the additional effect of gravity on light propagation which is not derivable from the Equivalence Principle. This location-dependent speed function leads to both deflection and retardation of light trajectories. (The equations of motion for matter and light depend on choice of coordinates for space and time. For solar system applications, coordinates in which the speed of light is isotropic to $1/c^2$ order are usually employed. Experimental observables must, of course, be independent of this choice of coordinate system.) For a ray making a complete passage by the Sun with distance of closest approach D, it produces a deflection $\delta\theta$ of light's direction of travel toward the Sun by an amount

$$\delta\theta = 2(1+\gamma)\frac{GM}{c^2 D} \qquad (6)$$

and it adds an amount δt to light's time of flight between two sites located at distances R_1 and R_2 from the Sun

$$\delta t \simeq 2(1+\gamma)\frac{GM}{c^3}\ln(4R_1R_2/D^2) \qquad (7)$$

with D again being the ray's distance of closest approach to the Sun.

Changes of the apparent angular positions of cosmologically distant radio sources, numbering in the many thousands, have been measured using very-long-baseline interferometry (VLBI) techniques in which the signals from each source recorded at two or more spatially separated radio antennas are cross-correlated as a function of time delay; the general relativistic prediction for the light deflection—double that given by the equivalence principle—has recently been confirmed by this means with precision of better than 1 part in 10^3. The time-of-flight delays of radio signals were earlier confirmed with slightly less precision using the Viking mission's ranging data to Mars accumulated during 1977–1982. Radar transponders placed on the Martian surface and on spacecraft orbiting that planet permitted measurement of the round trip time of travel for radio signals originated and detected at Earth, with the time delay signal in equation (7) being particularly important in the data produced during the periods when the Earth–Mars line of sight passed close to the Sun.

The equation of motion for planets such as Mercury which move with respect to an essentially fixed Sun is, to sufficient approximation, given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(1+\frac{1}{2}\frac{V^2}{c^2}\right)\vec{V} = -\frac{GM}{R^3}\vec{R}\left(1+\frac{2\gamma+1}{2}\frac{V^2}{c^2}\right) - (2\gamma+1)\frac{\mathrm{d}}{\mathrm{d}t}\frac{GM}{c^2 R}\vec{V} - \frac{1-2\beta}{2}\frac{G^2M^2}{c^2R^4}\vec{R} + \cdots \qquad (8)$$

with $\vec{V} = \mathrm{d}\vec{R}/\mathrm{d}t$. Eddington's γ parameter appears in this equation as a scale factor for the motional corrections to Newton's static-limit interaction, while his second parameter β scales the novel nonlinear feature of gravity. β also has value unity in general relativity, but both parameters will generally have different values in alternative theories which have a scalar field augmenting Einstein's tensor field in transmitting the gravitational interaction between matter. In these latter cases $1-\gamma$ quantifies the fractional participation or strength of the scalar field in producing the total phenomenon of gravity.

The expression from SPECIAL RELATIVITY for a body's momentum on the left-hand side of equation (8) (approximated to the $1/c^2$ order) plus both the motional and nonlinear modifications scaled by γ and β on the force side of this equation of motion together produce a precession of the Keplerian-like orbit around the central body of mass M. The precessional rate is

$$\frac{\delta\Omega}{\Omega} = (2+2\gamma-\beta)\frac{GM}{c^2(1-e^2)a} \qquad (9)$$

with Ω, e and a being the orbit's frequency, eccentricity and semimajor axis, respectively. For the general relativistic case, $\gamma = \beta = 1$, this precession amounts to 43 arcsec/century for Mercury's orbit and adds to a Newtonian precession of that planet's orbit caused by accelerations from other planets. A discrepancy of this size between predictions of Newtonian theory and the astronomical observations of Mercury's angular positions had already been established by the end of the 19th century, and the natural remedy for this anomaly was the first and immediate empirical triumph of Einstein's general relativity theory in 1916. Today, radar ranging between Mercury's surface and Earth, a somewhat less precise procedure than the ranging to specific transponder sites at Mars in the Viking mission, nevertheless confirms the predicted precession to about 1 part in 10^3 precision. This

serves at this time as a somewhat weaker test of general relativity than do observations of light propagation or lunar laser ranging, and further improvements in ranging precision to Mercury will not so much yield a better test of gravitational theory but will instead measure the Sun's quadrupole moment (a measure of the Sun's rotational flattening) whose Newtonian gravitational field also contributes to Mercury's orbital precession.

Revisiting a classic system—the orbit of the Moon—which has for centuries played a central role in studying details of Newtonian gravitational dynamics, it is found, thanks to implementation of the modern laser ranging technique, to also be a remarkably sensitive testing ground for measuring relativistic features of gravity. To new levels of precision the Equivalence Principle can be tested, the Eddington parameters, especially β, can be measured in novel ways and to high precision, and a sensitive search for time variation in the gravitational coupling parameter G can be made. The scientifically operable part of the Moon's equation of motion relative to Earth is remarkably Newtonian like:

$$\frac{\mathrm{d}\vec{v}}{\mathrm{d}t} = -G(t)\frac{m}{r^3}\vec{r} + \delta_{\mathrm{em}}\frac{GM}{R^3}\vec{R} + (2\gamma+1)\frac{GM}{c^2R^3}(\vec{R}\times\vec{V})\times\vec{v} + \cdots \qquad (10)$$

with m being the total Earth–Moon system mass, $\vec{v} = \mathrm{d}\vec{r}/\mathrm{d}t$ and $+\cdots$ indicating a host of Newtonian solar tidal accelerations and small relativistic accelerations of lesser interest for our purposes here. δ_{em} is the measure of a possible failure, from whatever cause, of equality of gravitational free-fall rates of Earth and Moon toward the Sun (breakdown of the previously mentioned Equivalence Principle of Einstein):

$$\delta_{\mathrm{em}} = \left|\frac{\vec{a}_{\mathrm{Earth}} - \vec{a}_{\mathrm{Moon}}}{\vec{g}_{\mathrm{Sun}}}\right|. \qquad (11)$$

This difference between free-fall rates can occur as a result of an unusual atomic composition dependence of long-range forces (discussed later) and it can also result from anomalous coupling between the external gravity of the Sun and the internal gravity within the Earth and Moon. The latter possibility is controlled by the same Eddington parameters γ and β introduced previously in equations (5) and (8); as auxiliary calculations show, the gravitational-to-inertial mass ratios of celestial bodies must differ among themselves in proportion to the fractional gravitational internal binding energies of the bodies if the Eddington parameters are anomalous:

$$\frac{|\vec{a}|}{|\vec{g}|} = \frac{M(G)}{M(I)} = 1-(4\beta-3-\gamma)\frac{1}{2Mc^2}\int\frac{G\rho(\vec{x})\rho(\vec{x'})}{|\vec{x}-\vec{x'}|}\,\mathrm{d}^3x\,\mathrm{d}^3x'. \qquad (12)$$

$\vec{a}$ is the acceleration of the body when in external gravitational field $\vec{g}$: $\rho(\vec{x})$ is the body's mass density, so the exhibited integral represents minus twice the gravitational potential energy within the body.

Universality of gravitational free fall

Thirty years of laser ranging to several passive reflectors placed on the lunar surface by some of the Apollo missions to the Moon have confirmed that the Earth and Moon fall at equal rates toward the Sun with a precision of 3×10^{-13} (a recent 1998 fit has even pushed this equality to 1×10^{-13}). The Earth has a substantial iron core while the Moon is composed of mantle-like silicate materials, so the lunar laser ranging (LLR) result confirms the composition independence of gravitational free fall to precision better than 10^{-12}, which compares quite favorably with the performance of the latest laboratory tests of the universality of gravitational free-fall rates for different materials. However, because the Earth possesses gravitational binding energy equal to about 5×10^{-10} of its total mass–energy, this experimental result permits a second interesting scientific interpretation; the factor $4\beta - 3 - \gamma$ in equation (12) is zero to precision of a few parts in 10^4, serving as the premier measurement of general relativity's nonlinearity quantified by the parameter β. This confirmation of general relativity is accomplished by measuring, in particular, the amplitude of the synodic month period (new moon to new moon) oscillation in Earth–Moon range with precision of a few millimeters; if δ_{em} were non-zero in equation (10), the anomaly in this synodic amplitude would be $2.9 \times 10^{12}\delta_{\mathrm{em}}$ cm.

Time variation of Newton's G

From analysis of the LLR data one also tests for a possible time variation in the gravity coupling parameter of Newton—$G \rightarrow G(t)$? There have been general speculations by Dirac and others that this coupling parameter might evolve in time as the universe expands, and theories alternative to general relativity such as the scalar–tensor theories usually predict such time variation with magnitude of the order of the Hubble rate:

$$\frac{\mathrm{d}G}{G\,\mathrm{d}t} \sim (4\beta - 3 - \gamma)H. \qquad (13)$$

$H \sim 7 \times 10^{-11}$ yr^{-1} is the observed Hubble expansion rate of the universe. The fit of the LLR data places the limit $\mathrm{d}G/G\,\mathrm{d}t \leq 2 \times 10^{-12}$ yr^{-1} on such variation (although a conservative allowance for possible unmodeled systematic secular effects is added by some to this result). Comparable limitations have been obtained by analysis of the radar ranging data between Earth and the planets Mars and Mercury and the arrival times of the pulsed signals from certain binary pulsar systems (see GENERAL RELATIVITY TESTS: BINARY PULSARS).

Geodetic precession of local inertial frames

The Coriolis-like acceleration term in the Moon's equation of motion is the basis of a third fundamental confirmation of general relativistic predictions achieved from LLR. Because the Earth–Moon system is not simply falling radially toward the Sun, but rather moves across the Sun's field, the local inertial frame rotates relative to distant inertial frames of reference at the average rate

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of 19.2 mas yr^{-1} (mas = milliarcsecond), as first derived by de Sitter in the context of general relativity, but later generalized to other metric theories to be

$$\vec{\Omega}_{\rm dS} \;=\; (\gamma + 1/2)\frac{GM}{c^2 R^3}\,\vec{R}\times\vec{V}. \qquad (14)$$

As a result of this acceleration, both the lunar orbit's major axis (its perigee) and its inclined orbital plane (line of nodes) precess at about this additional rate when referenced to the distant inertial frames. LLR confirms this precession to better than 0.1 mas yr^{-1} precision. NASA's GRAVITY PROBE-B mission, scheduled for launch in May 2002, will place gyroscopes in Earth orbit and measure their precessions with respect to the line of sight toward a distant star. This mission has the potential to measure the analogous de Sitter precession of the gyroscopes due to motion through Earth's gravitational field and to do so with precision approaching 1 part in 10^5, thereby determining the fundamental Eddington parameter γ appearing in equation (14) with a level of precision which goes well beyond present knowledge.

LLR is an on-going experiment, and the performance of the passive reflectors on the Moon shows no sign of diminishing with age. The three gravitational measurements here discussed can be further improved in precision as we go into the future, especially the latter two measurements whose intrinsic sensitivities grow decisively with total time span of observing the lunar orbit.

Gravitomagnetism

The full, testable content of the $1/c^2$ corrections to the Newtonian equations of motion only appears in situations of bodies in mutual motion. As in electromagnetism, these more general N-body dynamical configurations include what have become called *gravitomagnetic* forces, which are proportional to velocities of both interacting bodies, and *inductive* forces, in which the acceleration of one body accelerates the other. Successful modelings of astronomical binary pulsar systems, such as PSR 1913+16, which consist of bodies of comparable mass moving about their joint center of mass–energy in highly eccentric orbits, have necessarily brought these additional interactions into play as part of the modeling process which achieves precision fit of the pulse-arrival-time data. These interactions are particularly required for understanding the observed 4.2° yr^{-1} periastron precession rate of the PSR 1913+16 system's orbit. Closer to home, the computer computation of the Moon's position relative to Earth is routinely performed in the solar system's barycentric rest frame, and therefore the gravitomagnetic and inductive accelerations of the moving Moon by the moving Earth are indispensable components of that computation, which as a whole achieves the recent fits of the range data with precision at the subcentimeter level. Discrepancies of more than 1000 cm would otherwise be present. In fact, once local Lorentz invariance and fulfillment of the several conservation laws in gravitational physics have been experimentally confirmed, as they have, then such interactions as gravitomagnetism are necessarily specified in terms of the already discussed Eddington parameter γ.

Nevertheless, explicit and isolated experimental expression of the gravitomagnetic interaction has been sought. Marginal detection of this force has been achieved through measurement and modeling of the nodal precession rates of the near-Earth LAGEOS satellites, and the previously mentioned Gravity Probe-B mission is designed to also measure to better than 1% the precession of gyroscopes due to the gravitomagnetic torque generated by the spinning Earth.

The gravitational radiation reaction force in the binary pulsar

The binary pulsar system PSR1913+16 has also provided the pioneering, although indirect, evidence that the tensor gravitational field, like other dynamical fields, carries waves of energy, momentum and angular momentum away from its time-varying gravitational sources. Imprinted in the pulse arrival time data is, with better than 1% agreement with theory, the orbital rate speed-up which results from the order $1/c^5$ radiation reaction force derived from general relativity theory. Both ground and space-based laboratories for directly detecting and studying gravitational radiation arriving from distant astronomical sources are at present under development and construction.

Equivalence Principle violating interactions

A failure of the Equivalence Principle at some level of precision would probably be indicating the presence of an additional very weak, long-range force acting between bodies, and for which the coupling strength to sources is proportional to attributes of those sources other than total mass–energy content. The static-limit force between bulk matter resulting from most such additional interactions will then be a gradient of a potential with the form

$$\vec{F}_i = K_i\vec{\nabla}_i\sum_{j\neq i}\frac{K_j\,{\rm e}^{-\mu R_{ij}}}{R_{ij}}. \qquad (15)$$

$\mu \neq 0$ indicates the possibility of a finite-range, Yukawa-like interaction due to non-zero mass $m = \hbar\mu/c$ of the transmitting field's quanta ($\mu \to 0$ returns this interaction to inverse square). This force will produce differences in the acceleration rates of Earth and Moon toward the Sun:

$$\delta_{\rm em} = \left(\frac{K}{GM}\right)_{\rm Sun}\left[\left(\frac{K}{M}\right)_{\rm e} - \left(\frac{K}{M}\right)_{\rm m}\right](1+\mu R)\,{\rm e}^{-\mu R}. \quad (16)$$

If, for example, the coupling strengths K_i are proportional to matter attributes such as baryon number or nuclear electrostatic energy content, then the ratios K_i/M_i vary fractionally by about a part in a thousand among the different elements of nature. The mentioned experiments which have confirmed composition independence of free-fall rates to 10^{-12} then place strength limits of order $K^2/GM^2 \leq 10^{-9}$ on the long-range limit $1/\mu > 1$ AU

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

for such interactions. Experiments which exploit the advantages of an Earth-orbiting satellite environment in order to achieve several orders of magnitude higher precision in testing the universality of free fall are under development.

For any atomic clock whose frequency f is determined by the difference of two energy levels

$$f = \frac{E_i - E_j}{2\pi\hbar} \tag{17}$$

the potential energy assumed in equation (15) produces, in the vicinity of source body s, an additional clock frequency shift which depends on details of the clock's atomic mechanism; adding this to the previously discussed Equivalence Principle's shift, the total rate shift δf of this particular clock when near a source body s becomes

$$\frac{\delta f}{f} = \frac{GM_s}{c^2 R}\left[1 + \left(\frac{K}{GM}\right)_s \frac{K_i - K_j}{M_i - M_j}\,\mathrm{e}^{-\mu R}\right]. \tag{18}$$

However, GM_s in this expression can no longer be identified with the Sun's total attracting strength; in interaction with planet p it is now

$$\Gamma = GM_s\left(1 + \frac{K_s}{GM_s}\frac{K_p}{M_p}\,\mathrm{e}^{-\mu R}(1+\mu R)\right). \tag{19}$$

The Sun's total attracting strength Γ is the number measured to better than 1 part in 10^{10} precision in the solar system and is the standard by which clock gravitational rate shifts can be absolutely calibrated. From the above, it is then seen that clocks will in general show anomalous rate shifts both *absolutely* measurable with respect to a standard and to a differently located clock and *relatively and locally* measurable with respect to clocks of other physical mechanisms.

The difference between the expressions in equations (16) and (18) confirms that clock experiments and free-fall experiments are, in principle, independent probes of the Equivalence Principle. However, comparing these equations quantitatively reveals that the former can rarely compete in precision as fundamental tests. For example, an on-board measurement of the relative rates of two physically different atomic clocks sent together on a spacecraft to within 4 solar radii of the Sun could probe for an Equivalence Principle violating interaction with only slightly higher precision than today's best free fall observations already achieve.

Periastron precession and finite-range interactions

If the force given by equation (15) has finite Yukawa range ($\mu \neq 0$), it contributes to the precession rate of orbit major axes. In the case of orbits with small eccentricity this added precession $\delta\omega$ is

$$\frac{\delta\omega}{\omega} = \frac{K_i K_j}{2GM_i M_j}(\mu R)^2\,\mathrm{e}^{-\mu R}. \tag{20}$$

Near-Earth satellite, lunar and planetary orbit precession rates as measured by laser and radio ranging all strongly constrain the presence of any such additional interactions with the appropriately matched ranges. For instance, LLR constrains the strength ratio $K_\mathrm{e}K_\mathrm{m}/GM_\mathrm{e}M_\mathrm{m}$ of any new interaction to be less than 10^{-11} for range $1/\mu \simeq 2\times10^{10}$ cm, and similar constraints result from using data from near-Earth satellite and planetary orbits. These powerful results hold whether or not the coupling parameters K_i of the additional interaction are proportional to total mass–energies M_i. Periastron precession rate measurements have been underappreciated observations in the search for long-range Yukawa-like interactions, and they deserve more attention in the design of future ranging experiments.

Concluding remarks

During most of the period since publication of the general relativity theory of gravity, the prevailing interpretation of Einstein's revolutionary theory has not been the measured and restrained observation—that gravity modifies physical phenomena *as if* the geometry of space and time is non-Euclidean—but instead it has generally been the stronger ontological assertion—that gravity *is* space–time curvature. Experiment provides no support for this stronger interpretative stance, it played no part in this summary of the present-day experimental situation and indeed it tends to be a divisive viewpoint which suggests a difference in nature between the gravitational force and the other forces in physical law. The inverse assertion better describes the actual relationship—that the curved SPACE–TIME arena of our world is a consequence of the gravitational field.

We are left at century's end with a wide variety of experimental evidence, which considered as a whole indicates that a dynamical tensor field, governed by specific field equations and having a unique universal coupling to the other fields and particles of physical law, and nonlinearly to itself, all as formulated by Einstein's general relativity, provides the currently measured long-range interaction between bodies. The empirically confirmed, N-body gravitational equation of motion, applicable and valid for the most general dynamical configurations, is found to be Lorentz invariant and Lagrangian based

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \vec{v}_i} - \frac{\partial L}{\partial \vec{r}_i} = 0 \tag{21}$$

with the $1/c^2$ order Lagrangian being

$$L = \sum_i m_i\left(-c^2 + \frac{1}{2}v_i^2\right) + \frac{G}{2}\sum_{i,j\neq i}\frac{m_i m_j}{r_{ij}} \tag{22}$$

$$+ \frac{1}{8c^2}\sum_i m_i v_i^4 + \frac{G}{4c^2}\sum_{i,j\neq i}\frac{m_i m_j}{r_{ij}}$$

$$\times\left(3v_i^2 + 3v_j^2 - 7\vec{v}_i\cdot\vec{v}_j - \vec{v}_i\cdot\hat{r}_{ij}\hat{r}_{ij}\cdot\vec{v}_j - 2G\sum_{k\neq i}\frac{m_k}{r_{ik}}\right) \tag{23}$$

and possessing the conserved system properties of energy E, momentum $\vec{P}$ and angular momentum $\vec{J}$

$$E = \sum_i \vec{v}_i \cdot \frac{\partial L}{\partial \vec{v}_i} - L \qquad \vec{P} = \sum_i \frac{\partial L}{\partial \vec{v}_i} \qquad \vec{J} = \sum_i \vec{r}_i \times \frac{\partial L}{\partial \vec{v}_i} \tag{24}$$

and a system center of energy $\vec{R}$

$$\vec{R} = \frac{1}{E} \sum_i m_i \left(c^2 + \frac{1}{2} v_i^2 - \frac{G}{2} \sum_{j \neq i} \frac{m_j}{r_{ij}} \right) \vec{r}_i \tag{25}$$

which moves at constant velocity $\vec{P}/E$.

From solar system observations, there appears room for less than a part in a thousand presence of any additional inverse square, metrically structured interaction and room for less than 1 part in 10^9 presence of any inverse square, non-metrically structured interaction (and less than 1 part in 10^{11} Yukawa-like, solar system range interaction of either structure) to modify this exhibited dynamics derivable from general relativity theory.

Bibliography

The most comprehensive book on the interface of theory with the experimental foundations of the gravitational interaction is

Will C M 1993 *Theory and Experiment in Gravitational Physics* revised edn (Cambridge: Cambridge University Press)

although the reader should be cautioned that decisive improvements in experimental results and other innovations have occurred since publication of this edition.

A general article on the history of the Moon's role in probing gravity, including the modern lunar laser ranging experiment, is

General Theory of Relativity

The relativistic theory of gravitation that was devised in 1915 by Albert Einstein (1879–1955). The general theory extended Einstein's previous work on special relativity to deal with observers in accelerated frames of reference.

A central postulate of the general theory is the principle of equivalence, that 'all freely-falling, non-rotating, laboratories are fully equivalent for the performance of all physical experiments'. It follows from this that an observer in a small closed box (e.g. an elevator, or a windowless spacecraft) cannot tell whether that box is subject to uniform acceleration or is at rest in a uniform gravitational field; both situations would give the observer a feeling of 'weight'. Conversely, if a test particle floats freely inside a closed box, an observer cannot tell whether the box is in the depths of space, far from a gravitating body, or falling freely in the gravitational field of a massive body (for example, an observer inside an elevator falling freely down its shaft would have no sensation of weight).

General relativity embodies the concept that the three dimensions of space (length, breadth, height) and the dimension of time are linked together into a four-dimensional spacetime. The effect of a distribution of mass (or energy) is to induce curvature into (i.e. to bend) spacetime in its vicinity. Conversely, particles and rays of light follow paths that are determined by the curvature of spacetime in their locality. In general relativity, gravitation is regarded as a geometric property of spacetime rather than, as in Newtonian gravitation, a force acting directly between individual massive bodies.

Although Newtonian theory is perfectly satisfactory for most applications, general relativity is capable of dealing with circumstances in which Newtonian theory is inadequate. In particular, the perihelion position of the planet Mercury's orbit advances by an amount that exceeds the Newtonian prediction by 43 arcsec per century; general relativity predicts the correct rate of advance. Other important consequences of the theory, which have been tested to a high degree of precision by experiment and observation, include: the bending of light in a gravitational field (rays of light passing close to the edge of the Sun, for example, are deflected by an amount that is consistent with general relativity); gravitational time dilation (clocks run more slowly in strong gravitational fields than in weak ones); and gravitational redshift (light emerging from a strong gravitational field is stretched to longer wavelengths).

General relativity has important applications in many areas of astrophysics and cosmology, including describing the behavior and properties of very close binaries, binary pulsars, black holes, gravitational lensing and the universe as a whole.

Genesis

NASA Discovery mission to collect samples of charged particles in the solar wind. Genesis carries four instruments: solar wind collector arrays, made of materials such as diamond, gold, silicon and sapphire, and designed to entrap solar wind particles; an ion monitor, to record the speed, density, temperature and approximate composition of the solar wind ions; an electron monitor, to make similar measurements of electrons in the solar wind; and an ion concentrator, to separate and focus elements like oxygen and nitrogen in the solar wind into a special collector tile. Isotopes of oxygen, nitrogen, the noble gases and other elements of the solar wind will be returned to Earth in a capsule (planned for September 2004).

At 1903 UT November 16, 2001, the Genesis spacecraft entered into orbit around the balanced-gravity point Lagrange 1. Its instruments became fully operational on December 3, 2001.

Geodynamo

The existence of a large-scale magnetic field in the Earth has been known for over two millennia. The invention of the compass and the observation of the angle between magnetic and true north (declination), followed much later (16th century) by the discovery of inclination (angle of dip), led to the identification of the interior of the Earth as the prime source of magnetic activity. GILBERT believed that the Earth acted as a giant permanent magnet, but the realization that the Earth possesses a liquid metallic core, far above the Curie point, led to a search for generation mechanisms. In spite of the efforts of a number of eminent physicists to promote rival theories the only mechanism now considered viable is dynamo action, caused by electric currents driven in the core by Faraday induction. This article deals with the main theoretical considerations underlying the MAGNETOHYDRODYNAMICS of the core.

Manifestation of the magnetic field

For the purpose of this article, the Earth may be considered as a solid insulator (the mantle), surrounding a metallic core. In fact, the mantle is a conductor, although a poor one. There is some evidence that the region of the mantle nearest the core is relatively highly conducting; nonetheless, the assumption of an insulator is a good one for many purposes. The core itself has an outer, liquid part and an inner solid part (see EARTH'S INTERIOR). It is thought that the inner core is the result of freezing of heavy material from the mixed outer core. The buoyancy generated by the freezing process is an important ingredient of the energy source for the magnetic field, which dissipates energy by Joule heating. Other sources of energy that have been investigated include thermal buoyancy (for example due to internal radioactive heating in the core) and the energy that can be derived from the relative precession of core and mantle. While all these possible mechanisms can in principle provide enough energy to sustain the main field, details of the way in which precessional forces could sustain the dynamo are poorly understood. We can only observe the potential field at the Earth's surface and in the atmosphere, driven by the electric currents in the core (figure 1). Very short timescale phenomena are filtered out by the weakly conducting mantle. The field is relatively weak at the surface of the mantle (less than 1 G) but because of the algebraic decay of potential fields with distance fields in the core are rather stronger. In addition there is the invisible toroidal part of the magnetic field that is confined to the core (see below). The field is predominantly dipolar at the present epoch, but the declination changes in time as has been known since 1634. Many surface features of the field also migrate, mostly to the west, with a typical timescale of 10^2 yr. This is known as the secular variation. In addition we know from studies of remanent magnetism of rocks that the main dipole field has reversed direction many times over the Earth's history, at irregular intervals but with a typical interval of 10^5–10^6 yr (figure 2). Thus the dynamo process that sustains the field must be regarded as a fully dynamic phenomenon, requiring for its understanding a proper description of core dynamics as well as the kinematics of dynamo action.

Kinematic models

In the article on DYNAMO THEORY we have seen that the magnetic field $\boldsymbol{B}$ obeys the induction equation

$$\frac{\partial \boldsymbol{B}}{\partial t} = \boldsymbol{\nabla} \times (\boldsymbol{v} \times \boldsymbol{B}) - \boldsymbol{\nabla} \times (\eta \boldsymbol{\nabla} \times \boldsymbol{B}) \qquad \boldsymbol{\nabla} \cdot \boldsymbol{B} = 0. \quad (1)$$

Kinematic theories of the geodynamo suppose that the velocity $\boldsymbol{v}$ is given and seek eigenfunctions of the induction equation. Because of the near axisymmetry of the main field, it is natural to seek axisymmetric solutions. This is, however, prohibited by Cowling's theorem (see article on dynamo theory). There is a remedy which preserves the possibility of two-dimensional models. In mean-field (α effect) dynamos the velocity is supposed to exist on two length scales. The inductive effect of the small-scale motions on the large scales can be modelled by the inclusion of an extra term $\boldsymbol{\nabla} \times [\alpha(\boldsymbol{x})\boldsymbol{B}]$ in the induction equation. Because of this extra driving term Cowling's theorem may be avoided and axisymmetric solutions sought. Braginsky has developed another model based on the limit of small diffusivities and rapid zonal flows. Although completely different in spirit from the mean-field approach, the method yields equations that are essentially the same. Models of this type are discussed in the dynamo theory article. Because of the apparent size of the zonal flows as evidenced by the secular variation the more realistic model is of $\alpha\omega$ type, although models of the α^2 variety are more likely to lead to steady solutions. Depending on the choices of α and the differential rotation the preferred (fastest-growing) solutions may either have dipolar or quadrupolar symmetry. In this picture reversals may be explained by a change in the form of internal motion that leads to a change in the preferred symmetry of the solution. However, this quasi-kinematic approach cannot give any information on the dynamic details either of reversals or of secular variation, and so recent work has attempted to introduce a treatment of the fluid motion and the dynamical effects of the Lorentz (magnetic) force.

Core dynamics

The velocity field $\boldsymbol{v}$ can be supposed to obey the momentum equation (expressed in a frame rotating with angular velocity Ω)

$$\frac{D\boldsymbol{v}}{Dt} + 2\Omega \times \boldsymbol{v} = -\boldsymbol{\nabla} P + H\hat{\boldsymbol{r}} + \frac{1}{\mu\rho}(\boldsymbol{\nabla} \times \boldsymbol{B} \times \boldsymbol{B}) + \nu\nabla^2\boldsymbol{v} \quad (2)$$

where ν is the kinematic viscosity and ρ is the density (supposed constant, although this is a simplification). H is a source of buoyancy either due to concentration gradients associated with inner-core freezing or due to internal heat sources. This equation is to be solved together with the induction equation above and an equation for H, to give a dynamically self-consistent picture of the dynamo.

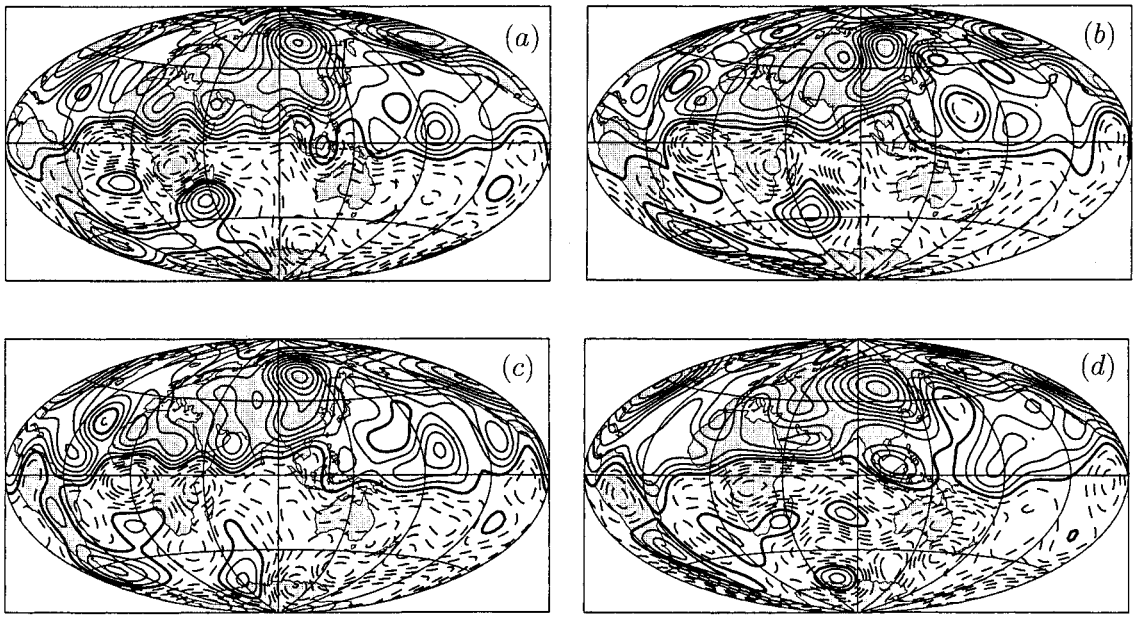

Figure 1. Contour plots of the vertical component of the magnetic field at the core–mantle boundary (from Bloxham *et al* 1989) for (*a*) 1980, (*b*) 1945, (*c*) 1915, (*d*) 1842. Solid curves are positive contours, broken curves are negative contours, bold curves are zero contours

Because of the marginal (although fully dynamic) nature of the geodynamo, we expect that $\boldsymbol{v}$ should be scaled with η/L where L is an appropriate lengthscale (presumably the core radius). Thus R_m, the magnetic Reynolds number based on this radius, is $O(1)$. For completeness we should distinguish between the poloidal part $\boldsymbol{B}_P$ and toroidal part $\boldsymbol{B}_T$ of $\boldsymbol{B}$, defined by $\boldsymbol{B}_P = \boldsymbol{\nabla} \times \boldsymbol{\nabla} \times S\boldsymbol{r}$, $\boldsymbol{B}_T = \boldsymbol{\nabla} \times T\boldsymbol{r}$. The toroidal field, which is predominantly zonal, cannot be directly observed and may be much larger than $\boldsymbol{B}_P$. Observations and stability considerations for large zonal fields suggest that $|\boldsymbol{B}_T| \sim |\boldsymbol{B}_P|$. Of course a different scaling might apply to the zonal flows, which are less constrained by rotation, but if there were to be very large zonal flows then $\boldsymbol{B}_T$ would be so large that the resulting field structure would be unstable.

The structure of the geomagnetic field is thus determined from the dimensionless constants that are implicit in the above system. These are:

the Elsasser number $\Lambda = B^2/2\Omega\mu\rho\eta$
the Ekman number $E = \nu/2\Omega L^2$
the Rossby number $R_o = \eta/2\Omega L^2$

Observations suggest that Λ is of order unity (corresponding to a field of about 20 G) while $E \ll R_o \ll 1$. The principal force balance would therefore appear to be between the Coriolis and Lorentz forces and the pressure, with viscosity and inertia playing a negligible role. Before examining the consequences of this so-called magnetostrophic balance, we consider the alternative of a weak magnetic field that plays a secondary role in any balance. Such weak-field dynamos have certainly been found in numerical simulations, but they are implausible candidates for the geomagnetic field. They are, firstly, too weak to be readily compatible with observations. Secondly, convection in a spherical shell at low Ekman number is characterized by very short ($O(E^{\frac{1}{3}})$) azimuthal length scales, which would dissipate too much energy to be a plausible dynamo. Finally in the absence of strong magnetic fields the primary force balance would be geostrophic. This causes severe difficulties at the cylinder aligned with Ω which is tangent to the inner core, causing large discontinuities in the velocity. For all these reasons the prevailing balance is likely to be magnetostrophic.

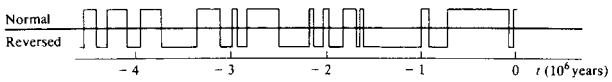

Figure 2. Record of reversals of the Earth's dipole polarity over the last 4×10^6 yr (from Moffatt 1978). Only the direction of the dipole, not its intensity, is shown

The role of viscosity

It turns out that viscosity (unlike inertia) cannot simply be ignored as pure magnetostrophic balance does not exist in general. The reduced equation

$$2\Omega \times \boldsymbol{v} = -\boldsymbol{\nabla} P + H\hat{\boldsymbol{r}} + \frac{1}{\mu\rho}(\boldsymbol{\nabla} \times \boldsymbol{B} \times \boldsymbol{B}) \qquad (3)$$

with the inviscid condition $\boldsymbol{v} \cdot \boldsymbol{n} = 0$ at the core–mantle boundary, has no solution unless the Lorentz force obeys Taylor's condition

$$\int_{C(s)} (\boldsymbol{\nabla} \times \boldsymbol{B} \times \boldsymbol{B})_\phi \, \mathrm{d}z \, \mathrm{d}\phi \equiv T(s) \equiv 0 \qquad (4)$$

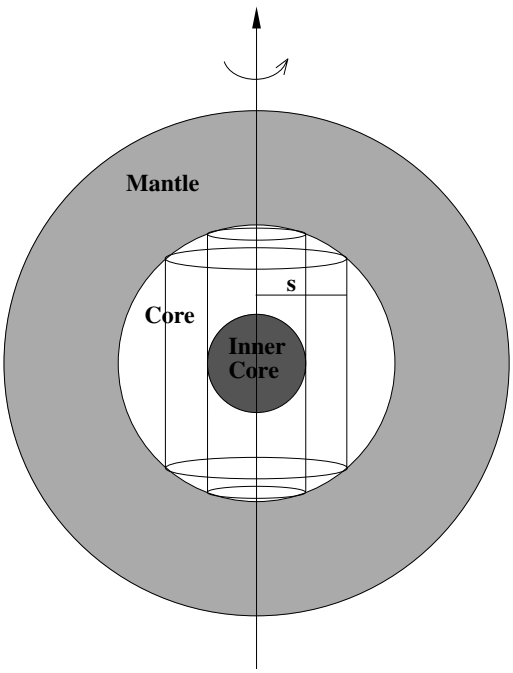

Figure 3. Sketch of the Earth. Shown are the mantle, core and inner core. Also sketched are a typical $C(s)$ and the tangent cylinder with the inner core.

where (s, ϕ, z) are cylindrical polar coordinates and $C(s)$ is the cylinder of radius s aligned with Ω and inscribed in the sphere (figure 3). (Note that the value of this integral is in general discontinuous at the tangent cylinder referred to above.) This very severe constraint is associated with a free geostrophic solution for the velocity of the form $\boldsymbol{v} = V_G(s)\hat{\boldsymbol{\phi}}$; while there might be hope that there is a choice of V_G that allows the Taylor integral to vanish, no proof is known and numerical simulations are far from providing conclusive results. Indeed, they suggest instead that the neglect of viscosity can lead to unacceptable radial singularities in the solutions, as well as removing the dynamical connection between core and mantle.

Thus many models of the geodynamo either retain the viscous term (which makes the problem extremely stiff and hard to solve numerically) or else note that viscosity is likely to be important only in thin Ekman boundary layers at the core–mantle boundary. The boundary layer equations can then be solved to produce instead of the Taylor condition $T(s) = 0$ a formula for V_G of the form $LV_G/\eta = \Lambda E^{\frac{1}{2}} f(s)T(s)$, where $f(s)$ is universal. This definition, like others, encounters problems at the tangent cylinder with the inner core, where further boundary layers may be important. Leaving the inner core aside, there remains the question of the behavior of fields and flows for very small E (which according to some estimates may be as low as 10^{-14}). Either Taylor's condition will be approximately met (a 'Taylor state') or else the zonal flows will become very large and severely limit the field growth (an 'Ekman state'). Braginsky has proposed an intermediate alternative in which the zonal flows are moderately large but also the meridional field is almost aligned with the rotation axis. The dominant balance in this case is between viscous damping and the input of energy from buoyancy forces, whereas in a Taylor state viscosity plays no role. While the idea of this balance remains appealing, it has proved hard to obtain satisfactory numerical models. While the Ekman regime can readily be found numerically, the magnetic field strength given by Λ scales as $E^{-\frac{1}{2}}$ and so this balance is unlikely to be relevant to the geodynamo.

Numerical models

While the above notions have proved challenging for theorists, the advent of fast computers has led to much progress via direct numerical simulation. Cowling's theorem, that no axisymmetric field can be generated by dynamo action, necessitates either a full 3D calculation or else a mean-field model in which only the axisymmetric mean fields and flows are calculated, with the presumed non-axisymmetric small-scale convection being parametrized by the α effect. (The convection having been parametrized, the heat equation can be dropped.) An intermediate ('2.5D') method sets up the full 3D framework but performs severe truncation in the azimuthal direction, retaining the axisymmetric modes and just one or two other zonal wavenumbers. Models of the last two types can be investigated in considerable detail. Viscosity is usually retained in the equations, and E made as small as possible. Geophysically realistic values have as yet not been attained, however. Solutions show irregular oscillatory behavior, but the field strengths are of the right order for the Earth.

The role of the inner core is particularly important in these simulations, although it was neglected in early computational work. Its influence is manifested in two ways; the tangent cylinder separates regions containing quite different types of flow, with the most vigorous activity within. More importantly, because the inner core is a conductor (with conductivity comparable with that of the outer core) any magnetic field lines penetrating it can only evolve on the diffusion timescale (as the inner core is solid). This helps to stabilize the otherwise very wild oscillatory behavior in the models and to stop frequent reversals of the main dipole field on unrealistically short timescales.

Glatzmaier and Roberts have recently carried out a series of ever more sophisticated numerical simulations of a fully three-dimensional dynamo model (figure 4). In essence the models are the same as the 2.5D simulations, but now with full azimuthal resolution. Ekman numbers as low as 10^{-6} are reported for some runs, but these used an artificial hyperviscosity, which has the effect of mimicking the effect of much larger values of E. Nonetheless the dynamics in the core is impressively detailed (although the field as observed at the Earth's surface is much less regular in the simulation). The runs have also uncovered

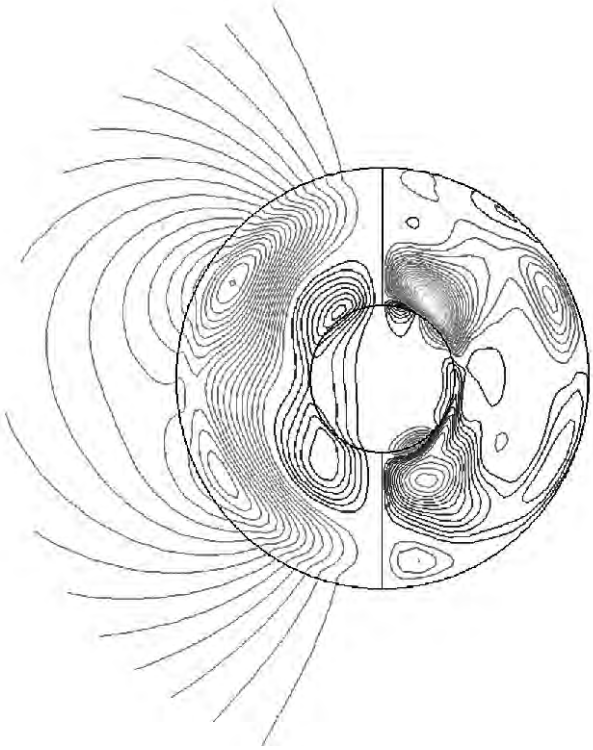
Figure 4. Lines of zonally averaged poloidal field (left halves) and contours of zonally averaged toroidal field (right halves) for a reversal in the model of Glatzmaier and Roberts (1995). Black–grey lines denote opposite directions–signs of the corresponding fields.

several reversal events, as well as a number of 'aborted reversals' whose signature is a large excursion of the virtual geomagnetic pole (defined as the axis of a mapping of the surface field onto a supposed dipole) without a complete change of sign. As before, the inner core seems to play a large role in the dynamics of reversals.



(c)

Figure 4. (Continued)

Calculations done by other groups also emphasize the crucial importance of the mechanical boundary conditions to be applied at the core–mantle boundary.

Sadly, even these massive computations, using hundreds of hours of supercomputer time, do not seem to be likely to be able to handle geophysically realistic parameters for the immediate future. For theorists the primary challenges over the next decade are likely to be an effort to understand the nature of the convective turbulence in the core, so as to produce better-parametrized models of the diffusion coefficients. Further understanding of the mechanisms associated with the solidification of the inner core will also bring better descriptions of the buoyancy forces that drive the motion. There can be little doubt that the recent computational successes, far from closing the subject down, will provide fresh impetus for further theoretical developments.

Geomagnetic Storm

A fluctuation in the Earth's magnetic field caused by the arrival of a disturbance in the solar wind. Also known as a magnetic storm. The sequence of events in a typical major storm is as follows. The shock wave associated with a cloud of plasma ejected by the Sun, as a result of a solar flare or coronal mass ejection, compresses the Earth's magnetosphere, producing a rapid intensification of the geomagnetic field at ground level. This phase, which takes place over a few minutes, is called the 'sudden storm commencement'. This is followed by the 'initial phase', which lasts for up to a few hours, during which the plasma cloud flows past the Earth and the geomagnetic field strength remains higher than normal. During the next stage, the 'main phase', charged particles flow through the inner magnetosphere, thereby creating an electrical current, the 'ring current', which flows around the Earth. The ring current generates a magnetic field opposite to that of the Earth and causes a pronounced drop in the geomagnetic field lasting from a few hours to about a day. As the current declines, the field strength gradually returns to normal, this recovery phase lasting typically for a few days. Geomagnetic storms are often accompanied by displays of the aurora.

Geomagnetic storms induce currents and surges in telephone lines and power cables that sometimes cause significant damage. For example, circuit breakers in transformer stations may be caused to trip out, thereby giving rise to power blackouts.

Geotail

Japanese–US mission to study the dynamics of the Earth's magnetotail over distances ranging from 8 Earth radii to 200 Earth radii. Part of the International Solar-Terrestrial Physics (ISTP) programme. Launched in July 1992. During the first two years, the spacecraft spent most of its time in the distant magnetotail. Its orbit apogee was kept on the night side of the Earth by using the Moon's gravity in a series of double-lunar-swingby maneouvres. In February 1995, the apogee was reduced to 30 Earth radii to study near-Earth magnetotail processes.

Gerard of Cremona (*c.* 1114–87)

Italian scholar, born in Cremona, Italy, flourished in Toledo, a centre of Islamic culture, learned Arabic to be able to translate lost classical works. He translated 92 works in all, including the *Almagest*, *Elements*, AL-KHWARIZMI'S works, the Hippocratic writers, and the physical works of ARISTOTLE. Unfortunately, no mathematician, he could not understand the *Almagest* after translating it.

German Astronomy

The first larger observatories in Germany started their work at the beginning of the nineteenth century. The earliest was founded in Gotha in 1791, followed by Göttingen in 1803, where C F GAUSS became director in 1818 after the observatory had been completed. The observatories in Königsberg and Munich were established in 1813 and 1816 respectively, with F W BESSEL and J G Soldner as the first directors. The cities of Hamburg (J G Repsold) and Berlin (W W Encke) followed in 1825 and 1832 and the Observatory of Bonn (F W Argelander) was founded in 1845.

Spectroscopy has been one of the great traditions in German astronomy. J FRAUNHOFER (Munich) detected hundreds of absorption lines in the solar spectrum in 1823. Together with Soldner he investigated the spectra of the brightest stars and planets and reported morphological differences of the stellar spectra. In 1838, the second director of the Munich Observatory, J LAMONT, used the large 'Fraunhofer Refractor' to perform spectroscopy of stars down to fourth magnitude. G R KIRCHHOFF and R W Bunsen (Heidelberg) developed the concept of spectral analysis in 1859 and gave a first qualitative interpretation of the solar spectrum in 1860. H C VOGEL started his pioneering work on the radial velocities of stars in Bothkamp/Kiel in 1870. Four years later, he moved to the newly founded observatory in Potsdam and detected the line shifts and binary nature of Algol in 1889. Together with F Scheiner he published the first radial velocities of stars in 1890. With more refined methods they reached an accuracy of 3 km s^{-1} per photographic spectrum. F Küstner in Bonn was able to improve this accuracy at the turn of the century. Observing F- and M-stars he obtained an accuracy of 1.4 km s^{-1}. Inspired by K SCHWARZSCHILD in Göttingen, E HERTZSPRUNG started his spectroscopic work on color–magnitude diagrams in 1910 in Potsdam. K Schwarzschild, A Unsöld, L Biermann and W Grotrian contributed fundamentally to the development of the quantitative spectroscopic analysis of stellar spectra. UNSÖLD's book '*Physik der Sternatmosphären*' (first edition 1938, second edition 1955) became the 'Bible' for generations of stellar spectroscopists.

Parallel to spectroscopy, photometry developed as another important branch of German astronomy. The *Potsdamer Durchmusterung* (1905) by G Müller and P Kempf provided magnitudes for 14 195 stars based on a photometer developed by ZÖLLNER (1861). It was the most precise photometric catalog of the time. In 1896, K Schwarzschild (then in Vienna) transformed photometry with photographic plates into a quantitative science. J Wilsing and J Scheiner (Potsdam) performed the first determinations of stellar temperatures by measuring intensities in five spectral bands in 1909. K Schwarzschild (now in Göttingen) published the *Göttinger Aktinometrie* in 1910, a catalog of photometric magnitudes of 3522 stars down to magnitude 7.5 .

All early research on the photoelectric effect was done in Germany (H Hertz 1887, W Hallwachs 1888 and J Elstner and H Geitel 1889). Subsequently, P Guthnick (Berlin) and H Rosenberg and E Meyer (Tübingen) were the first astronomers to use a photoelectric cell for astronomical measurements in 1912. A year later Guthnick published his photoelectric lightcurve of the short-period (4.6 h) low-amplitude (0.086 mag) variable star β Cephei obtained with a sodium cell. In the following years Guthnick, R Prager and K Bottlinger experimented with color filters and published the colors of more than 400 stars using a potassium hybrid cell.

The founder of astrometry in Germany was F W Bessel (Königsberg). In 1838 he determined the parallax of 61 Cygni, the first direct determination of a distance to a star. J G GALLE (Potsdam) detected the planet Neptune in 1846 based on the theoretical predictions by U Leverrier, who analysed the orbit perturbations of Uranus. The *Bonner Durchmusterung* organized by F W ARGELANDER and collaborators from 1852 to 1862 provided positions and finding charts for 73 500 stars in the northern hemisphere down to ninth magnitude. In 1867 the ASTRONOMISCHE GESELLSCHAFT organized an international collaboration of 16 observatories to produce the *Fundamentalkatalog*, a catalog with precise stellar positions of northern hemisphere stars. This work has been extended and improved through to the present day under the responsibility of the Astronomisches Recheninstitut in Heidelberg. It formed an important basis to constrain models for the dynamics of our galaxy.

The investigation of variable stars as a tool to understand stellar evolution started with the work of Argelander in 1840 and 80 years later led to the systematic search for variables by C HOFFMEISTER carried out in the observatories of Sonneberg and Bamberg. More than 4500 variable stars were detected by Hoffmeister. The photographic plate archive of the two observatories contains more than 200 000 sky exposures.

MAX WOLF in Heidelberg used his new astrophotographic methods to investigate the structure of the Milky Way and to detect many minor planets during the years from 1887 to 1932.

There has also been a remarkable tradition in the development of telescopes, optics and instrumentation. At the beginning of the nineteenth century Fraunhofer invented new technologies to produce large lenses of excellent optical quality. He also invented the grating spectrograph. Together with Metz and Utzschneider he constructed the largest and best refractors of the time. Repsold (Hamburg) became famous for the quality of his meridian circle telescopes. In 1905, K Schwarzschild formulated the complete third-order aberration theory of large telescopes with one or two mirrors, which became the basis for the development of all modern reflecting telescopes. In 1930, B SCHMIDT (Hamburg) used an aspheric refracting plate to built his famous wide-field telescope.

The present situation of German astronomy

German astronomy deals with practically all aspects of modern astrophysical research in theory and observation. Stellar astronomy (including the investigation of the Sun) through all stages of stellar evolution is a field of great activity. This includes the important areas of star formation and the formation of planets and proto-planetary disks and, of course, the solar system. The investigation of the physics of the interstellar medium and of the structure and evolution of our galaxy is another very important area. Observational extragalactic astronomy and cosmology had difficulties in the early phases of their development because of the very limited access to large telescopes. However, after the completion of the large ESO telescopes on La Silla, the national CALAR ALTO OBSERVATORY in Spain, the EFFELSBERG and IRAM RADIO TELESCOPES and space observatories such as the ROSAT x-ray satellite this situation has improved dramatically. There are now many competetive groups, both in observation and theory, working in extragalactic astronomy and cosmology.

The development of telescopes and instrumentation has again become a very important part of present German astronomy. This comprises radio, mm and sub-mm telescopes (Effelsberg, IRAM and the Heinrich Hertz Telescope in Arizona), IR astronomy from the ground and in space (instrumentation for ESO La Silla and the VLT, the Calar Alto and the ISO and FIRST space observatories), optical astronomy (instrumentation for the ESO VLT and ESO La Silla, the Calar Alto, the LARGE BINOCULAR TELESCOPE (LBT) in Arizona and the Hobby–Eberly Telescope (HET) in Texas), UV astronomy (ORFEUS), x-ray astronomy (ROSAT, ABRIXAS, Chandra, XMM, XEUS) and gamma-ray astronomy (COMPTEL on GRO, INTEGRAL). The HEGRA EXPERIMENT on Tenerife provides an observatory for very high energies and there is also development of a gravitational wave telescope. In solar physics a new vacuum tower telescope has been constructed as the most important part of the solar observatory on Tenerife by three German institutes in collaboration with Spanish colleagues.

At present, astrophysical research in Germany is performed at 36 institutes distributed over the reunified country. Of these, 22 are university institutes (including the observatories of Bonn (with the observatory Hoher List at Daun), Hamburg, Göttingen and Munich (with the observatory at Mount Wendelstein)). They are integrated parts of the physics faculties of their universities, since in Germany an astronomer is basically a physicist with specialization in astrophysics during the last semesters before the diploma (masters degree) and in PhD thesis work. Though they have most of the teaching load and responsibility for the education of astronomy students, the university institutes are usually small (between one to five professors and three to fifteen scientific staff) and have a very low scientific budget provided by their universities. For the funding of graduate students, post-docs and instrument development they rely completely on grants, which are distributed by the funding agencies in a competitive system. Used to being continuously forced to survive in this competition, several university institutes do extremely well. Most astronomers at the universities make observations as guests at ground-based or space facilities or do theoretical work. Only a few of them at a handful of institutes are involved in instrument development. German universities are state universities, which means that they are funded through the science budgets of the individual states ('Länder') of Germany.

The funding situation is much more positive at the seven MAX-PLANCK INSTITUTES (MPIs) dealing with astronomy. These institutes have usually several (up to four) directors, more than 30 staff scientists and an excellent infrastructure, which allows them to engage in large-scale instrumentation projects, ground-based and in space, and to run their own observatories (Calar Alto Observatory, IRAM, Effelsberg, ROSAT). They are also able to form large theoretical groups and perform observational astronomy as guest observers. All these institutes are located close to universities with astronomical institutes. However, the amount of interaction between MPIs and universities in research and the education of students varies strongly from place to place. The funding of the MPIs is based on equal contributions from the federal science budget and from the science budget of the states in which the institutes are located. There is also a contribution from German industry.

The situation at the Institutes of the Wilhelm-Gottfried-Leibniz-Gesellschaft (WGL), of which there are two, and the two Institutes of the Deutsches Zentrum für Luft- und Raumfahrt (DLR) dealing with astronomy is similar to that of the MPIs. There are also four state institutes in the states of Baden-Württemberg and Thüringen, of which two are active observatories (the 'Landesternwarten' (LSW) in Heidelberg and Tautenburg). Their sizes and resources are comparable to university institutes.

The number of professional astronomers in Germany with a PhD is estimated to be 500. The ratio of tenured to non-tenured staff is roughly 1:1. Most of them are members of the Astronomische Gesellschaft (AG), which organizes scientific meetings every year. Many amateur astronomers and friends of astronomy have also joined the AG.

The extramural funding comes from separate budgets of the federal ministry for education and research (BMBF). For astronomy there are two important funding agencies—the DLR which sponsors a national program of space science and the Deutsche Forschungsgemeinschaft (DFG) which supports almost all branches of research in Germany. The DLR has contributed or contributes to space missions such as ROSAT, ORFEUS, ABRIXAS, SOFIA etc and also provides funding for focal instrumentation for ESA/NASA space missions such as Giotto, Chandra, XMM, ISO, Pathfinder etc when German groups are involved. The DFG has basically three different programs, the normal program, where tenured scientists from universities, WGL and state institutes can apply to obtain

Copyright © Nature Publishing Group 2001

funding for all kinds of individual smaller science projects involving PhD students and post-docs, special programs concentrating on selected topics such as 'cosmic plasmas' or 'star formation', which are open to all institutes, and local programs, where different institutions in and around one or two universities focus on special subjects such as 'the evolution of galaxies' or 'particle astrophysics'.

A new program is the 'Verbundforschung Astronomie' financed directly through the BMBF and the DLR, which supports instrumentation proposals by university groups for ground-based national and international telescopes (to compensate for the lack of internal resources of these groups) and provides research funds for those astronomers who succeeded in obtaining observing time on international space missions such as HST, ISO and ROSAT. This new program has turned out to be a tremendous success and has improved the competitiveness of German astronomy significantly.

The German contributions to international organizations like ESO and ESA are funded directly through the BMBF. Membership in these organizations is fundamental for German astronomy. It has widened the scope of astronomical research in Germany significantly and has internationalized the working style, in particular of the university institutes, substantially. Most importantly, it has enabled German astronomy to participate in instrumentation projects clearly beyond the means of national or bi-national collaborations.

The German system is characterized by an enormous independence of each research institute. While this certainly has significant advantages with regard to scientific originality and creativity, it is also the cause of difficult problems. Collaboration between universities of different states in larger projects is hampered by obstacles intrinsic to the German federal system. The same is true for the collaboration between universities and MPIs. This is one of the reasons why the German national observatory on Calar Alto in Spain is managed by a MPI, the Max-Planck-Institut für Astronomie in Heidelberg, and why it is difficult to organize direct participation of German universities in large telescope projects such as the LBT in Arizona, where so far only three MPIs (MPIA Heidelberg, MPIE Garching, MPIfR Bonn), one WGL institute (Astrophysikalisches Institut Potsdam) and one state observatory (LSW Heidelberg) are involved. Two university observatories (Göttingen and Munich) have, however, managed to become partners of American universities in the HET project in Texas. They have also embarked on a collaboration together with the LSW Heidelberg to build the faint object spectrographs FORS 1 and 2 for the ESO VLT.

In view of the complication caused by the federal system and the independence of the individual institutes an element of coordination is needed. This is the task of the 'Rat Deutscher Sternwarten' (RDS, Council of German Observatories). It was founded in 1959 as the 'Rat Westdeutscher Sternwarten' to nationally and internationally represent the joint interests of the astronomical institutes in West Germany. In 1990, shortly after the reunification of Germany, the renamed 'Rat Deutscher Sternwarten' became the representative organization for all German astronomical institutes. At present 31 such institutes represented by their directors are members of this important committee, which coordinates the main directions of German astronomical research, defines priorities for future large projects, and interacts with the funding agencies, state and federal ministries. It also represents German astronomy within the IAU and in the interaction with ESO. The RDS is headed by a chairman, who is elected for three years and can be re-elected for one additional term and a General Secretary.

Giacconi, Riccardo (1931–)

Astrophysicist, born in Genoa, Italy, American astronomer and international project director. Worked on x-ray astronomy, and with a rocket-borne x-ray telescope intended to study the composition of the Moon, discovered Scorpius X-1, the first known x-ray source outside the solar system. Built the Uhuru x-ray satellite that made the first surveys of the x-ray sky. Led the construction and successful operation of the powerful x-ray satellite Einstein. Directed the Space Telescope Science Institute, laying the foundation for the impact of the Hubble Space Telescope and directed the EUROPEAN SOUTHERN OBSERVATORY, bringing to a successful completion its Very Large Telescope.

In 2003, Giacconi received the Nobel Prize in physics for 'pioneering contributions to astrophysics', which led to the discovery of cosmic x-ray sources. Giaconni, currently president of the Associated Universities Inc., in Washington, and Research Professor of Physics and Astronomy at Johns Hopkins University, Baltimore, discovered the first x-ray stars and the x-ray background in the 1960s and conceived of and led the implementation of the UHURU and High Energy Astronomy Observatory-2 (HEAO-2) x-ray observatories in the 1970s. He also detected sources of x-rays that most astronomers now consider to contain black holes.

Giacobinids

A periodic meteor shower associated with the comet 21P/Giacobini–Zinner which takes place in October. The radiant lies in the constellation Draco, and the shower is also known as the *Draconids*. Debris from the comet remains in a swarm close to the nucleus, and shower activity is possible only when the Earth passes the descending node of the comet's orbit shortly after the comet has passed through it. Zenithal hourly rates were high in 1933 (up to 450), 1946 and 1985. Radio-echo observations in 1946 detected a peak rate of 170 per minute.

Giant Impactor Theory

The theory, also known as the *big splash* theory, that a planetoid about the size of Mars collided with the newly formed Earth, and ejecta from the collision accreted in orbit around the Earth to form the Moon. Support for the theory comes from the very close correspondence of oxygen isotope ratios in lunar and terrestrial material, and the similar mineralogies of the two bodies. In addition, the theory explains the large amount of angular momentum in the Earth–Moon system.

Giant Planets

A collective term for the major planets Jupiter, Saturn, Uranus and Neptune, which are the four largest planets in the solar system. They are characterized by their size (of the order of 100 000 km in diameter), their density (of the order of 1000 kg m^{-3}), their largely gaseous nature, with no visible solid surface, and their extensive families of satellites. They also all possess ring systems. Of the giant planets Jupiter is the largest and most massive, and rotates the most rapidly. Saturn is the most oblate and the least dense, and has the most extensive ring system. Saturn and Uranus tie for the largest retinues of confirmed satellites, at 18. The most distant, Neptune, is the densest and has the largest measured atmospheric wind speed. The majority of exoplanets—objects orbiting other stars—are more massive than Jupiter, and may be classed as giant planets.

Compare: terrestrial planets.

Gibbous

The phase of a body in the solar system when more than half of its sunlit side is visible, but not all of it. From the Earth, the inferior planets, Mercury and Venus, and the Moon show gibbous phases. Of the superior planets, Mars is the only one that can appear markedly gibbous (with a minimum of 84% of its disk illuminated); of the outer planets, Jupiter can show a slight gibbous phase but the planets beyond are too distant to do so.

Gilbert [Gilberd], William (1544–1603)

Doctor and scientist, born in Colchester, England, wrote *De Magnete* (*On the Magnet*), published in 1600. The magnetic compass was one of most useful the navigational instruments before the chronometer, but little was known about the lodestone (magnetic iron ore). Gilbert made his own experiments, such as testing the folk-belief that garlic destroys the magnetic effect of the compass needle. He draws the first clear distinction between magnetic effects and static electricity, reviewing everything about magnetism. His theory of terrestrial magnetism was curiously animistic: magnetism was the soul of the Earth and a spherical lodestone, aligned with the Earth's poles, would spin on its axis like the Earth. KEPLER and GALILEO were very interested in this aspect of Gilbert's magnetic researches, since they were seeking arguments that the Earth rotated.

Gill, Sir David (1843–1914)

Astronomer, born in Aberdeen, trained as a watchmaker, had a private observatory near Aberdeen, became Her Majesty's Astronomer at the Cape of Good Hope. He redetermined the solar parallax by observing the close approach to the Earth in 1889 of the minor planets Iris, Victoria and Sappho (his was the standard value for nearly a century). His measurement was repeated by HAROLD SPENCER JONES during the close approach of Eros in 1931. Inspired by the unexpected discovery in 1882 of stellar images on a photograph of a comet, he pioneered astronomical photography. He photographed the southern sky for the *Cape Photographic Durchmusterung*, CPD, adding to ARGELANDER'S *Bonner Durchmusterung*. This initiated the international Carte du Ciel project and the subject of photographic astrometry.

Ginga (Astro-C)

Japanese x-ray satellite, launched February 1987. Carried three instruments: a large-area proportional counter array developed with the UK, an all-sky monitor and a US gamma ray burst detector. Observed supernova 1987A soon after its appearance, and discovered several pulsars and other transient sources. Re-entered the atmosphere in November 1991. Ginga means 'galaxy'. (See also ASTRO.)

Giotto

The purpose of the Giotto mission was to study the coma and nucleus of Comet P/Halley at close quarters during its 1986 perihelion passage. It was the EUROPEAN SPACE AGENCY's first deep space mission and was named after the famous medieval Italian artist, Giotto di Bondone, who, inspired by the reappearance of COMET HALLEY in 1301, had portrayed the Star of Bethlehem as a golden comet in his fresco 'Adoration of the Magi'.

Giotto was originally proposed as part of a joint US–European mission to Halley's Comet, but after NASA withdrew, ESA decided to proceed alone. It was later included in an international program to investigate the comet. Five space probes—two Soviet, two Japanese and one European—were launched towards the comet on its return to the inner solar system. While the Japanese spacecraft (Sakigake and Suisei) made long-distance measurements, the Soviet VEGAS acted as pathfinders for Giotto by accurately locating the comet's nucleus.

The cylindrical spacecraft weighed 960 kg. Its design was based on the GEOS Earth-orbiting research satellites, which were built by British Aerospace at Bristol (UK). The most significant modification was the addition of an aluminum–Kevlar buffer to protect it from high-speed dust particles during the comet encounter. The spacecraft was eventually launched by an Ariane 1 rocket (flight V14) on 2 July 1985.

Giotto carried ten scientific instruments which included

- a narrow-angle, multicolor CCD camera to obtain pictures of the nucleus,
- three mass spectrometers to measure gas and dust composition,
- a dust impact detector to measure the mass of dust particles striking the shield,
- two plasma experiments to study the solar wind and charged particles,
- an energetic particles analyser to study electrons, protons and alpha-particles,
- a magnetometer to study changes in the magnetic field,
- an optical probe to study the brightness of the coma and
- a radio science experiment to investigate the electron environment by comparing signals sent at different frequencies from the spacecraft.

The first comet data arrived at 21.00 GMT on 12 March 1986, when the spacecraft's instruments detected hydrogen ions 7.8 million km from the nucleus. Giotto crossed the bow shock, where the solar wind slowed to subsonic speed, 22 h later and entered the coma (see COMA, COMETARY).

Excitement rose as the stream of pictures and data came in to the European Space Operations Centre in Darmstadt, Germany, at a rate of 46 000 bits s^{-1}. The first of 12 000 dust impacts was recorded 62 min before closest approach (290 000 km out), but the rate of impacts rose sharply as the spacecraft passed through a jet of material from the nucleus.

Only 7.6 s before closest approach, the spacecraft was sent spinning by an impact from a 'large' (c 1 g) particle. Although contact with the Earth was lost, the spacecraft's thrusters were able to stabilize its motion and contact was restored 32 min later. By then Giotto had passed within 596 km of the nucleus on the sunward side and was heading back into interplanetary space.

The remarkably resilient spacecraft continued to return scientific data for another 24 h. The last dust impact was detected 49 min after closest approach. The historic encounter ended at 02.00 GMT on 15 March when Giotto's experiments were switched off.

Altogether 2112 images were returned before communications were disrupted. A unique series of images sent back by the spacecraft revealed the comet nucleus to be a dark, peanut-shaped body, about 15 km long and 7–10 km wide. Its surface was very irregular, with hills and depressions, while its density (0.3 g cm^{-3}) indicated a 'fluffy', porous texture. The black surface was composed of organic compounds (see also COMETARY NUCLEI).

Seven jets that were identified on the warmer sunlit side threw out 3 t s^{-1} of material, but only about 10% of the surface was active. These jets gave the comet a strange, wobbling rotation which seems to be stable on a time scale of centuries or even millennia.

Water accounted for about 80% by volume of all of the material ejected by the comet. There were also substantial amounts of carbon monoxide (10%), carbon dioxide (2.5%) methane and ammonia. Traces of other hydrocarbons, iron and sodium were also found. The surface of the nucleus had an albedo of 4–5%—blacker than coal.

Most of the dust was no larger than specks of cigarette smoke. Two major classes of dust particles were found. One was dominated by the light 'CHON' elements—carbon, hydrogen, oxygen and nitrogen. The other was rich in mineral-forming elements—sodium, magnesium, silicon, iron and calcium. All of the comet's light elements (except nitrogen) were found in the same relative abundance as for the Sun, confirming that Comet Halley consists of primitive material derived from the original solar nebula.

Giotto also discovered a magnetic cavity—a region where the magnetic field was essentially zero—around Halley's Comet. This is the only time that such a feature has been recorded.

Despite the damage sustained during the flyby, eight instruments remained operational and the mission was extended to allow an unprecedented second encounter with a comet—P/Grigg–Skjellerup. After an Earth flyby and a long hibernation, Giotto was reawakened on 4 May 1992, 12 days before the comet reached perihelion. Sweeping past at a distance of only 100–200 km on 10 July, it was the closest ever cometary encounter.

Conditions were very different from those during the Halley flyby. Grigg–Skjellerup approached Giotto at an angle of 68° instead of head on, so the relative approach speed was 14 km s^{-1} (as opposed to 68 km s^{-1} for Halley).

Giotto crossed the bow shock and entered the coma about 17 000 km from the nucleus. Grigg–Skjellerup's dust production rate was about 0.5% that of Halley, and only three sizeable particles were detected, the largest with a mass of about 30 μg.

The first cometary ions were detected 440 000 km from the nucleus, about 12 h before the closest approach. Two peaks were seen in the brightness of the coma, due to scattering of sunlight by cometary dust particles. One peak coincided with the closest approach to the nucleus. The second peak a little over 1 min later remains a mystery.

Scientists were surprised when an abrupt shock wave—caused when the supersonic solar wind slammed into plasma around the comet—was detected on Giotto's outbound leg, but not clearly identified on the inward journey (see also SOLAR WIND: INTERACTION WITH COMETS).

Magnetic field strength was slightly higher than at Halley, but no magnetic cavity was detected around the much smaller nucleus. Strangest of all was the discovery of unusual magnetic waves, each about 1000 km apart, out to at least 300 000 km from the comet. Activity rose and fell over a period of about 70 s and increased in amplitude as time went by.

The science experiments were switched off for the last time at 03.00 GMT on 11 July. On 23 July 1992, Giotto operations were officially terminated.

Globular Cluster Systems in Interacting Galaxies

GLOBULAR CLUSTERS are dynamically bound and dense collections of large numbers of coeval stars. Typical globular clusters have roughly one million stars within a radius of a few parsecs. They are also usually close to spherical, hence the name globular. By virtue of their rich, isolated population of stars they provide an important laboratory for studies of STELLAR EVOLUTION. Moreover, because of their high densities, globular clusters are prime regions for the study of STELLAR DYNAMICS. Globular clusters are also ubiquitous, being found around nearly all galaxies. This suggests that the formation of globular clusters is closely connected to the formation of the galaxies to which they belong.

At young ages, globular clusters are expected to be very bright and blue because of the concentration of many young stars in a compact region. Their high luminosities, blue colors and compact sizes make young globular clusters easy to detect and identify in imaging surveys. Therefore, the absence of known examples of young globular clusters in the Milky Way and M31 is strong evidence that the current STAR FORMATION in these galaxies is somehow not conducive to the formation of globular clusters. This was not always the case, as these two major SPIRAL GALAXIES in the LOCAL GROUP both have substantial populations of old globular clusters. Similarly, ELLIPTICAL GALAXIES, which have no ongoing star formation, also typically have rich populations of globular clusters. These observations led to the general idea that the formation of star clusters as massive and dense as globular clusters was somehow favored at early times. However, the same absence of nearby examples of the process of globular cluster formation strongly limited the understanding of the key physical processes involved in globular cluster formation.

The most nearby example of a galaxy in which there is recent formation of young stellar systems with the high luminosities, blue colors and compact sizes expected of young globular clusters is the LARGE MAGELLANIC CLOUD (LMC). The LMC has several STAR CLUSTERS with ages ranging from a few Myr to several Gyr which have the properties expected for globular clusters at these ages, as well as about a dozen old (10+ Gyr) globular clusters. However, in the LMC the handful of massive, dense young clusters are strongly outnumbered by many more low-mass young star clusters that are not likely to survive processes such as stellar mass loss, tidal shocks and evaporation. Prior to the launch of the HUBBLE SPACE TELESCOPE (HST), there were a few other potential examples of similar objects in more distant galaxies, but existing observations did not have sufficient spatial resolution to determine whether objects beyond the Local Group had compact sizes characteristic of a globular cluster.

The subject of globular cluster formation in galaxy mergers has been revolutionized by HST observations, which have the image quality to resolve the starbursts in galaxy mergers and reveal large numbers of highly luminous, compact, blue star clusters (see also GALAXIES: INTERACTIONS AND MERGERS). These were first discovered by Holtzman (1992) and Whitmore (1993) and their collaborators and were immediately recognized as having the properties of globular clusters at young ages predicted by Ashman and Zepf (1992) and by Schweizer (1987). Specifically, HST images of galaxies previously recognized as the merger of two disk galaxies based on morphological and dynamical information show that these systems have large numbers of bright, blue, compact objects. These objects are striking with their bright magnitudes ($M_B < -10$) and compact sizes ($r < 10$ pc). The colors, magnitudes, and sizes of these objects are consistent with those expected for globular clusters in our own Galaxy when they were young. Subsequent moderate-resolution spectroscopy of some of the brighter examples has shown strong Balmer absorption lines, confirming the identification of these objects as young star clusters.

These candidate young globular clusters have colors, luminosities and sizes that globular clusters like those in the Milky Way are believed to have had when they were young. An important further step for testing the connection between the candidate young globular clusters and old globular clusters is to compare the masses of the clusters in the two populations. In nearly all cases, the mass of a candidate young globular cluster is determined by estimating the age of the cluster from its color or spectral characteristics, using that age and a stellar populations model to estimate the mass-to-light ratio, and then combining the mass-to-light ratio with the observed luminosity to estimate the mass. While all of these calculations are standard, they do depend on parameters that are not directly observed, including the metallicity and, most importantly, the initial stellar mass function in the young cluster. Fortunately for this purpose, the initial mass function appears to be similar in old globular clusters and young star-forming regions, so it is difficult to imagine that all of the candidate young globular clusters formed with dramatically different stellar initial mass functions. Morever, the ages of some of the young globular clusters are several hundred Myr, which is many crossing times. Thus their compact sizes suggest that they are bound, which would be unlikely if the clusters are deficient in low-mass stars, which play an important role in the mass budget of a cluster with a standard initial mass function. Finally, in the one or two cases in which a mass has been estimated dynamically from the widths of absorption lines, the masses are broadly consistent with those given by stellar population models with standard initial mass functions. It is therefore very likely that the inferred masses for the young star clusters observed in galaxy starbursts and mergers are roughly correct. This then implies that many of these objects then have masses and densities like those of Galactic globular clusters.

All globular clusters were once bound clusters of typically $(10^5$–$10^6)M_\odot$ of young stars. However, not all bound young star clusters of similar masses and densities

Copyright © Nature Publishing Group 2001

will evolve to become old globular clusters because there are a number of important dynamical processes that act to destroy globular clusters. These include evaporation, tidal shocking and dynamical friction. These dynamical processes that destroy clusters depend on the properties of the young globular clusters such as mass, radius and concentration, and also on the orbit of the cluster and the mass distribution of its host galaxy. Therefore, on an individual basis it is not possible to predict the effect of these processes on a candidate young globular cluster, as this would require detailed knowledge of its orbit, and the mass distribution of the host galaxy, even if the cluster's mass profile was well constrained. However, it is possible to address the question of the role of dynamical evolution by testing predictions for the global properties of globular cluster systems. Comparisons of systems of different ages and in different galaxies may be particularly useful in this regard (see also GLOBULAR CLUSTER SYSTEMS IN NORMAL GALAXIES).

Understanding the effects of these dynamical processes on the evolution of globular cluster systems is important for determining the relationship between the systems of massive, dense young star clusters in mergers and starbursts and systems of old globular clusters such as the Galactic globular cluster system. One critical example is that the young cluster systems appear to form with a power-law mass function. This may not be particularly surprising since the giant molecular clouds out of which they probably form also have a power-law mass function. However, it is in strong contrast to the log-normal mass function of old globular cluster systems, such as that in the Milky Way and M87, which has a peak at $1–2 \times 10^5 M_\odot$. If the young cluster systems are to be identified as globular cluster systems at young ages, then dynamical processes must preferentially destroy lower-mass clusters so that the mass function of the cluster system evolves a Hubble time from a power law to log-normal with a peak at slighly more than $10^5 M_\odot$.

Theoretical analyses suggest that dynamical processes, particularly evaporation and tidal shocking, do preferentially destroy low-mass clusters. This work has been most thoroughly pursued for the Milky Way, where it has been shown that it is plausible that the Galactic globular cluster system was once much more numerous and had a power-law mass function extending to low masses. A significant role for dynamical destruction is also indicated by the study of the structural parameters of Galactic globular clusters, which generally fall only within the bounds allowed by models of evaporation and tidal shocking. Although there are obvious uncertainties in running the clock backwards to infer the initial conditions of the Milky Way gobular cluster system, the consistency of these data with significant dynamical evolution leading to a log-normal mass function is suggestive that similar processes may apply to the candidate young globular cluster systems seen in galaxy starbursts and mergers.

Some observational constraints can be placed on the evolution of young globular cluster systems by studying systems of different ages and by looking at joint constraints on the luminosities, color and radii within a given system. Perhaps the most stringent constraints come from the studies of the gobular clusters of NGC 1275 and NGC 7252, which are about 500 Myr old based on colors and moderate-resolution spectroscopy. Both of these systems appear to have power-law mass functions to the limit of the observations at inferred masses of a few times $10^4 M_\odot$. Thus, any dynamical alteration to the mass function at masses above this lower limit must happen at later ages. This is plausible, as long as the dependence of radius on mass is not too steep. Of course, many clusters can be lost at younger ages, but the strong preferential loss of clusters with masses between this limit and the peak of the old globular cluster mass function must happen at later times. The alternative is that the young clusters are not the same type of objects as the older clusters, even though they have the same masses and densities. A critical challenge for observers in this field is to test these ideas about the dynamical evolution of systems of globular clusters.

A striking characteristic of the systems of compact young star clusters is that they make up an appreciable fraction of the recent star formation in some starbursts and mergers, as measured by the fraction of blue light in the young clusters as compared with the galaxy as a whole. In the most energetic starbursts observed, this fraction of blue and ultraviolet light in bright, compact young star clusters is up to 20%, with smaller fractions being more typical of systems not at the peak of the starburst. This result suggests that the formation of compact, massive star clusters is not a negligible mode of star formation. It also suggests that the formation of massive, compact star clusters may be efficient in starburst and mergers. This has important implications for the understanding of the globular clusters systems around early-type galaxies and bulges, which the mergers and starbursts are believed to evolve into. Specifically, if the formation of young globular clusters is efficient, then it is possible to account for much of the globular cluster populations of bulges and ellipticals through similar processes. The roughly solar metallicity of about half of the globular clusters in ellipticals is consistent with this idea. It is also interesting to note that if 20% of the star formation in a starburst is in compact clusters, then most of these clusters must not survive for a Hubble time, as old globular clusters make up only about 1% of the light in old stellar populations such as the Galactic halo and in giant ellipticals.

Globular Cluster Systems in Normal Galaxies

All but the smallest dwarf galaxies possess a family of GLOBULAR CLUSTERS (GCs). They are among the oldest stellar systems in the universe. As such these 'astronomical fossils' provide valuable clues about the formation and evolution of their host galaxy. They offer a unique probe of the metallicity and kinematics at large radii in galactic halos, including our own Milky Way Galaxy.

For LOCAL GROUP galaxies, spectroscopic studies of GCs are well advanced. However the bulk of our knowledge about extragalactic GCs comes from imaging. Imaging studies received a boost from wide-field-of-view CCDs in the late 1980s and from the HUBBLE SPACE TELESCOPE (HST) in the 1990s. It is now possible to study the magnitude, color and spatial distribution of GC systems at the distance of the COMA CLUSTER and beyond. Imaging can be hundreds of times more efficient than spectroscopy for studying GC systems but it supplies little information about age, independent of metallicity, and nothing about kinematics or abundance anomalies.

Perhaps the most basic property of a GC system is the total number of GCs associated with a galaxy. This number varies from dwarf galaxies with a single GC to over 10 000 in the case of some cD galaxies. The number of GCs associated with a galaxy correlates roughly with the host galaxy luminosity (i.e. $N \sim L^2$). In order to facilitate comparison between galaxies, the number of GCs is normalized to $M_V = -15$. This is termed the *specific frequency*,

$$S_N = N10^{0.4(M_V+15)}.$$

The S_N value is affected by environment, with cluster ellipticals having $S_N \sim 5$ and their field counterparts $S_N \sim 3$. Some of the most luminous galaxies, typically cD galaxies, have $S_N \sim 15$, i.e. several times more GCs per unit starlight than other early-type galaxies. Therefore high-S_N galaxies have either formed or acquired GCs more efficiently than they have field stars. It appears that high-S_N galaxies have a high S_N value at all radii throughout the galaxy. Although suggestions to explain the high-S_N phenomenon have been proposed, none is, as yet, universally accepted. Spiral galaxies have $S_N \sim 1$, but if we take account of the lower mass-to-light ratio of the young stellar populations in spiral disks then this rises to $S_N \sim 2$.

Local Group

Magellanic Clouds

Both Magellanic Clouds appear to contain young (<1 Gyr), intermediate (∼5 Gyr) and old (∼15 Gyr) GCs. At a distance of only 50 kpc, this would make the Magellanic Clouds ideal laboratories to study GCs with a range of ages (see also LARGE MAGELLANIC CLOUD, SMALL MAGELLANIC CLOUD). However, there are also some disadvantages of studying the Magellanic Cloud GC systems. First, assuming that GCs have been correctly associated with each Magellanic Cloud, the GC systems are small. The LMC has ∼13 *bona fide* (i.e. old) GCs and the SMC may only have one (NGC 221). Second, it is difficult to distinguish GCs from open clusters (the ratio of open to globular clusters is about 20:1). The LMC GCs have a similar mean magnitude and metallicity to the Milky Way halo ones. They differ in their shapes (slightly more extended and flattened) and kinematics (both young and old GCs reveal evidence for a bulk rotation about the LMC).

M31

The GC system of our sister galaxy, M31, reveals many similarities to our own, with the advantage of greater numbers (i.e. $N \sim 400$ compared with $N \sim 160$ for the Milky Way). For example, the GC luminosity function shows a similar peak and width. The metallicity distribution, although not as obvious, shows a similar metal-poor ([Fe/H] ~ -1.5) and a metal-rich ([Fe/H] ~ -0.5) dichotomy. Associating these with halo and disk populations via kinematics is complicated by the nearly face-on nature of M31. Nevertheless there is some evidence that the metal-rich GCs form a disk-like rotating system. As with the Milky Way and other galaxies, there is a deficit of GCs in the very inner galactic regions. An interesting difference in the M31 GCs is the presence of abundance anomalies. In particular, the CN and Ca H+K lines have enhanced line strengths relative to Milky Way GCs. It has been suggested that this difference may have a primordial origin.

M33 and other Local Group galaxies

The late-type spiral M33 contains ∼25 old GCs, and perhaps as many again which are young or intermediate aged. The magnitude distribution, mean metallicity and kinematics of the old GCs appear similar to the Milky Way halo system. Most other Local Group galaxies are dwarf spheroidals, many of which possess a handful of GCs. These GCs tend to be metal-poor and show similarities in their color–magnitude diagrams to the young halo GCs in our own Galaxy. Direct evidence for accretion of such GCs comes from the Sgr dwarf (and its 3–4 GCs) which is in the process of merging with our Galaxy. Most dwarf galaxies have relatively normal S_N values but the Fornax dwarf has $S_N \sim 20$ indicating that GC formation can be very efficient in some small galaxies.

Luminosity function

The GC luminosity function (GCLF) is simply the number of GCs per luminosity interval (see also LUMINOSITY FUNCTION OF GALAXIES). If the number is plotted against magnitude then it is well approximated by a Gaussian distribution, i.e.

$$N = A\exp[-(M - M^0)^2/2\sigma^2]$$

where σ is the width of the Gaussian, M^0 is the turnover or peak magnitude and A is the number of GCs at the peak. An example of a GCLF for a giant elliptical is shown in figure 1. What is remarkable about the GCLF is that the peak is nearly universal, i.e. all well-studied systems

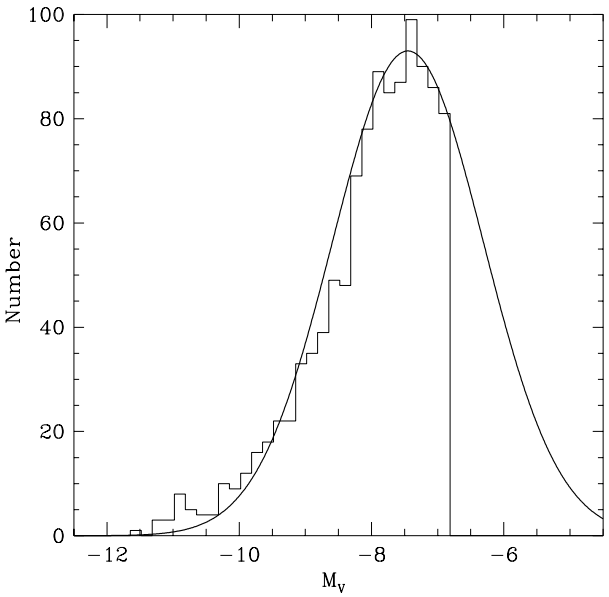

Figure 1. GCLF for the giant elliptical galaxy NGC 5846. The histogram shows the binned GC counts and the solid curve shows the best-fit Gaussian with a peak magnitude of $M_V^0 = -7.4$.

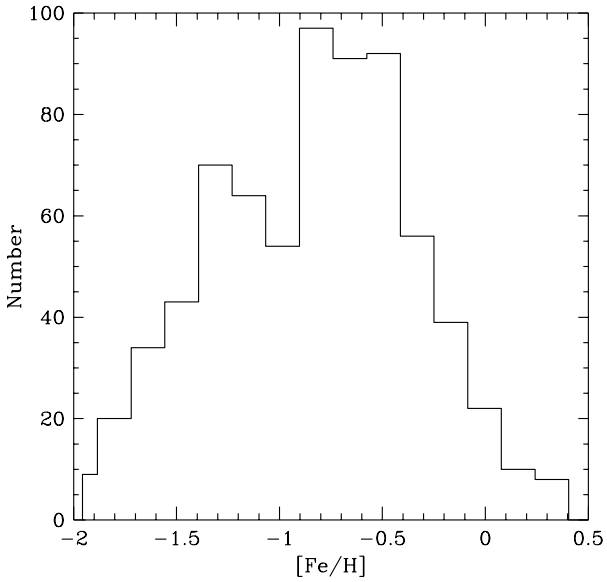

Figure 2. GC metallicity histogram for the giant elliptical galaxy NGC 5846. The histogram reveals clear evidence of a bimodal metallicity distribution indicating two distinct populations of GCs. Metallicities are estimated from photometry assuming a standard color-to-metallicity transformation.

have a peak at $M_V^0 = -7.4 \pm 0.2$. For a V band mass-to-light ratio of 2 this corresponds to a mean mass of $1.6 \times 10^5 M_\odot$. The small deviations from a universal M_V^0 value do exist and various causes have been suggested, namely luminosity, Hubble type, color (metallicity) or environmental effects. This issue has yet to be settled. However, the mass function of GCs seems to be even more robust, and closely resembles that of giant molecular clouds (GMCs). Prompted by this observation, it has been suggested that GCs form in the cores of large GMCs.

If GCs do indeed have a nearly universal mean absolute magnitude, then this can be used as a standard candle for distance determination. This has many advantages over other distance determination methods: GCs are available in large numbers around all large galaxies, they do not require repeat measurements (e.g. the study of variable stars) and the method can work for a variety of Hubble types. Its main disadvantage is perhaps a lack of a well-established theory to explain the preferred mass of GCs. The Hubble Space Telescope has made a significant impact in this area with its ability to obtain high-precision photometric data several magnitudes fainter than the peak. The GCLF method now shows excellent agreement with surface brightness fluctuations and Cepheid variable determined distances, giving values of the Hubble constant around 75 km s^{-1} Mpc^{-1}.

Metallicity distribution

In the last few years it has become clear that several, perhaps all, massive early-type galaxies have two distinct populations of GCs. These subpopulations are apparent in high-quality photometric observations as a bimodal color distribution. It is generally assumed that the color separation in the two peaks largely reflects differences in metallicity, and to a lesser extent age. The typical separation between the relatively metal-poor and metal-rich peaks is ∼1 dex in [Fe/H]. Breaking the age–metallicity degeneracy for GCs with spectroscopy and near-IR photometry is an active area of research. For the two cD galaxies studied to date (i.e. M87 and NGC 1399), their GC (metal-poor and metal-rich) populations appear to be quite old (∼10–15 Gyrs).

The relative numbers in each population are typically similar, although there is some evidence that the ratio of metal-poor to metal-rich GCs scales with S_N. In other words, high S_N galaxies have relatively more metal-poor GCs. An example of a bimodal metallicity distribution, for an elliptical with a low S_N value, is shown in figure 2.

The presence of two GC populations appears to explain the long-standing observation that the mean metallicity of the GC system is ∼0.5 dex lower in [Fe/H] than the stars in massive ellipticals. This simply arises because the metal-rich GCs have a similar metallicity to the host galaxy stars while the metal-poor ones are ∼1 dex lower in [Fe/H]. Radial metallicity gradients for the entire GC system are due to the changing relative mix of the two populations with galactocentric radius (i.e. the metal-poor to metal-rich ratio increases with radius). Thus there may be no true radial metallicity gradient, suggesting a dissipationless formation process.

The existence of multimodal color distributions indicates that GCs formed in distinct star formation

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

episodes from different metallicity gas, perhaps at different times. A simple monolithic collapse (expected to result in a unimodal color distribution) appears to be ruled out by such data. Interestingly, unimodal distributions may be present in low-luminosity ellipticals although the smaller number of GCs present makes any bimodality more difficult to detect.

Metallicity–luminosity relation

The correlation between the mean metallicity of the GC system and the luminosity of the host galaxy has been subject to much debate. As the number of systems studied has increased, it now seems clear that some relationship exists from dwarf to cD galaxies. The type of relation, contribution of observational errors and second-parameter effects are the subject of ongoing debate. For a linear fit, the slope of the GC system metallicity–galaxy luminosity relation is $Z \propto L^{0.4}$. This is similar to the slope of the galaxy metallicity–galaxy luminosity relation. Taken together these indicate that the GC system has had a similar chemical enrichment history to its host galaxy.

If we subdivide the GC system into the mean metallicity of the metal-poor and metal-rich peaks, then we find that it is the metal-rich peak which correlates with galaxy luminosity. This provides further evidence that the metal-rich GCs are closely coupled to the formation of the galaxy itself. The metal-poor peak shows little or no correlation.

Spatial distribution

Radial distribution

When plotted logarithmically, the radial surface density distribution for a GC system typically shows a flat 'core' region (i.e. approaching zero slope) in the central few kpc and a roughly power-law-like decline to larger galactocentric radii. The GC system surface density is often more extended than that of the galaxy starlight. Low-S_N galaxies cover a range of power-law slopes but high-S_N galaxies only have relatively flat slopes (i.e. an extended distribution). For cD galaxies there is a change in slope at the radius of the cD envelope indicating that the outer GCs and the stellar envelope have a similar origin.

Azimuthal distribution

Less is known about the azimuthal distribution of GCs than their radial profile. However, it appears that GCs generally track the position angle and ellipticity variations of the underlying galaxy starlight. In the future, a number of GC systems may have been studied in enough detail to make comparisons with the spatial properties of x-ray-emitting gas. This will provide a unique probe of the dark matter distribution at large galactocentric radii.

Kinematic properties

The kinematics of large samples of GCs has been determined for only a few galaxies to date, although the combination of multiobject spectrographs on large telescopes is rapidly improving this situation. Studying the kinematics of the subpopulations promises to yield important clues as to their origin and ultimately place new constraints on the formation and dynamical evolution of their host galaxy.

An additional use of GC kinematic studies is their application to mass estimates of galaxies. They act like test particles in the gravitational potential and have the advantage of extending well beyond the optical limit of the galaxy. Masses are typically determined using either the projected-mass method or the virial theorem. For a system of N GCs the projected-mass is

$$M_{PM} = \frac{f_p}{G(N-\alpha)}(\Sigma_i^N V_i^2 r_i)$$

where f_p is a numerical factor which describes the type of GC orbits, α is a small correction factor, V_i is the velocity difference between the ith GC and the system mean velocity and r_i is the radial separation from the system centroid position. For small samples of GCs, the mass is likely to be overestimated. The mass from the virial theorem is

$$M_{VT} = \frac{3\pi N}{2G}\frac{\Sigma_i^N V_i^2}{\Sigma_{i<j} 1/r_{ij}}$$

where r_{ij} is the radial separation between the ith and jth GC.

Only a few galaxies have mass estimates from GC motions, although this is likely to be an active area in the coming years. Such estimates can be compared with those from x-ray satellites for massive ellipticals. However, for small ellipticals, without extended hot gas halos, GC-based estimates may be the only feasible method for estimating mass at large galactocentric radii.

Formation and destruction

The origin of GC systems is not currently known. Traditionally models fell into three main categories: primary (formation before the galaxy), secondary (formation of GCs and galaxy contemporaneously) and tertiary (formation after galaxies). The current formation ideas tend to be more hybrid in nature, motivated by the recent discoveries of two GC populations in massive ellipticals. Ideas include creation of new GCs in the gaseous merger that forms the elliptical, *in situ* formation plus accretion from smaller galaxies and *in situ* formation in two distinct star formation phases. The reality may be a combination of these basic processes (i.e. *in situ* formation, tidal accretion and the creation of new GCs), operating at varying degrees in different systems.

Once formed, a GC can be destroyed by a variety of internal and external mechanisms. In the case of protoglobular clusters, they will disrupt themselves if supernovae inject more energy than is binding the cluster together. Low-mass protoglobular clusters may evaporate or be tidally shocked. Either way low-mass clusters must be destroyed if their observed power-law luminosity function is to eventually resemble the log-normal distribution of old GCs. Other long-term

dynamical destruction effects include bulge and disk shocking. Disk shocking may destroy a GC as it passes through the increased density of a galactic disk. Bulge shocking is strongest in galaxies with high central densities, i.e. low-luminosity ellipticals. Only recently have predictions for GC destruction rates in different types of galaxies become available.

Globular Cluster X-ray Sources

Twelve of the 147 globular clusters associated with our Galaxy contain a bright ($L_x \gtrsim 10^{29}$ W) x-ray source; many more contain dim ($L_x \lesssim 10^{28}$ W) x-ray sources, of which more than 40 are now known. X-ray sources have also been detected in globular clusters of the ANDROMEDA GALAXY M31.

The x-ray properties of the bright cluster sources in our Galaxy are similar to those of the low-mass x-ray binaries in the galactic disk (see also X-RAY BINARY STARS). The bright x-ray sources in globular clusters are therefore thought to be binaries in which a NEUTRON STAR accretes matter from a low-mass companion.

The nature of the dim x-ray sources in globular clusters is more diverse. A single cluster can contain several dim sources. Soft x-ray transients, cataclysmic variables, recycled radio pulsars, and RS CVN binaries all can have x-ray luminosities in the range observed for the dim sources, and are known to exist in globular clusters.

Twelve bright cluster sources correspond to about 10% of the bright x-ray sources of our Galaxy, a surprisingly large fraction if one considers that the globular cluster system holds less than 0.1% of the stars in our Galaxy. The efficient formation of x-ray binaries in globular clusters is ascribed to two processes: tidal capture and exchange encounters. Tidal capture occurs when a neutron star transfers some of its kinetic energy to tides in another star during a close passage, and enough tidal energy is dissipated to bind the neutron star in orbit around its captor. An exchange encounter occurs when a neutron star ejects one of the stars in a binary in a close encounter, and takes its place. These processes are efficient especially in globular clusters with dense cores, where the average distance between stars is relatively small.

Table 1. Table of the bright x-ray sources in globular clusters, giving the position of the source, its (approximate) x-ray luminosity, and where known the binary period. All sources except Terzan 6 are x-ray bursters. For transients, marked with T, the luminosity at maximum is given.

Cluster	Position	$\log L_x$ (W)	P_b
NGC1851	0512 − 40	29.2	
NGC6440	1745 − 20	T30.4	
NGC6441	1746 − 37	29.6	5.7 h
NGC6624	1820 − 30	30.8	11.4 min
NGC6652	1836 − 33	T29.4	
NGC6712	1850 − 09	29.1	20.6 min
NGC7078	2127 + 12	29.4	17.1 h
Terzan 1	1732 − 30	29.3	
Terzan 2[a]	1724 − 31	29.5	
Terzan 5	1745 − 25	28.8	
Terzan 6	1751 − 31	T29.7	12.4 h
Liller 1[a]	1730 − 33	T30.0	

[a] X-ray source discovered before the globular cluster!

The bright x-ray sources

The x-ray luminosities of the bright x-ray sources in globular clusters are between $L_x \simeq 10^{29} - 10^{31}$ W (see table 1). The color temperature of the x-ray spectrum in the 2–10 keV energy range is $kT_c \leq 5$ keV. At these luminosities, the x-ray source must be either a neutron star or a BLACK HOLE, that accretes matter from a companion. Eleven of these twelve cluster sources have shown x-ray bursts. (An x-ray burst is a sudden rise in the x-ray luminosity followed by a more gradual decline (see X-RAY BURSTERS), and is thought to be caused by explosive fusion into carbon of a thin helium layer on the surface of a neutron star, see figure 1.) These eleven sources are accreting neutron stars. The remaining one—in Terzan 6—may be a neutron star as well; if not, it is a black hole.

Some of the bright sources are transients, i.e. bright only occasionally. The source in NGC6440, for example, was detected in December 1971/January 1972 and in August 1998; between these dates its flux level decreased to less than 0.001 of the outburst level.

The first ever measurement of the radius of a neutron star was made from an x-ray burst of the source in the globular cluster Terzan 2 (figure 1). The spectrum can be fitted with a black body of temperature $T_{\rm bb}$; this temperature decreases during the burst. The luminosity of the burst is $L_x = 4\pi R^2 \sigma T_{\rm bb}^4$, where R is the radius of the neutron star. Assuming that the luminosity is emitted isotropically, and that the globular cluster is at a distance D (which can be determined in the optical), we can determine R from the flux f_x measured on Earth via the equation

$$f_x = \left(\frac{L_x}{4\pi D^2}\right) = \left(\frac{R}{D}\right)^2 \sigma T_{\rm bb}^4. \qquad (1)$$

For the burster in Terzan 2, $R \sim 10$ km. The uncertainty in the radius is appreciable, due mainly to deviations of the x-ray spectrum from a black body, and also to uncertainty of the distance to the cluster, and to uncertainty in the absorption by the interstellar medium. Nonetheless, x-ray bursts prove that the x-ray sources are very small, compatible with the theoretically predicted size of a neutron star.

The hypothesis that the neutron star is accreting from a binary companion has been confirmed by the determination of the orbital period for five sources; for three of these sources a counterpart has been identified at optical and ultraviolet wavelengths. Surprisingly, the orbital periods of two sources are the shortest known for x-ray binaries, 685 s in NGC6624 and 1236 s (or 792 s) in NGC6712; in these cases the mass donor must be an undermassive ($M < 0.1 M_\odot$) white dwarf. The 12.4 and 17.1 h orbital periods of the sources in Terzan 6 and NGC7078 (M15) point to a subgiant donor; the (less secure) 5.7 h period in NGC6441 suggests a donor on the main sequence.

The x-ray source in the globular cluster Liller 1 is a recurrent transient, showing outbursts lasting a month at irregular intervals of roughly half a year; when bright,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

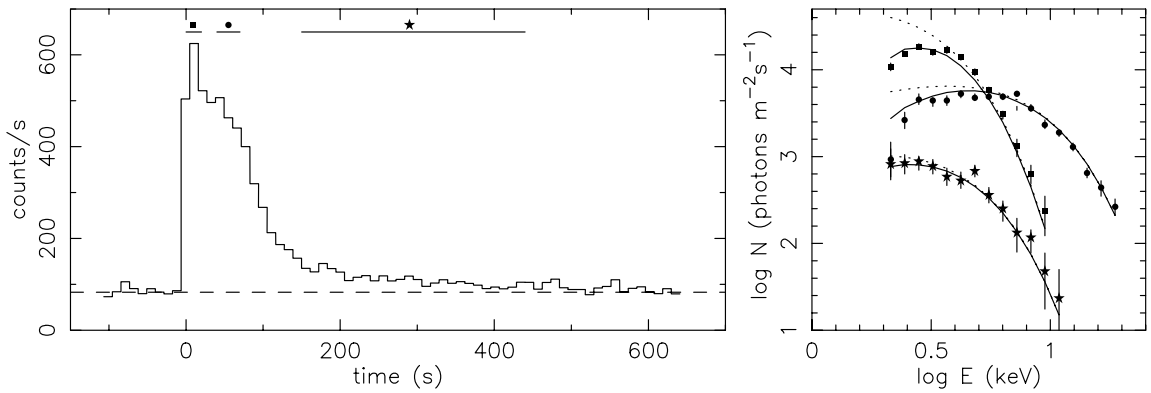

Figure 1. Left: An x-ray burst of the source in the globular cluster Terzan 2, observed with the OSO-8 satellite. Right: spectra of the x-rays at subsequent phases of the burst, with black body fits (full curve: as observed; dotted curve: corrected for interstellar absorption). From the fit of the spectrum 40–70 s into the burst, a radius of ∼10 km is derived for the neutron star.

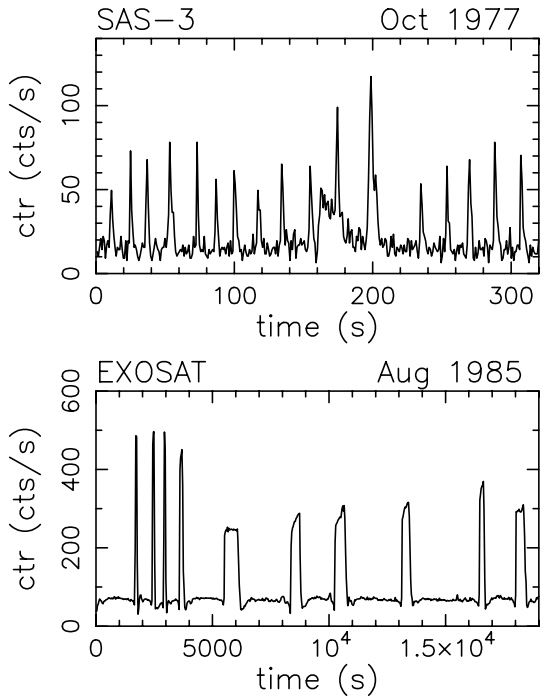

Figure 2. The Rapid Burster in Liller 1 emits its x-rays mainly in discrete bursts. The burst rate was high when the source was discovered in 1977 (top), but rather lower during some later observations (below). A thermonuclear burst starts in the 1977 observation at $t = 160$ s.

this source is remarkable because it emits all its x-rays in discrete bursts (figure 2). When first discovered in 1977 these bursts lasted a few seconds and occurred at a rate of four per minute, and the source was named the Rapid Burster. Later observations have found the source emitting its x-rays in longer bursts (up to $\sim 10^3$ s) at longer intervals (up to about an hour); and occasionally emitting a steady x-ray flux. The nature of these x-ray bursts is not clear; they are different from the thermonuclear bursts observed in many other systems in having a different time scale and in the absence of temperature evolution. Maybe they correspond to discrete accretion events onto the neutron star. The rapid bursts are occasionally interspersed by ordinary, thermonuclear bursts. Thermonuclear bursts are often called type I, and accretion bursts type II.

Some 30 x-ray sources in M31 have been identified with globular clusters of that galaxy. Their x-ray luminosities are comparable with those of low-mass x-ray binaries in (the globular clusters of) our own Galaxy.

The dim sources

At lower flux levels ($f_x \sim 10^{-17}$ W m^{-2}, say) fore- or background sources must be considered; as a result, dim sources can be safely asserted—in a statistical sense—to be related to globular clusters only when they are found in or close to the cluster cores. Currently some 40 of such dim ($L_x \simeq 10^{24} - 10^{28}$ W) sources are known in some 15 clusters, i.e. several clusters contain multiple sources.

The positional accuracies of the x-ray sources hamper identification with optical or ultraviolet counterparts, even if one limits onself to blue or variable objects (figure 3). The situation will improve when observations from the CHANDRA X-RAY OBSERVATORY become available. The only secure counterpart is the recycled pulsar of which the rotation period of 3.054 ms is present in the x-ray flux from NGC6626 (M28). Cataclysmic variables have been found with the Hubble Space Telescope as plausible counterparts for dim x-ray sources in NGC6397, 47 Tuc and NGC6752. In NGC5904 (M5) a dwarf nova discovered well outside the core in optical observations in 1941, has been detected in x-rays. For most dim x-ray sources in globular clusters no optical counterpart has as yet been found.

The x-ray flux of the dim source in NGC5272 varies by at least a factor 30, and is also remarkable because of its very soft spectrum, with a characteristic temperature $\lesssim$50 eV, when the source is bright.

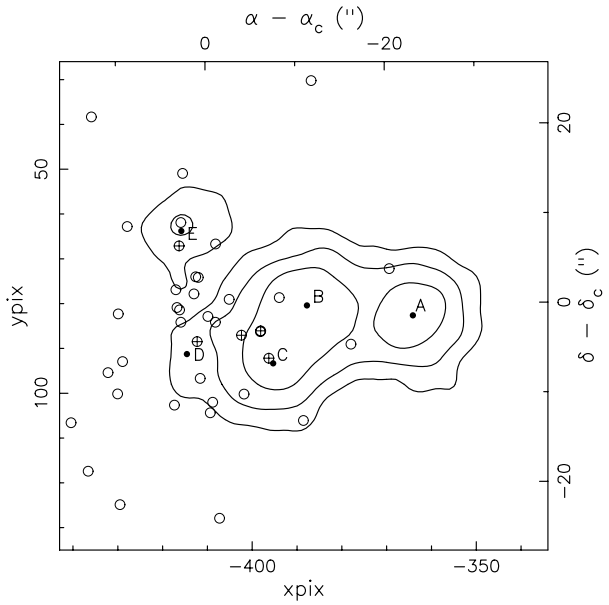

Figure 3. X-ray image of the core of the globular cluster 47 Tuc (contours at 0.4, 0.16 and 0.064 times the maximum level observed, best positions for five x-ray sources A–E indicated with •). Blue and variable stars in the core are indicated with ◦. The limited accuracy of the reconstruction of the satellite pointing leaves an uncertainty of about 2 arcsec between the x-ray coordinate system (lower and left axes, in pixels of the ROSAT HRI detector) and optical coordinates (upper and right axes, with respect to the center of 47 Tuc). Of the suggested counterparts (indicated with ⊕) two, both cataclysmic variables, are good candidates for x-ray sources C and D.

The detection of dim sources in globular clusters is subject to strong selection effects: they can be found only in relatively nearby clusters, which are not highly reddened. Taking these effects into account, one finds that the number of x-ray sources $\mathrm{d}N$ in a luminosity interval $\mathrm{d}L_x$ depends on the luminosity L_x and on the number density n of stars in the cluster core as $\mathrm{d}N \propto n^{1.5} {L_x}^{-1.5}\,\mathrm{d}L_x$. This scaling is in agreement with the observation that the total x-ray luminosity of a globular cluster is dominated by individual sources.

Theory of formation mechanisms

The fraction of neutron stars or WHITE DWARFS expected to have experienced a close stellar encounter can be several per cent in a globular cluster with a dense core. In the disk of the Galaxy—where close stellar encounters don't occur, and where binaries evolve unperturbed by third bodies—only a tiny fraction of neutron stars is found in a binary. A neutron star binary in a globular cluster is therefore much more likely to be the result of a close stellar encounter than of the unperturbed evolution of a primordial binary in the cluster. The fraction of white dwarfs in a binary in the disk of the Galaxy is much higher: a white dwarf in a binary in a cluster can therefore be the result either of a close stellar encounter or of ordinary binary evolution.

The basic principle of tidal capture of a neutron star can be understood with a simple calculation: consider a neutron star with mass m and velocity v at large distance ('infinity') relative to a main-sequence star with mass M and radius R. The relative kinetic energy E_k of the two stars is given by

$$E_\mathrm{k} = \frac{1}{2}\frac{mM}{m+M}v^2. \tag{2}$$

As the neutron star closes in, it deforms the other star. The height h of the bulge, and its mass m_t can be estimated for distance d with

$$h \simeq \frac{m}{M}\frac{R^4}{d^3};\; m_t \simeq k\frac{h}{R}M \simeq k\left(\frac{R}{d}\right)^3 m \tag{3}$$

where k is the apsidal motion constant, which depends on the central condensation of the star, and indicates how easy it is to deform the star. For a star with a deep convective envelope $k \simeq 0.14$. Thus the energy E_t in the tidal deformation is of order

$$E_t \simeq m_t\frac{GM}{R^2}h \simeq k\frac{Gm^2}{R}\left(\frac{R}{d}\right)^6. \tag{4}$$

If $E_t > E_\mathrm{k}$, the two stars cannot escape from one another anymore, and a binary is formed. This condition can be written:

$$d \lesssim 3R\left(\frac{m}{M}\frac{m+M}{2M_\odot}\frac{R_\odot}{R}\right)^{1/6}\left(\frac{10\ \mathrm{km\ s^{-1}}}{v}\right)^{1/3}. \tag{5}$$

Because of the strong dependence of E_t on d, this rough estimate is in fact pretty accurate, as more detailed calculations confirm.

The initial binary orbit is highly eccentric, $e \lesssim 1$, with a velocity at PERIASTRON close to the escape velocity. Tidal forces are expected to circularize the orbit, during which process angular momentum is conserved. The semimajor axis a_c of the circularized orbit is given by

$$a_c \leq 2d \ll a_e \tag{6}$$

where a_e is the semimajor axis immediately after capture. Thus the final orbit after circularization can have a semimajor axis of up to twice the capture distance.

The energy difference ΔE between the initial, highly eccentric, and the final circularized orbit is comparable to the binding energy E_* of the main-sequence star.

$$\frac{\Delta E}{E_*} = \left(\frac{-GMm}{2a_e} - \frac{-GMm}{2a_c}\right)\left(\frac{3GM^2}{5R}\right)^{-1} \simeq \frac{5}{6}\frac{m}{M}\frac{R}{a_c}. \tag{7}$$

The circularization process provides enough energy to destroy the main-sequence star. If the energy has to be dissipated very rapidly, it is hard to avoid destruction of

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the donor. It has been suggested, however, that the energy present in the tidally induced oscillations of the star can be fed back into the orbit; in a very eccentric orbit, the energy exchange between (oscillations in) the star and the orbit is chaotic. This would mean that the star has much more time to dissipate, and thus has a much better chance of surviving.

The cross section σ for closest passage within distance d follows from conservation of energy and angular momentum in a Keplerian orbit:

$$\sigma = \pi d^2 \left(1 + \frac{2G(m+M)}{v^2 d}\right) \simeq \pi d \, \frac{2G(m+M)}{v^2}. \quad (8)$$

The second term within brackets gives the effects of gravitational focusing. This term dominates for the small relative velocities between stars in globular clusters, which justifies the subsequent approximation.

With number densities n_c and n for the neutron and target stars respectively, the capture rate of neutron stars per unit volume can be written:

$$\Gamma = n_c n v \sigma. \quad (9)$$

To obtain the formation rate in a cluster, one must integrate equation (9) over the cluster volume. Because the density is strongly peaked near the cluster center, virtually all close encounters occur in the cluster core. In a relatively dense core of a globular cluster, $n_c \sim 100$ pc^{-3} and $n \sim 10^5$ pc^{-3}. With a characteristic core volume of $\sim$1 pc^3 and stellar velocities of $\sim$10 km s^{-1} it follows from that a close binary with a neutron star is formed every 10^9 yr. For an average lifetime of a bright source of 10^9 yr, we then expect to see of order 1 x-ray source in such a cluster, in accordance with observations.

If a neutron star directly hits a giant, then the core of the giant and the neutron star may spiral in towards one another, leaving a close binary of an undermassive white dwarf and a neutron star. Such an encounter may explain the x-ray sources in NGC6624 and NGC6712.

Another way of getting a neutron star in a binary is an exchange collision: when a neutron star approaches a binary to a distance comparable with the semimajor axis of the binary, the three stars may temporarily move in complicated orbits around one another. Such a three-body system is not stable, and one star is ejected at the end, usually the lightest star. In this way, a neutron star may take the place of an ordinary star in a binary. The frequency of such encounters is proportional to the number density of binaries $n_{\rm bin}$ in the cluster core, and to the semimajor axes a of these binaries. The capture rate Γ_3 from these three-body processes may be compared with tidal capture, roughly according to:

$$\frac{\Gamma_3}{\Gamma} \simeq \frac{n_{\rm bin}}{n} \frac{a}{R} \quad (10)$$

when all three stars have equal mass. Thus the smaller number of binaries is offset by their larger size, as compared to single stars. The actual importance of exchange encounters is not clear, because the number of binaries in cluster cores is not known.

The formation of a close neutron-star binary in a globular cluster may also arise from a tidal capture between stars involved in a three-body encounter. Two-body or three-body encounters can also cause direct collisions between stars, a process which may be important for the formation of single recycled pulsars in globular clusters.

Globular Clusters

Globular clusters (GCs) are aggregates of approximately 10^4–10^6 gravitationally bound stars, highly concentrated to the center, spread over a volume ranging from a few dozen up to more than 300 light-years (ly) in diameter. They resemble shining, old islands orbiting the Milky Way. As the name indicates, GCs show a largely spherical symmetry about their centers. A picture of the classic GC ω Centauri is shown in figure 1.

The stellar density in the cluster's center is so high (up to a few 10^3 stars ly^{-3}) that it is generally impossible to separate the individual stars from ground-based observations. Only recently has the refurbished Hubble Space Telescope (HST) allowed astronomers to dig into the very central regions of many Galactic globulars, where members (sometimes peculiar or even exotic) move randomly like molecules of gas, interacting according to the basic laws of gravity.

Early studies of GCs date back to the birth of modern astronomy. Since then, GCs have continued to offer excitement to both professional astronomers and sky-lovers with surprising results, and they constitute a basic benchmark for our astrophysical understanding.

The Milky Way hosts about 200 GCs. They form a halo of roughly spherical shape which is highly concentrated around the Galactic center, in the Sagittarius–Scorpius–Ophiuchus region. The most distant Galactic globulars (such as NGC 2419) are located far beyond the edge of the Galactic disk, at distances out to 300 000 ly.

RADIAL VELOCITY measurements have shown that most of the GCs are orbiting the Galaxy in highly eccentric elliptical orbits (see figure 2), with orbital periods of about 10^8 yr or even longer.

While following their orbits around the Galactic center, GCs are subject to a variety of perturbations (tidal forces from the parent galaxy, passage through the Galactic plane, star escape, internal dynamical evolution, etc) which make the existing GCs perhaps just the survivors of a much wider population, partially disrupted and spread out throughout the Galactic halo and far beyond. In this respect, it has been estimated that, within the next ten billion years or so, most of the present Galactic GCs could disappear. On the other hand, we know today that four clusters in Sagittarius (M54 in particular) are likely members of the Sagittarius Dwarf Elliptical Galaxy (discovered in 1994), currently merging into the central regions of the Milky Way.

A large majority of the galactic GCs have high relative velocities (100–300 km s^{-1}) with respect to the Sun, as they do not participate in the Galactic disk rotation. There is, however, a subsample, commonly referred to as 'disk globulars', which show properties closely connected to the disk.

Spectroscopic observations of stars in Galactic GCs have revealed that their chemical composition differs from that of the Sun in heavy elements content. GC stars are in fact typically metal poor and old. This is a signature that they were presumably born during the early stages of the Galaxy's formation and thus represent a sort of archeo-astronomical site where the universe in its youth can be studied.

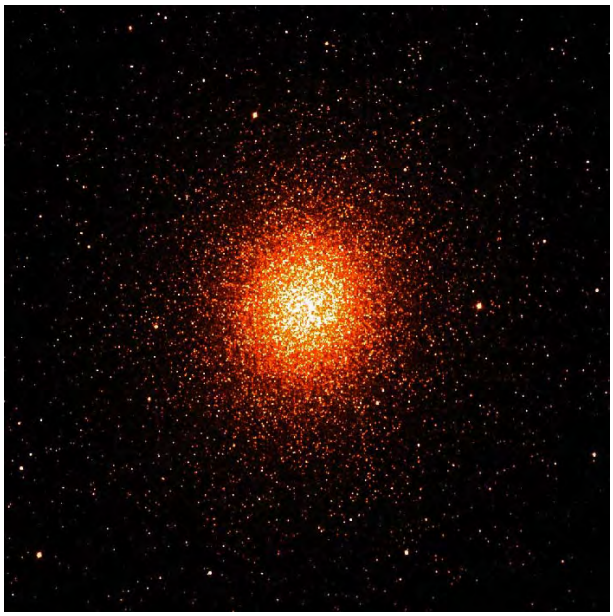

Figure 1. The GC ω Centauri.

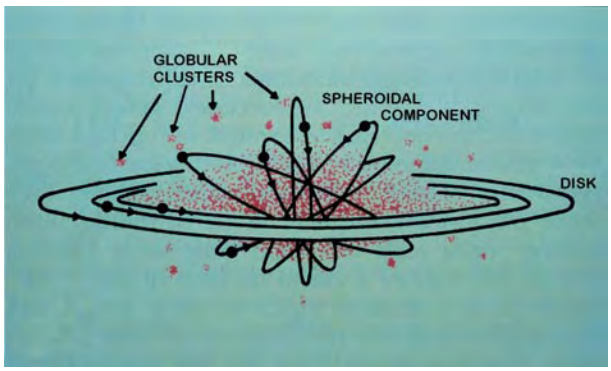

Figure 2. Orbits of GCs in the Galaxy.

Globular clusters seem to be ubiquitous. Edwin Hubble pionereed the search for globulars in the galaxies of the LOCAL GROUP with the detection of about 100 GCs in M31, the Andromeda Nebula (more than 350 GCs are known nowadays). However, it was only in the 1970s that the identification of any significant number of GC candidates became feasible around galaxies beyond the Local Group. The main reason for this difficulty in the search is that, with increasing distance, a typical cluster becomes progressively indistinguishable in shape from foreground stars or distant background galaxies.

It is now fairly well established that almost all galaxies have GC systems, in some cases (e.g. M87) containing several thousands of globulars (see GLOBULAR

CLUSTER SYSTEMS IN NORMAL GALAXIES). There are, however, important differences. While all the globulars in our Galaxy and in M31 are old (ages of about 10 Gyr, at least), there are galaxies, such as the two Magellanic Clouds and M33 (the Triangulum Galaxy), hosting much younger GCs (ages of a few Gyr, or less).

The latest GC searches also reveal that dense, massive star clusters seem to be currently forming in the halos of some interacting galaxies (see GLOBULAR CLUSTER SYSTEMS IN INTERACTING GALAXIES). These objects are commonly interpreted as young and metal-rich GCs. This idea is not universally accepted, however. In fact, observational evidence, still quite meager, needs to be confirmed. Furthermore, astronomers seem somehow reluctant to change their traditional view of the GCs and to admit that massive, young and metal-rich GCs could possibly be even more frequent in the universe than the 'classic', ancient and very metal-poor ones.

Historical background

Perhaps the first historical detection of a globular cluster goes back to the mists of time, when human eyes first saw ω Centauri, the biggest Galactic GC, barely visible in the southern hemisphere.

The first 'astronomical' detection dates back to the 18th century. John Herschel, in the 1830s, realized that a large number of these clusters are concentrated in a relatively small portion of the sky in the direction of Sagittarius. Later on, HARLOW SHAPLEY detected variable stars in several GCs and, on the assumption they were Cepheids of known (calibrated) absolute magnitude, derived distances to them and to the Galactic center. Doing this, in 1917, Shapley understood that the Galactic center is located very far away from the Sun, in the direction of Sagittarius, and was also able to estimate the size of the Milky Way.

Today we know that Shapley significantly overestimated (by a factor of 2 or so) the size of the GCs system and of the Milky Way as a whole, mainly because the cluster variables he identified as Cepheids are actually RR Lyraes, whose absolute magnitude is about 2–4 mag fainter than Cepheids.

A key role in astronomy

Individual clusters as well as GC systems are of great worth as specific targets but also represent a powerful tool to obtain a deep insight into a large variety of astrophysical and cosmological problems (see table 1). Their study still represents a benchmark and a major field of interest in the international astronomical community.

Members of any given GC share a common history and differ one from another only in their initial mass. Consisting of a 'simple' STELLAR POPULATION (i.e. coeval, chemically homogeneous and isolated), GCs are ideal laboratories for testing the theories of stellar structure and evolution. In fact, thanks to the very large number of stars, almost every evolutionary stage (even those with very short lifetimes, down to a few 10^4 yr) is present at the appropriate statistical significance among the GC stars. This allows a direct check on the validity of the detailed evolution theory. When GCs are considered just as a million or so pointlike masses in a small volume, subject to internal and external dynamical interactions, they represent an ideal workbench to study STELLAR DYNAMICS and to test most exquisite theoretical dynamical models.

If studied as a global system, GCs constitute fossil tracers of the dynamical and chemical evolution of the parent galaxy and can be used as test particles to evaluate both the galaxy's total mass and its radial distribution.

GCs contain a variety of exciting objects by themselves worth a continuous investigation, for instance strong and weak x-ray sources, neutron stars and millisecond pulsars, white dwarfs, cataclysmic variables, binaries, blue stragglers, planetary nebulae, etc. Moreover, they contain one of the most popular intrinsic variable stars, the so-called RR LYRAE STARS. These stars have light variation amplitudes less than a couple of magnitudes and periods ranging from 0.2 to 1.1 days. Since their mean absolute magnitude is constant and fairly independent of metallicity (to within 0.3 mag), the RR Lyrae variables and the GCs, in turn, are ideal standard candles to measure distances.

Perhaps one of the most remarkable impacts of GC reasearch on other fields of astronomy is provided by the estimate of the ages of the Milky Way's globulars. GCs are, in fact, among the few objects in the Galaxy for which relatively precise ages can be derived. Since they are the oldest objects observed in the Milky Way so far, and were born during the very early stages of the Galaxy's formation, they provide a very stringent lower limit to the age of the universe. On the other hand, their age distribution and how ages vary with varying metallicity, spatial location in the Galaxy and kinematic properties make these systems direct tracers of the chronology of the first epoch of star formation in the Galactic halo and may help in understanding the whole process of galaxy formation.

Color–magnitude and Hertzsprung–Russell diagrams, and stellar evolution

The color–magnitude diagram (CMD) as well as its twin, the HERTZPRUNG–RUSSELL DIAGRAM (H–R diagram), substantially plot the temperature of a star on the X-axis, with increasing temperature to the left, and the star brightness on the Y-axis, with brighter stars at the top. Traditionally, the observational CMD reports on the X-axis the color of the stars (generally $B–V$) and on the Y-axis the observed apparent magnitude (generally V) or, if distance is known, the absolute magnitude (M_V).

The CMD is a basic, very powerful tool which allows a direct calibration of the observables in terms of fundamental intrinsic parameters (e.g. metallicity, age) as well as stringent comparisons to be made with theoretical model predictions (after 'tricky' transformations from the theoretical into the observational plane).

Figure 3(*a*) shows the observed CMD of the GC M3, and figure 3(*b*) displays the schematic CMD of a typical GC.

Table 1. Importance of GCs.

Subject	Reasons for importance
Witnesses of the early Galactic evolution	• First to form • Chemically uncontaminated
Stellar Evolution Laboratories	• Simple stellar populations • Test of the 'stellar clock'
Distance indicators	• Standard candles: the RR Lyrae stars • GC system integrated luminosity function
Age indicators	• The turn-off luminosity = 'the clock' absolute ages: lower limit to the age of the universe relative ages: 'second parameter' and Galaxy formation and evolution
Dynamics probes	• Dense environment core collapse evaporation collisions merging–surviving segregation • Test particle of the galactic gravitational field
Containers of peculiar objects	• X sources (strong–weak–diffuse) • Blue stragglers • Binaries • Planetary nebulae • White dwarfs • Cataclysmic variables • Millisecond pulsars • Neutron stars

Labels indicate the main branches of the diagram. The modern STELLAR EVOLUTION theory is able to predict quite precisely the physical processes undergone by stars which evolve along the CMD, and the whole evolutionary path of a Population II star is nicely described from the early to the final stages. Each specific evolutionary phase is labeled in figure 3(*b*), along with the corresponding basic nuclear burnings. A brief description of these main evolutionary stages is presented below.

The evolutionary tracks drawn in the CMD by GC stars of given initial mass (below $1M_{\odot}$, actually $\sim 0.8M_{\odot}$) and chemical composition closely resemble the observed main ridge lines shown in figure 3(*b*). However, there is a fundamental difference. Each point of the evolutionary track is the locus reached by the same star at different ages during its evolution; conversely, each point on the observed CMD does indeed correspond to the locus of stars with same age and chemical composition, but different masses.

Given a collection of stars having the same chemical composition but different masses, each star will evolve along its evolutionary track, at its own evolutionary rate (depending on the star's mass). It will thus be possible to define loci of constant time along the various evolutionary tracks, which will yield constant-age sequences. These sequences are generally referred to as 'isochrones'. The isochrones thus represent the loci of stars with the same age and chemical composition, but with different masses. Since members of a GC can be thought of as being born from the same cloud at the same time, but with different masses, the comparison of theoretical isochrones (transformed into the observational plane) with the observed CMD is the key procedure to obtain information on the evolutionary status of GC stars.

The main sequence and the turn-off

After a free-fall phase, the gravitational contraction leads the proto-star to increase its central temperature until the ignition of the first nuclear reactions in the stellar core takes place. The nuclear energy production slows down and eventually stops the contraction. The star reaches a nice equilibrium, balancing energy production and transfer and global brightness, and enters into the main sequence (MS). This equilibrium holds on the MS for more than 70% of the total stellar lifetime ($\sim 10^{10}$ yr), until the nuclear fuel (hydrogen, i.e. 1 proton) in the very central core is completely burnt out. It should be recalled that there is a theoretical lower limit to the stellar mass ($\sim 0.08M_{\odot}$) below which H burning does not take place in the stellar core. Stars smaller than this threshold are usually called very low-mass (VLM) stars and brown dwarfs (BDs), and for masses far below this limit ($\sim 0.001M_{\odot}$) one has the giant planets.

Stars spend most of their lifetime quietly burning hydrogen in their core via nuclear fusion. Our Sun is still on the MS. As hydrogen gradually runs out in the center, a nucleus of helium (produced by the fusion of four protons) grows up, and the star core begins to contract owing to gravity, while the outer layers progressively expand and cool down. The star leaves the MS.

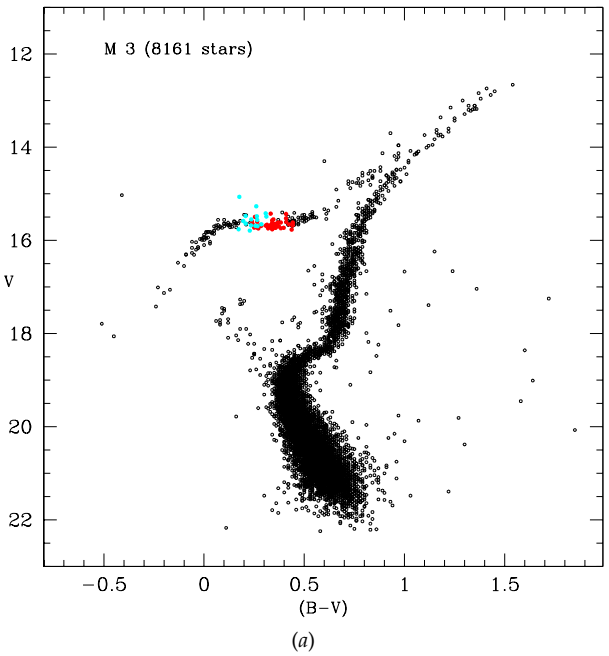

Figure 3. (*a*) Color–magnitude diagram of the globular cluster M3 and (*b*) schematic color–magnitude diagram of a typical globular cluster.

The central H exhaustion corresponds quite precisely to the bluest and hottest point on the MS, usually called the turn-off (TO) point. The precise location of the TO depends on the stellar initial mass, and theoretical models show that both luminosity and temperature of the TO increase with increasing stellar mass. Since, in turn, the initial mass depends on the age (stars burn out central H more and more slowly with decreasing mass), the TO is actually the 'stellar clock'. Turning to the isochrones, since less massive stars are still in the MS phase, while more massive ones are in more advanced evolutionary stages, the upper MS becomes more and more depleted with increasing age, while the TO becomes fainter and cooler. A straightforward relation can thus be derived between luminosity of the TO point and age. This relation provides a unique, powerful tool for determining the age of the GCs.

It should be pointed out that (a) the engine of the 'stellar clock' relies on theoretical models and (b) any method for dating stellar populations is finally founded on this 'stellar clock'. Were our understanding and running of this 'clock' incorrect, our description of the universe, as derived from the stars, would be in error. It should also be recalled that recent model calculations based on improved equation of state and radiative opacity, as well as the inclusion of element diffusion, have significant effects on both the luminosity of the TO, which is increased, and the MS lifetime, which is decreased with respect to previous 'classic' models.

Finally, the sharp MS TO observed in most clusters indicates that stars within individual GCs all formed roughly at the same time. The narrowness of the MS indicates that stars in a given GC all have very similar chemical composition, and also it constrains the fraction of binary stars within GCs. Unresolved binaries are in fact expected to produce a population just above the MS since the combined luminosity of the two stars exceeds that of a single star at the same color (see BINARY STARS IN GLOBULAR CLUSTERS).

The red giant branch

When the central fuel is exhausted, hydrogen starts burning in a thick shell which surrounds the growing helium core. A complex balancing between energy production and transfer, substantially driven by opacity, takes place. Core contraction and heating is accompanied by a progressive expansion of the outer envelope. The star cools down and brightens, owing to the larger and larger increase of the total radius, climbing along the red giant branch (RGB).

During this phase the deepening of the surface convection may reach the internal He-enriched zone and bring some extra helium to the stellar surface. All canonical computations confirm that, because of convective mixing phenomena (dredge-up) during the RGB phase, the surface He abundance exceeds the original He abundance. This increase of the He abundance may have important consequences in the subsequent evolutionary stages.

The comparison of the giant branches of different clusters has revealed that GCs of higher metallicity exhibit giant branches that are shallower and redder than those of low-metallicity clusters. The detailed astrophysics of the stars on the RGB is very complex, and the exact location of the RGB is dependent on details of the convective

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

processes within such stars commonly treated using the so-called mixing length (l) theory.

At the tip of the RGB the temperature in the He-rich core has grown up enough (10^8 K) to ignite the central He burning, via the 3α reaction ($1\alpha = 1$ He nucleus $= 2$ protons + 2 neutrons). Contrary to most of the other evolutionary stages, this ignition occurs on a very short time-scale (a few years or even less), and it is thus often referred to as the 'He flash'.

The horizontal branch

After the He flash, the star quickly rearranges its structure and starts a quiescent He core burning phase, which will last for about 10^8 yr or so. In the CMD, the star jumps on the horizontal branch (HB) where the helium in the core is converted into carbon (C) and oxygen (O). Slightly afterwards, H burning re-ignites in a shell immediately outside the He core. The relative balancing between central He burning and H shell burning has important effects on both HB lifetime and star behavior.

The precise location in luminosity and temperature of a star which arrives on the so-called zero-age HB (ZAHB) is driven by (at least) three parameters: the chemical composition of the envelope, the size of the He core mass at the He flash and the mass of the envelope (which was generally affected by mass loss during the previous RGB phase).

At given metal abundance—the so-called 'first parameter'—and helium content, the ZAHB becomes bluer and bluer (i.e. hotter and hotter) with decreasing stellar envelope mass. In turn, the position taken on the ZAHB by a given GC star will depend on the amount of mass lost during the RGB phase; the larger the mass lost, the bluer the ZAHB location.

Given the absence of quantitative observational estimates and with the persistent lack of any reliable theory about mechanisms driving the mass loss, it is difficult to evaluate the amount of envelope actually lost by stars evolving along the RGB. To reproduce the observed HB morphologies (i.e. the color distribution of HB stars), it has become common procedure (a) to introduce a free parameter, which accounts for the whole mass loss process, and (b) to adopt an arbitrary dispersion in the total mass lost by individual stars. In fact, if no mass loss (or the same amount of mass loss) is assumed for stars of equal initial mass, the whole HB would collapse to a single clump, contrary to any observational evidence. Indeed, in order to reconcile theoretical He burning models with the color distribution of their observational counterparts, i.e. the HB stars in GCs, it seems conceivable that during the RGB phase stars lose up to $0.2 M_{\odot}$ of their envelopes. However, mass loss affects only the very external layers of an RGB star, without altering the physical conditions in the core, where nuclear energy generation takes place.

Theoretical models show that both the ZAHB luminosity and the temperature location of the star on the ZAHB increase with increasing helium abundance Y, while both quantities decrease with increasing metal content Z. On the other hand, since with increasing age the initial mass decreases, at fixed total mass loss the HB distribution will become bluer and bluer with aging GCs. This property has a very deep impact on the description of formation and evolution of the Galaxy as in many studies the HB morphology is actually adopted as a 'secondary clock' (see below) for dating the GCs.

HB stars of appropriate mass may fall inside the so-called 'instability strip', also known as the 'RR Lyrae gap'. The envelopes of stars living inside or simply passing through this narrow region of the CMD (see figure 3(*b*)) become unstable for radial pulsation. The HB star thus becomes a variable of RR Lyrae type, so named from the historical prototype of this class of variables. The frequency of such stars in GCs is so high that the presence of RR Lyrae variables within the 'instability strip' of the HB is a well-defining feature of the population II stars. According to the periods of their RR Lyraes, Galactic globulars can be separated into two distinct subsets, the two Oosterhoff groups. It has been shown that the Oosterhoff separation, often referred to as the 'Oosterhoff effect', reflects a difference in the metal abundance of the host clusters, with variables in metal-poor clusters having longer mean periods than those in the metal-rich ones.

Since the HB is a bright and 'horizontal' feature of the CMD (hence, all its members have a very similar absolute magnitude), and since HB stars spend most of their HB lifetime at luminosities very close (0.1–0.2 mag) to their ZAHB luminosities, they are 'standard candles' to measure distances. RR Lyrae variables, in particular, are among the most used 'classic' standard candles of population II stellar systems. (See also HORIZONTAL-BRANCH STARS.)

The asymptotic giant branch and the white dwarfs

Eventually, when helium also vanishes in the central regions of the He core, the core contracts and He burning starts in a shell around it. The stellar structure, characterized at this stage by a carbon–oxygen core surrounded by a first He burning shell and by a second, more external, H burning shell, evolves upward in the CMD, asymptotically merging into the RGB during the asymptotic giant branch (AGB) phase.

Most AGB stars exhibit significant mass loss in the form of stellar winds, exactly in the same vein as shown while evolving along the brightest part of the RGB. Other peculiarities include He shell flashes, believed to be a consequence of the He burning shell being spatially thin, which can cause the star to migrate briefly to the instability strip and to mix burnt material into the outer layers. This results in significant peculiarities in the abundance of some chemical elements, whose detection and measurement offer important tests of the global evolutionary theory, including mass loss.

The normal AGB stage culminates, after the onset of thermal pulses and a phase of rapid mass loss or 'superwind', with the star blowing off its outer layers until all that is left is a central hot WHITE DWARF (WD) in the middle of a PLANETARY NEBULA.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

Eventually, the white dwarf becomes faint and cools down, ending its evolution along the WD cooling line, a sequence almost parallel but about 4 mag fainter than the MS.

Blue stragglers

Discovered first in M3 more than 40 yr ago by Allan Sandage, and until recently just peculiar objects detected in only one or two clusters, a large number of BLUE STRAGGLERS (BSs) are being discovered nowadays by the HST observations of the central regions of almost any GC. Although all stars above a certain mass and luminosity in a given cluster are expected to have evolved off the MS, yet the BSs seem to sit nodding on the bright extension of the MS (see figure 3(*b*)), as if they were loitering on their evolutionary path compared with the other members of the cluster. Since BSs always seem to be more centrally concentrated than all other visible stars in a given cluster, their masses are expected to be significantly higher than either RGB or normal MS stars, and this would explain their brighter location along the extension of the MS. Since they are still not evolved, although more massive than the TO stars, one has to explain their origin, which is commonly associated with binaries. BSs could originate from collisions of individual stars in the very crowded central regions of the cluster or could be the merger product of primordial binaries. Some BSs have actually been found to be members of eclipsing binary systems.

Chemical composition

Galactic GCs are old, metal-poor population II stellar objects with metal abundances usually in the range -0.7 dex $<$ [Fe/H] $<$ -2.5 dex (where [Fe/H] $= \log(N_{\rm Fe}/N_{\rm H}) - \log(N_{\rm Fe}/N_{\rm H})_{\odot}$ and N is the number of atoms of the given element; our Sun has thus [Fe/H] $=$ 0.0). Although clusters almost as metal rich as the Sun (and perhaps even more) have been recently discovered near the Galactic center, the bulk of the GC population has metallicities around [Fe/H] $= -1.3$. The average metallicity of the GC system generally correlates with the total mass of the host galaxy; the bigger the galaxy, the richer the average GC.

A commonly accepted basic property of the stars in a given GC is that they all have about same age and chemical composition (at least primordial).

While no indication has ever been put forward for any age variation among stars of a single cluster, there is now gathering observational evidence that small differences in chemical composition are perhaps present. It is still a matter of debate whether they are primordial or due to evolution.

Besides the use of spectroscopic observations at intermediate and high resolution, direct information on the chemical properties of a given cluster can also be derived from its CMD. In fact, the location and intrinsic width of the main branches in the CMD both depend on chemical abundance. In particular, as a general rule, an increase in the helium fraction leads to bluer colors, while an increase of the metal content leads to redder colors. Moreover, any significant abundance spread yields a spread-out of the stars along the various branches with respect to the mean ridge line, which is different from one branch to another and increases with increasing abundance variation.

The observed color dispersion of the MS in the best-studied clusters implies upper limits to star-to-star variations in helium abundance of 0.03 dex (if dispersion is attributed to He variations only, but differential reddening, metallicity spreads, blending and intrinsic binarity may also contribute). This figure compares with an overall helium abundance of about 0.23–0.25 (mass fraction).

Similar reasoning can be applied to the giant branch. Here, since elements with low ionization potential such as Fe, Si and Mg significantly affect the opacity in the stellar envelopes, star-to-star variations would result in a color dispersion of the giants. Observations show that, with the exception of ω Cen which clearly displays a wide giant branch, compatible with abundance variations up to a factor of 10 at least, the vast majority of the Galactic GCs have quite narrow giant branches and, in turn, small intrinsic variations in the abundance of iron-peak elements.

Spectroscopy of giants is potentially a more powerful technique to detect metallicity variations. However, such observations require high resolution and are highly time consuming on large telescopes. The still poor samples already available actually confirm the general indications of the CMDs. Only ω Cen (the biggest and most elliptical Galactic GC) and perhaps M22 show a dispersion in [Fe/H].

One reason why metal homogeneity within GCs is so remarkable is that galaxies, including dwarf spheroidals of integrated luminosities comparable with GCs, all show quite wide dispersions in chemical abundances, suggesting that star formation probably occurred in a different way and that self-enrichment was at work much more efficiently.

Despite the homegeneity in [Fe/H] within stars of individual clusters, there are significant star-to-star variations in the abundances of other heavy elements. The best famous are the CN variations, known among GC stars for many years. The central question is whether these variations are primordial star-to-star differences built in when GCs formed or whether they result from stellar evolutionary processes.

Stellar evolution is expected to produce some abundance variations among stars at different evolutionary phases. If the convective envelope of an RGB star reaches sufficiently deep inside the star, it mixes material which underwent CNO processing up to the surface of the giant. This theoretical prediction is now supported by many observational results, although observational evidence would require more mixing than currently predicted by theory.

Other elements also exhibit abundance variations in the GCs. The [O/Fe] ratio in cluster giants sometimes

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

shows considerable depletion compared with halo field stars, which are enhanced by a factor of several relative to the solar abundance. However, it is still not clear whether there is a real systematic ehnancement of [O/Fe] in GCs with respect to the solar fraction, and, if any, how it varies with varying total metal abundance. At present, metal-poor clusters with [Fe/H] $= -2.0$ dex seem to have approximately [O/Fe] $= +0.3$ dex, while this figure perhaps decreases to about 0 at [Fe/H] $= -0.7$ dex.

Finally, it should be mentioned that Al, Na and Mg show variations which seem to be hardly compatible with just evolutionary processes. In particular, Al and Na tend to be overabundant in GCs, show wide variations and are correlated with each other and anti-correlated with [O/Fe]. If these Al and Na variations are primordial, their anticorrelation with [O/Fe] suggests that CNO variations are also primordial, and this may have a deep impact on the description and understanding of star and cluster formation.

The horizontal branch morphology and the 'second parameter' problem

The color (temperature) distribution of the cluster stars along the HB is often referred to as the 'HB morphology' of the cluster. The number of stars within (V) and on both red (R) and blue (B) sides of the 'RR Lyrae gap' describes the overall HB morphology of a given cluster through the parameter

$$C = \frac{B - R}{B + V + R}.$$

Observations show that Galactic GCs exhibit a fairly broad variety of HB morphologies, with the C parameter ranging from -1.0, for clusters where only the red portion of the HB is populated, to $+1.0$, for clusters with stars only to the blue of the instability strip.

Since the color (temperature) of HB stars depends primarily on the stellar metal content—HB stars in metal-rich clusters are redder than those in metal-poor clusters as a result of the higher opacity in their envelopes and of higher initial masses (at fixed age)—metallicity is commonly considered the 'first parameter' driving the HB morphology.

However, metallicity variations alone cannot account for the extension in effective temperature and for the differences observed between HBs. In fact, were the HB morphology strictly driven just by metallicity, both the high chemical homegeneity among cluster members and the fine tuning of the TO masses would lead to a highly peaked clump of HB stars. The common evidence that most of the observed HBs display a wide coverage in color (only very metal-rich clusters show in fact a red stubby HB) suggests that mass loss affects in rather different ways GC stars of identical initial mass, no matter whatever mechanism(s) drives it.

On the other hand, although the HB morphology–metallicity correlation accounts for a large part of the observed HBs and most clusters exhibit a 'blueing' of their HBs with decreasing metal abundance, several other clusters do not obey this general rule. This is the essence of the long-standing historical 'second parameter problem': another parameter besides metallicity must be at work on the HB of the GCs.

Age, helium abundance and metal abundance ratios are the 'classical' second parameter candidates most often invoked to explain the observed HB morphologies.

Age has long been claimed to be the second parameter, but with no unanimous consensus among the astronomical community as not all second parameter clusters seem to be explicable in terms of age variations. Theoretical calculation shows that the average mass of a stars evolving onto the HB decreases with increasing cluster age. Since the He core mass is roughly constant for ages older than $\sim$10 Gyr, the mass of the envelope decreases with age. Hence, at fixed metallicity, older cluster ages would imply less massive HB stars, with increasingly thin evelopes and, in turn, bluer HBs. If age is the second parameter, the HB morphology could be used as a 'secondary clock', besides the TO luminosity, to test the existence of possible age gradients with varying distance from the Galactic center and the metallicity. This approach has been widely used in recent years to show that the GC system in the Milky Way is perhaps formed by different subgroups: (a) the halo GCs, possibly further subdivided into young and old, metal poor and spherically distributed throughout the wide halo; (b) the disk GCs, of intermediate metallicity, somehow kinematically related to the disk; (c) the bulge GCs, in general fairly metal rich (almost solar) and preferentially located in the central regions of the Galaxy; (d) the (possibly) captured GCs, originally members of disrupted or tidally interacting satellites of the Milky Way.

Variations in the helium content, with increasing helium abundance producing bluer HBs, could possibly explain some of the observed HB morphologies. On the other hand, also a variation in the CNO abundance (at fixed [Fe/H] content) would affect the HB morphology, with increasing CNO abundance yielding redder HBs, since elements of the CNO group directly control the opacity and energy generation within HB stars.

Also many other physical phenomena could affect the HB star properties. For instance, the stellar core rotation, if increased, would probably lead the star (a) to have a higher He core mass, consequently (b) to climb up brighter portions of the RGB and (c) if mass loss increases with increasing luminosity, as it appears to, to suffer in turn a larger mass loss, yielding bluer HBs.

Environmental conditions have also been shown to have some impact on the evolution of GC stellar populations. In particular, there are observational indications suggesting that higher cluster densities and concentrations would favor bluer HBs since stellar mass loss could be enhanced, because of the increased stellar interactions.

In conclusion, there is growing observational evidence that just a single 'second parameter' may be insufficient to explain the observed HBs and that a comprehensive understanding of the full range of the observed HB

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

morphologies may require a 'third parameter', at least, although age is perhaps a dominant parameter in most GCs.

In this respect, a distinction could be made between a 'global' second parameter ruling the HB morphology and second parameters most likely determining the HB morphology of individual clusters. The former deals with the Milky Way globulars as a system and aims at describing the 'global' properties of the HB morphology compared with the other clusters of similar metallicity. In particular, it has been found that HB morphology correlates with Galactocentric distance, suggesting that the intrinsic quantity or phenomenon which causes the anomalous HB star distribution at that metallicity is also varying with varying cluster location within the Galaxy. Several authors have concluded that, of the various second parameter candidates, only age differences can reproduce the global second parameter effect and, at the same time, successfully reproduce the observed properties of RR Lyraes and the MS TOs. On the other hand, most observed HBs present special features (gaps, clumps, distortions) which naturally require the existence of 'non-global' effects, which relevance could also vary from star to star in a cluster.

In conclusion, any choice is uncertain at this stage, and the whole issue of the 'second parameter' effect is still matter of hot discussion and tireless study.

Absolute and relative ages

One of the most frequently asked questions in astronomy is, how old is the universe we live in? Since GCs (the most metal-poor ones, in particular) were formed during the very early times of the Galaxy, and represent the oldest stellar systems for which age can be estimated fairly accurately, their absolute ages set a very stringent lower limit on the universe's age itself, since the universe cannot be younger than the oldest objects it contains.

The observational parameters required to estimate the absolute age of a given GC are the apparent magnitude and color of the TO, along with the distance to the cluster, its helium and metal content and the interstellar reddening along the line of sight. This allows the calculation of the absolute magnitude of the MS TO (the 'observational stellar clock'). Once the absolute magnitude of the MS TO has been determined, ages can be estimated by comparison with appropriate model isochrones (the 'theoretical clock') properly transformed into the observational plane.

The primary source of uncertainty in the absolute ages derived from the luminosity of the MS TO is our poor knowledge about distances to clusters, although uncertainties in quantities such as metallicity, reddening and elemental abundance ratios must also be taken into account. It should be remembered that errors of 0.07 mag in the absolute luminosity of the MS TO or 0.01 mag in its color bring a corresponding error in the derived age of about 1 billion years.

Several methods exist to measure distances to GCs. Until recently, all of them were uncertain at about a 20% level. The effects of model uncertainties on the derived age estimates are more difficult to assess as they are dependent (with different weights) on parameters and calibrations which are not directly observable (reaction rates, opacities, treatments of convection and mixing, basic input physics, etc).

A recent attempt to quantitatively evaluate the global uncertainty of both observations and stellar models concluded that the age of the oldest clusters lies in the range 11–21 Gyr (Chaboyer *et al* 1996). These figures do not allow us to discriminate among different cosmological models.

Nearby subdwarfs, whose distances can be determined to high accuracy through trigonometric parallax, provide the best standard candles to estimate GC distances, especially after the results yielded by the ESA's astrometrical satellite HIPPARCOS. The magnitude offset between the observed cluster MS and the absolute-calibrated MS of the local subdwarfs (assumed to be 'bona fide' representatives of GC subdwarfs of the same metal abundance) eventually gives the distance to the cluster.

Before HIPPARCOS, the available sample of local subdwarfs with known metallicity and accurate PARALLAXES was extremely poor. In early 1997, HIPPARCOS substantially increased the observational database, bringing the number of subdwarfs with very accurate parallaxes to about 900 stars, 30 of which have metallicities comparable with those of the GCs ([Fe/H] ≤ -1.0). The enlarged sample of subdwarfs and the use of new metal abundances in the same metallicity scale as used for GC stars have led to an almost halving of the uncertainty in derived cluster distances and, in turn, ages.

The discussion on the ages of the galactic GCs has been stirred up because of the global modifications of the astronomical distance scale implied by the HIPPARCOS results, which suggest that many Galactic objects, including the GCs, may be at distances about 10% larger from us than previously thought. The intrinsic luminosity of their TO stars should thus be about 20% brighter and they should also be roughly 15% younger, given the quoted relationship between TO luminosity and age.

The latest estimates yield therefore an age of 12–14 billion years for most of the GCs, and 13–14 billion years is perhaps the age of the most metal-poor and (presumably) oldest GC: M92.

An independent check of the distances derived from the subdwarf technique is absolutely necessary. A promising alternative is offered by the use of the WD cooling sequence. This technique relies on the matching of local WDs to WDs observed in GCs, as a matter of fact so exploiting, to a much fainter level, the same technique used with the subdwarfs. With the refurbished HST, it has become technically feasible to observe WDs in GCs. The first result from this technique for the GC NGC 6752 was obtained by Renzini *et al* in 1996. They find a distance consistent with other estimates, and derived ages of around 15 Gyr.

Although not totally incompatible, absolute ages derived for GCs in the pre-HIPPARCOS era were poorly

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

consistent with most cosmological age determinations, such as those obtained through measurements of the Hubble constant. However, if the latest estimates of the GC ages obtained via HIPPARCOS parallaxes for the local subdwarfs are correct, the problems of the compatibility between the so-called 'stellar route' to cosmology and alternative routes are reduced, and would possibly disappear.

Relative ages of GCs are more reliable than absolute ages, primarily because determinations of age differences are less sensitive to stellar models and, second, and most important, because they do not depend on the assumed cluster distance. Their use allows one to address outstanding questions concerning the process of formation of our Galaxy. In particular, if we could define a reliable age–metallicity relation, as well as determine a variation of age with Galactocentric distance, we would be able to make a choice between the scenario suggested first by Eggen, Lynden-Bell and Sandage (1962), who think that the Galaxy was formed in a rapid, monolithic collapse (in a few 10^8 yr), and that proposed by Searle and Zinn (1978), who rather believe that the Galaxy formed much more gradually through the accretion of independent fragments (with masses ranging from $10^7 M_\odot$ up to $10^9 M_\odot$), over a few billion years or so. The detection of age differences among the Milky Way's GCs would in fact provide stringent constraints on the time scale and mechanism of formation of the Galactic halo.

Several methods have been employed so far to derive GC relative ages.

The most widely used technique exploits the difference in luminosity between MS TO and HB. Since the core mass of GC stars on the HB is roughly constant, the HB luminosity is almost independent of cluster age. On the contrary, the MS TO luminosity decreases with increasing the age, so the magnitude difference between the MS TO and the HB provides an estimate of the age of the GCs.

This method is elegant and simple in principle; however, it does suffer from several problems. The basic observational limitation is that while it works nicely for clusters having HBs well populated on both sides of the instability strip, it can hardly be applied when only red stubby HBs or just blue HB tails are present in the CMD. The latter case is particularly worrying since, if age is the second parameter, metal-poor clusters with blue HBs could be the oldest ones. A second basic problem is the still poor accuracy in our knowledge of the absolute magnitude of RR Lyrae stars (and thus of the HB (to yield absolute ages)) and of its dependence on metallicity.

The magnitude versus metallicity relation for RR Lyraes is usually described as: $M_V(\mathrm{RR}) = a[\mathrm{Fe/H}] + b$. The values currently obtained for a cover the range 0.15–0.35 mag dex^{-1}. This uncertainty is large enough to prevent any reliable determination of the GC age distribution since an error in the absolute magnitude of $\sim$0.20 mag implies a 2.5 Gyr error in the age. Furthermore, an estimate of the absolute age, with an error less than 1 Gyr, based on the RR Lyrae variables as absolute standard candles, requires knowledge of b to better than 0.07 mag.

The detailed comparison of the CMDs offers an alternative technique to deriving relative ages for GCs of similar metallicity. In fact, the relative distance of the clusters can be measured by simply superimposing the ridge lines of the main branches in the observed CMDs, after taking into account any differential interstellar reddening. If clusters of different metallicity are compared, further corrections (often uncertain) must be drawn from stellar atmosphere models. Once the best matching is achieved, however, the difference in the magnitude of the MS TO between the two compared clusters yields a straightforward measure of the age difference, if any.

Recent analyses of the relative ages of the best-observed Galactic GCs seem to indicate in general the existence of a small (less than 1 Gyr) spread. However, there is now also compelling evidence for larger age differences between some globulars. Probably the best-established cases are Ruprecht 106, Palomar 12, Terzan 7 and Arp 2. They (especially the first two) appear to be around 3 Gyr younger than other GCs of similar metallicity. It is unknown whether they are truly exceptions or whether other 'young' clusters lie still undetected. They could perhaps originally belong to a satellite galaxy tidally disrupted and captured by the Milky Way, but further confirmation is necessary.

In conclusion, the current status of our knowledge about the age of the Galactic GCs is consistent with an age distribution in which most Milky Way globulars are quite uniformally old (with ages of about 13 Gyr), and the oldest ones as old as 14 Gyr, but also with a few globulars significantly younger (by about 2–3 Gyr).

Globule

A small, round dark nebula thought to represent a stage in the collapse of a concentration in a molecular cloud toward a protostar. They range in mass from about 1 to 1000 or more solar masses, and in size from about 10 000 AU to 3 light-years, and are visible in silhouette against bright nebulae such as the Rosette Nebula, or against bright Milky Way starfields. Bart Bok was the first to suggest that they might be the precursors of protostars; they are sometimes called *Bok globules*. What appear to be protostars have been detected within some globules by orbiting infrared telescopes.

Goddard Space Flight Center

The Goddard Space Flight Center (GSFC), in Greenbelt, MD, named for Dr Robert H Goddard, a pioneer in rocket research, was established in 1959. Since that time, GSFC has played a major role in space and Earth science.

Goddard's fundamental mission is to expand knowledge of the Earth and its environment, the solar system and the universe through observations from space. The center is committed to excellence in scientific research and investigation, the development of space systems and the advancement of essential technologies.

Approximately 11 740 people work at the Goddard Space Flight Center at all of its sites. Goddard has personnel and facilities capable of creating, building, testing, launching and operating various satellite projects in support of Earth science, space science and advanced technology programs.

Goddard's Greenbelt campus includes the Earth Observing System Data and Information System (EOSDIS) facility built in 1995, and the Earth Systems Science Building built in 1998.

The EOSDIS facility serves as a key data-retrieval node in the Earth Observing System communications system, as well as a distribution center for Earth data from numerous spacecraft and instrument sources, such as the Total Ozone Mapping Spectrometer and Tropical Rainfall Measuring Mission.

The Earth Systems Science Building houses the laboratories of Goddard's Earth Sciences Directorate: the Laboratory for Atmospheres, Laboratory for Terrestrial Physics and Laboratory for Hydrospheric Processes.

To support NASA's Space Science Enterprise, Goddard leads the mission of space-based physics and astronomy to create opportunities for conducting research through a broad variety of flight opportunities. Goddard promotes the development of advanced technology designed to enhance scientific capabilities at an affordable cost.

Goddard provides agency leadership to advance next generation spacecraft, sensor and instrument technology. Goddard scientists and engineers have gained significant expertise in areas such as optics development, cryogenics, microelectronics, x-ray astronomy, Earth observation and information systems.

Goddard, Robert Hutchings (1882–1945)

American rocket pioneer, whose achievements in rocketry, sometimes in the face of official disapproval or ridicule, form a long list. He was the first to prove, by static test, that a rocket will indeed work in a vacuum—that it needs no air to push against. He received a US patent on his idea for a multistage rocket (1914). In the document (1920) which laid out his life's work, entitled 'A method of reaching extreme altitudes', he outlined methods of raising weather-recording instruments higher than balloons and developed the mathematical theories of rocket propulsion to reach high altitudes. He foresaw the possibility of a rocket reaching the Moon and suggested that it could explode flash powder there to signify its arrival. This was the most dramatic, eye-catching part of the report, and was widely (and sceptically) reported in both the USA and Germany, where it coincided with the surge of interest in rockets there. He developed and fired the world's first liquid fuel rocket (gasoline/petrol and liquid-oxygen fuelled) in 1926, and was the first to launch a scientific payload (barometer and camera) in a rocket flight (1929). He made various technical advances in the use of pumps, gyros and other rocket mechanisms, as evidenced by the 200 patents in his name. NASA's Goddard Space Flight Center, located near Washington, DC, is named after him.

Gold, Thomas (1920–)

Astronomer born in Vienna, Austria, emigrated to Britain and then the USA. Noted for provocative, imaginative and sometimes wholly incorrect theories, he proposed the now discredited steady-state theory of cosmology (with BONDI and HOYLE), in which matter was continuously created to maintain the density of the Universe while it expanded. At Cornell University, he directed the Center for Radio Physics and Space Research, where he named the magnetosphere and studied pulsars, proposing that they were rotating magnetic neutron stars, as now thought to be correct. Gold caused some concern for the safety of US astronauts when he incorrectly theorized that the Apollo lunar lander would sink into meters of lunar dust. He is at the present time offering an unconventional view of terrestrial carbon fuel deposits (coal, oil), that they are not of biological origin but are cosmic carbon welling up from the Earth's central regions.

Gould Belt

Most stars in the solar neighborhood younger than about 60 million years are located in a flattened structure of about 700 parsec (pc) in size, surrounding the Sun. This structure also contains much interstellar atomic and molecular gas, and is called Gould's Belt. It is inclined by nearly 20° relative to the general stellar population of the Galactic plane, which has an average age of several billion years. The properties of the Gould Belt can be used to trace the recent star formation history in our part of the Galaxy.

Discovery

Sir John Herschel noted in 1847 that the brightest stars in the sky are not arranged symmetrically about the Galactic plane. From observations made in South Africa (see HERSCHEL FAMILY) he concluded that the Galactic equator is crossed by a zone of bright stars which is delineated by the southern constellations Orion, Canis Major, Carina, Puppis, Vela, Crux (the Southern Cross), Centaurus, Lupus and Scorpius. The great circle which connects the stars ε Orionis (Alnilam) and α Crucis (Acrux) defines the axis of this zone of stars. Benjamin Gould pointed out in 1874 that the feature observed by Herschel is traced in the northern sky by the constellations of Taurus, Perseus, Cassiopeia, Cepheus, Cygnus and Lyra, although less conspicuously. Gould studied the distribution of these stars in detail and concluded that together they define a great circle with an inclination of 20° to the Galactic equator (see figure 1). This apparent distribution on the sky implies the presence of a flattened structure, with the Sun located in its interior, which is nowadays known as the Gould Belt.

Stars

The stellar spectral classification scheme which was developed shortly after the discovery of Gould's Belt showed that most visible stars in the Belt were of early spectral type (O and B type stars). When the principles of STELLAR EVOLUTION were established in the middle of the 20th century, it became clear that early-type stars are massive and young (less than a few tens of Myr). At the same time the Russian astronomer Ambartsumian recognized that groups of O and B stars, OB ASSOCIATIONS, are gravitationally unbound. These groups therefore expand and quickly dissolve into the Galactic disk star population, which led Ambartsumian to postulate that the observed associations must be young. Thus, both O and B stars in associations and the associations themselves were formed recently (∼10–100 Myr ago).

The realization that most O and B stars reside in OB associations immediately led to the conclusion that many of the nearby OB associations are connected with Gould's Belt. Figure 2 shows that the Scorpio–Centaurus–Lupus–Crux (Sco OB2), Orion (Ori OB1), Perseus (Per OB2), and Lacerta (Lac OB1) associations lie in the Gould Belt. These groups have typical ages of less than ∼15 Myr.

Many detailed photometric, radial velocity and astrometric studies of stars in the Solar neighborhood have been carried out in order to investigate the existence and characteristics of the Gould Belt. It was found that stars within 500–1000 pc of the Sun older than ∼60 Myr generally tend to be distributed symmetrically with respect to the Galactic plane, while ∼90% of the stars of spectral type O, B and A younger than 30 Myr, and ∼70% of early-type stars with ages between 30 and 60 Myr, define a distinct spatial and kinematical feature within the MILKY WAY GALAXY. The Gould Belt stars are distributed in a flattened elliptic structure with a semi-major axis of ∼360 pc and a semiminor axis of ∼210 pc, which is tilted by ∼20° with respect to the Galactic plane. The distances of the Gould Belt stars indicate that its three-dimensional structure is not a thin ring but rather resembles a 'disk with a hole'. The center of the Gould Belt is located ∼170 pc from the Sun in the direction $(\ell, b) \sim (130^\circ, -15^\circ)$, so that the Sun is located inside the Gould Belt. The ascending node of the ring lies in the direction of $\ell \sim 280^\circ$. The kinematics of the Gould Belt stars, which was recently much improved with the addition of astrometric data from the HIPPARCOS satellite, cannot be explained by differential galactic rotation alone but shows evidence for an additional expansion and rotation of the system as a whole.

Recently it was found that Gould's Belt is also associated with young low-mass stars. These stars are bright in X-RAYS, and ROSAT satellite observations made in 1998 show that they outline the same inclined flattened structure as observed in the early-type stars. Figure 3 shows the distribution of these low-mass stars on the sky; the Gould Belt as determined from the early-type stars is also indicated in this figure. The total stellar mass of the Gould Belt is estimated to be at least a few times 10^5 solar masses.

Interstellar matter

STAR FORMATION is an inefficient process; less than half of the available gas is generally converted into stars. This implies that recently formed stars should still be associated with copious amounts of interstellar matter. Indeed, many nearby molecular cloud complexes (e.g. the Great Rift stretching from Ophiuchus through Aquila to Cygnus, and the Orion and Perseus molecular clouds) are related to the recent formation of Gould's Belt (see also figure 2); Herschel already recognized the relation of the Orion Nebula to the Gould Belt. The molecular gas in Gould's Belt interacts with the recently formed massive stars: (1) these stars illuminate nearby gas and dust resulting in REFLECTION NEBULAE, and (2) COSMIC RAYS from supernovae produce high-energy GAMMA RAYS through the interaction with the gas. Measurements by the ESA COS-B satellite in the 1970s and the IRAS infrared satellite in the 1980s indeed revealed that the distribution of bright stars in Gould's Belt is correlated with high-energy gamma rays and nearby reflection nebulae, respectively. The latter correlation had already been noted in the 1920s by Hubble, who found, unaware of their true nature, that nearby

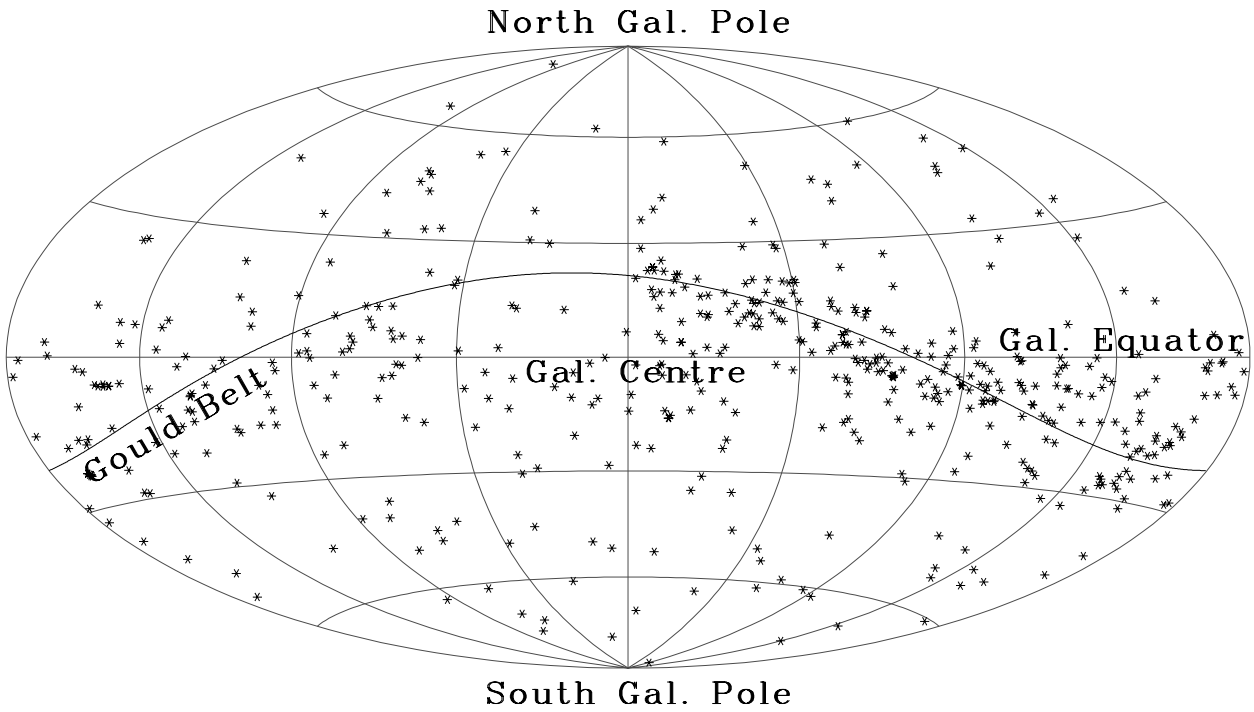

Figure 1. The distribution in GALACTIC COORDINATES of young stars (spectral type B) brighter than visual magnitude 5.25. These stars are visible to the naked eye. The curved solid line labeled 'Gould Belt' depicts a great circle inclined at 20° to the Galactic equator. The Belt is most conspicuous at its ascending node, which is in the southern celestial sky.

reflection nebulae (at the time simply called 'large diffuse nebulae') are distributed on the sky along the Gould Belt.

There is also ample evidence for atomic gas associated with the Gould Belt. Soon after the prediction of the hydrogen 21 cm line transition by Van de Hulst in 1944, and the first detection of interstellar neutral hydrogen (H I) in 1951 by Ewen and Purcell, Heeschen and Lilley observed the galactic center and anti-center regions. In the late 1920s Oort and B Lindblad had proposed a model which assumed that gas follows circular orbits around the Galactic center in a thin disk. Therefore, Heeschen and Lilley expected to find H I gas only at low Galactic latitudes ($|b| < 5^\circ$) and with radial velocities equal to zero km s^{-1} with respect to the local standard of rest. To their surprise, they found significant amounts of H I gas at $(\ell, b) \sim (0^\circ, 20^\circ)$ and $(\ell, b) \sim (180^\circ, -20^\circ)$ moving with radial velocities of $\sim +5$ km s^{-1}. This result provided the first evidence that H I gas is associated with the early-type stars in Gould's Belt (cf figure 1).

Firm evidence for the association of neutral gas with Gould's Belt was presented in 1967 by P Lindblad. Using the Dwingeloo Telescope he identified several distinct low-velocity-dispersion components in the low-latitude H I distribution in the direction towards the Galactic anticenter. Inspired by Blaauw's idea that the early-type stars in Gould's Belt form an expanding system, Lindblad showed that the velocity–longitude data for one of these local peculiar H I components (feature A) could roughly be modeled as a ballistically expanding gas ring (Lindblad's Ring) with the Sun located off-center in its interior. Later investigations expanded Lindblad's data set to include other longitude ranges and improved the quality of the data. These studies confirmed Lindblad's original hypothesis. The total mass of the interstellar matter associated with the Belt is estimated to be a few million solar masses.

Origin and evolution

In order to understand the stellar and gaseous content of Gould's Belt as one physical system all observational facts presented in the previous sections must be accounted for by one consistent formation and evolution scenario. It is thought that Gould's Belt is the result of a large-scale star formation event which started with the passage of the Carina SPIRAL ARM. This arm is currently at a distance of ∼4 kpc from the Sun along the Solar circle at $\ell \sim 280^\circ$ and passed a large gaseous condensation in the Solar neighborhood (a giant molecular cloud) roughly 60 Myr ago. This passage triggered star formation, resulting in the birth of the Cassiopeia–Taurus OB association and α Persei cluster (figure 4, panel 1). Both groups have similar ages and kinematics.

Based on the present-day stellar content of the Cas–Tau association Blaauw estimated that roughly 15 semi-simultaneous supernova explosions must have occurred shortly after its formation. The energy output of the

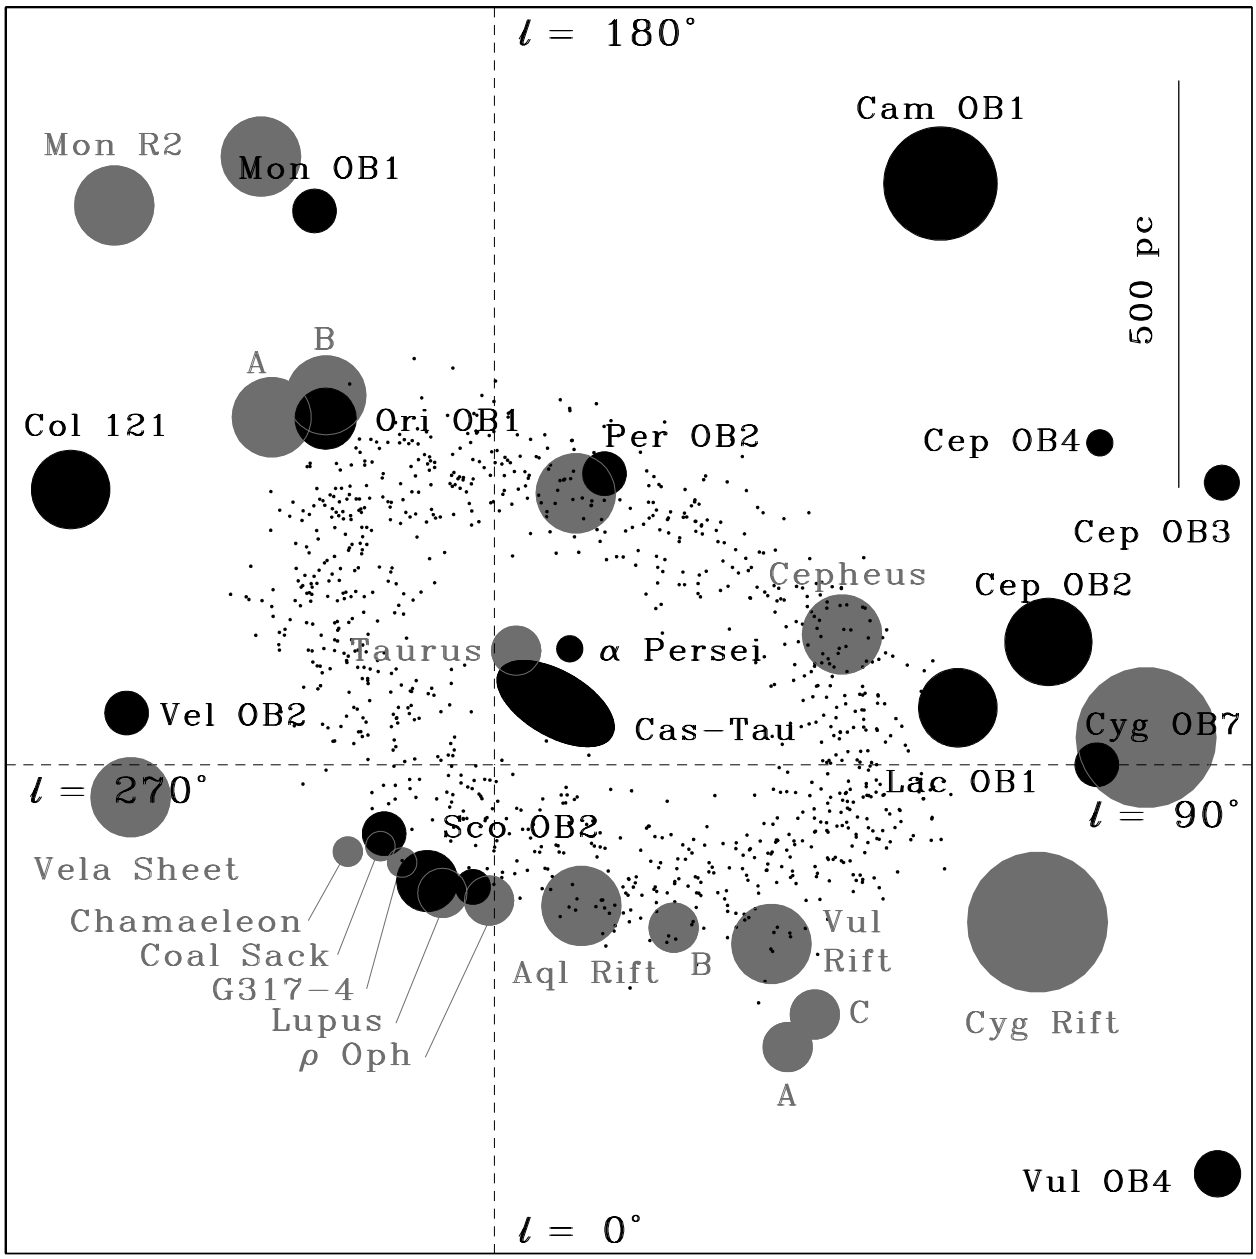

Figure 2. OB associations and molecular clouds near the Sun, projected onto the Galactic plane. The Sun is at the center of the broken lines which give the principal directions in Galactic longitude, ℓ. The size of the black-filled circles represents the projected dimension of the associations. The gray-filled circles represent molecular clouds; the circle radii are proportional to the cube roots of the cloud masses and are close to the clouds' actual radii. The distribution of small dots indicates a schematic and simple model of the gas distribution at low latitudes in Gould's Belt. Adapted from de Zeeuw *et al* (1999 *Astron. J.* **117** 354–99) and Dame *et al* (1987 *Astrophys. J.* **322** 706–20).

SUPERNOVAE, combined with the stellar winds of other massive stars, was sufficient to clear the association of its parental gas and create a rapidly expanding hydrogen shell (figure 4, panel 2). This initially spherical shell traveled through the interstellar medium while sweeping up and compressing gas and dust near the Galactic plane (Lindblad's Ring), leaving behind a cavity in the molecular cloud. The interaction between the shell and the interstellar medium caused the expansion velocity of the shell to decrease slowly. The effects of the Galactic tidal field gradually deformed the shell's circular shape into an elliptical one (figure 4, panel 3). In the direction perpendicular to the Galactic plane, the shell did not encounter much resistance, with the result that it broke

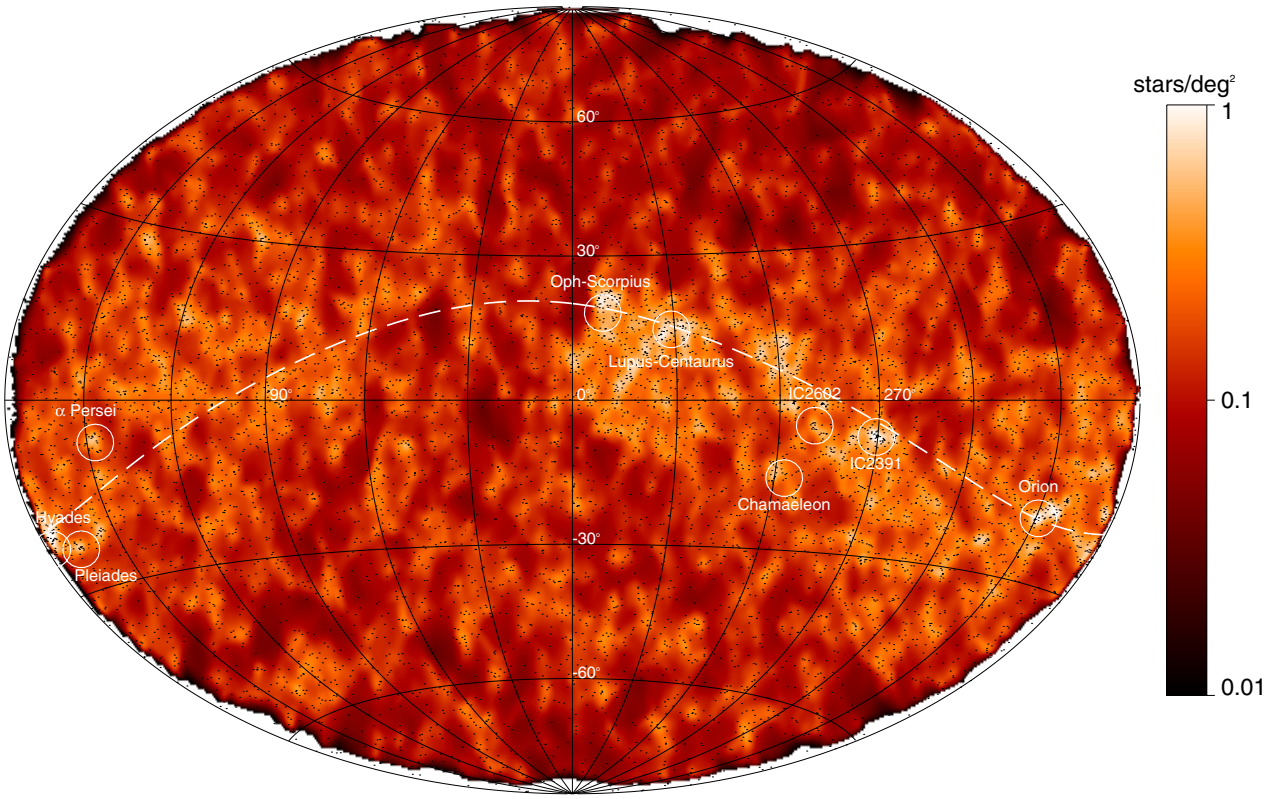

Figure 3. The all-sky distribution in Galactic coordinates of ∼8600 x-ray-bright low-mass young stars identified by the ROSAT satellite (small black dots). The gray scale represents the surface density of these stars on a logarithmic scale from 0.01 to 1 star per square degree (see gray-scale coding bar). The white broken line indicates the Gould Belt (see also figure 1). Circles denote some nearby young Galactic clusters and star forming regions. Adapted from Guillout *et al* (1998 *Astron. Astrophys.* **334** 540–4). **A color version of this figure is reproduced as Color Plate 19.**

open allowing the hot gas in its interior to blow out of the plane into the lower galactic halo through a so-called Galactic fountain.

After ∼45 Myr the physical conditions of the gas and dust (density and temperature) in the shell were suitable for the formation of stars. Low-mass stars formed throughout the entire shell (figure 4, panel 3) while STAR CLUSTERS and OB associations formed in dense clumps. These clumps are the result of fragmentation of the hydrogen shell. The new (second) generation of stars currently defines the Gould Belt (figure 4, panel 4, and figure 2). The observed motions of these stars still bear the signature of the expanding parental gas shell. Whereas the stars continued their expansion unobstructed since their birth, the gas shell continued to slow down owing to braking forces. Observations indeed show that the Gould Belt stars have radial velocities which are slightly larger than the +5 km s^{-1} gas velocities.

The most conspicuous stellar complexes in Gould's Belt are the OB associations Sco OB2, Ori OB1, Per OB2 and Lac OB1. These aggregates themselves have already induced the formation of a third generation of stars (e.g. ρ Ophiuchus, Orion Nebula Cluster, IC 348).

Open issues

The evolutionary history of Gould's Belt presented in the previous section is a simplified representation of reality and some complications remain that have not been addressed.

- Star formation in the expanding shell influences its density and velocity structure because of, e.g., local bubbles blown by the supernovae and stellar winds of the second generation of massive stars. Examples of such local bubbles are the Orion–Eridanus superbubble and the shells around Sco OB2, Col 121, Per OB2 and Lac OB1 (see, e.g., figure 5 and figure 3.15 in Pöppel (1997)).
- High-galactic-latitude observations show infalling gas near the Galactic Poles. This gas was originally blown out of the plane of the Galaxy (Galactic fountain) and is now falling back on a collision course with the Gould Belt itself. Such collisions can produce disturbances of the expanding shell, e.g. the North Celestial Pole Loop.
- The presence of several large dark cloud complexes, notably the Taurus molecular cloud and Pleiades cloud, inside Lindblad's Ring cannot be explained if the expanding shell encountered these clouds in the past.

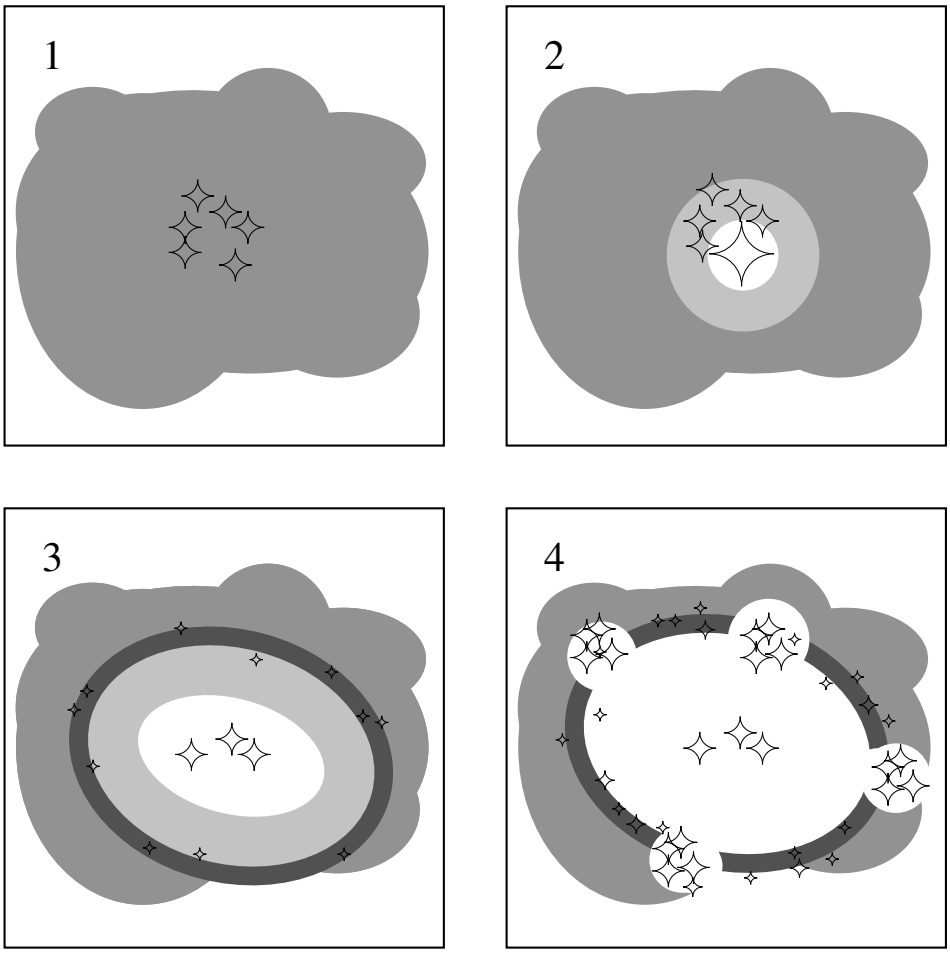

Figure 4. Schematic representation of the formation of Gould's Belt. Sixty Myr ago the Cassiopeia–Taurus (Cas–Tau) association formed inside a giant molecular cloud (panel 1). The stellar winds of the massive stars and the supernovae in Cas–Tau cleared the association from its primordial gas creating an expanding shell sweeping up material of the molecular cloud (panels 2 and 3). Star formation occurred throughout the entire shell and approximately 15 Myr ago several OB associations formed where the shell fragmented into dense condensations (panel 4). The expanding shell of gas and the newly formed stars are at present denoted as Gould's Belt.

These complexes may have been ejected inwards from the shell in the past.

- One of the most noticeable and remarkable properties of Gould's Belt is its 20° tilt with respect to the Galactic plane. There are three possible explanations for this tilt. (1) The tilt is the coincidental result of the fragmentation of the superbubble blown by Cas–Tau (this would be consistent with the fact that Gould's Belt is dominated by two associations Sco OB2 and Ori OB1). (2) The shell blown by Cas–Tau expanded into a pre-existing tilted gas layer (shingle). (3) The original burst of star formation was caused by the oblique impact of a HIGH-VELOCITY CLOUD. This scenario naturally explains the tilt of Gould's Belt.

Expectations for the future

The distribution and kinematics of the atomic and molecular gas associated with the Gould Belt have been studied by a number of authors, although it is clear that the details remain an open question; observations and analyses need to be pursued. By contrast, we still lack much information on the properties of the stars in the Belt, despite the major contributions by the Hipparcos satellite for the massive stars, and by ROSAT for low-mass stars. This situation can be considerably improved by the proposed GAIA satellite, which is currently under study by ESA. This satellite will provide accurate distances, space motions, and photometry throughout the Gould Belt region. At a limiting magnitude of ∼20, GAIA will even observe many low-mass stars. This will allow a full understanding of the Gould Belt and a reconstruction of the sequence of star formation in the Solar neighborhood

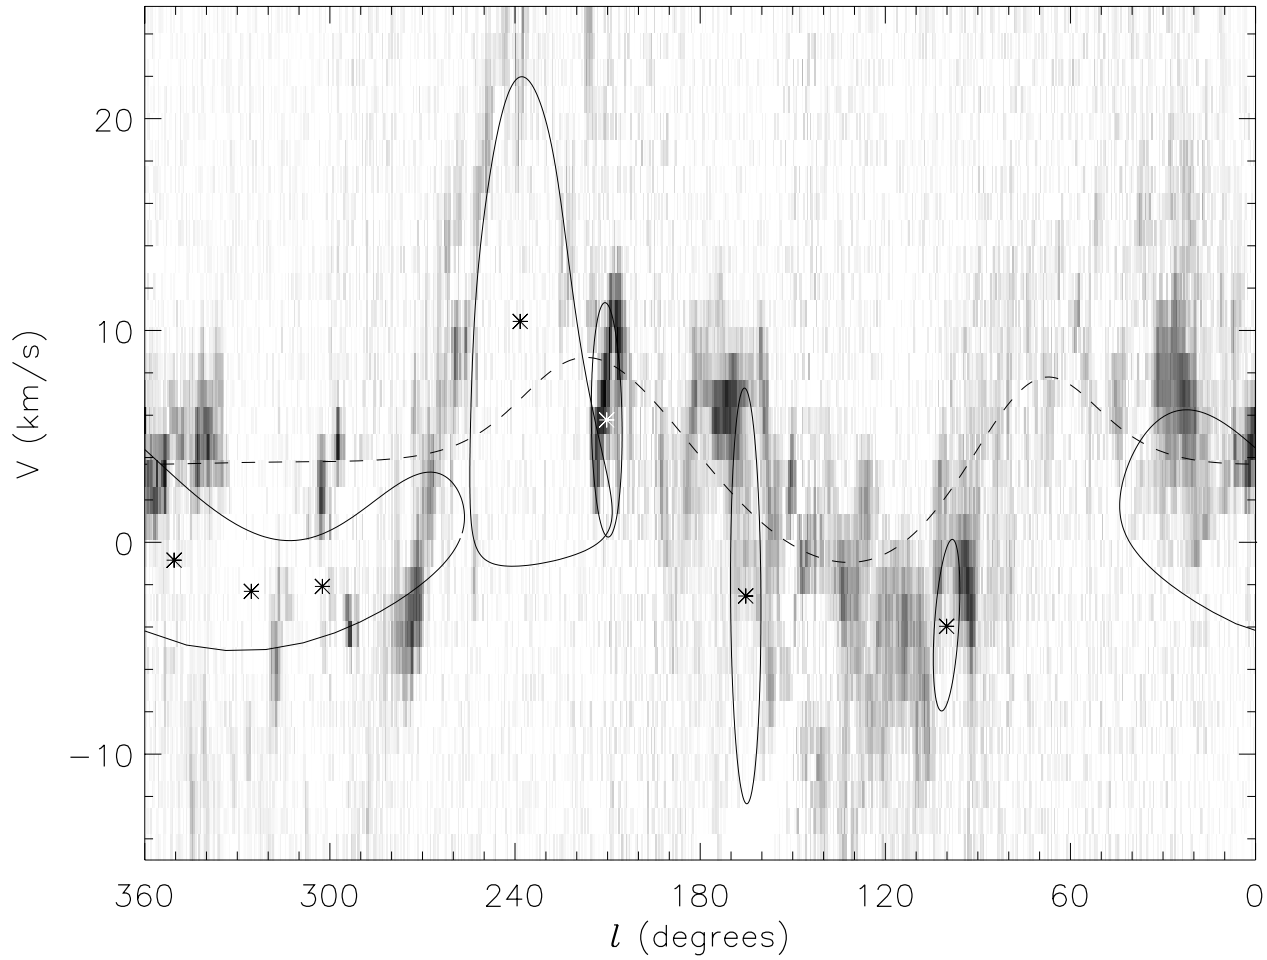

Figure 5. Position–velocity diagram of local CO gas: radial velocity of the gas versus Galactic longitude. The gray scale represents the brightness temperature of the CO clouds. The nearby OB associations are indicated by asterisks (the three subgroups of Sco OB2 at $\ell = 300^\circ$–360°, Collinder 121 at $\ell = 240^\circ$, Ori OB1 at $\ell = 210^\circ$, Per OB2 at $\ell = 165^\circ$ and Lac OB1 at $\ell = 100^\circ$). The curves (solid or broken) show the expected velocity fields for gas shells assuming that the shell velocities reflect both differential Galactic rotation and expansion powered by the energy released by the early-type association members. The broken curve denotes the supershell powered by the at present fossil Cas–Tau association (Lindblad's Ring); the solid curves denote local bubbles powered by the young OB associations in the Solar neighborhood (see above). Note that the association Collinder 121 is not part of Gould's Belt although its shell does interact with Lindblad's Ring. Adapted from Bally, Theil and Sutherland (2000 Orion's superbubble *The Orion Complex Revisited (ASP Conf. Ser.)* ed M J McCaughrean and A Burkert).

in the past 60 Myr. Detailed knowledge of the local star formation history will ultimately be of great value in the study of extragalactic Gould Belt analogs (i.e. massive-star formation in spiral DISK GALAXIES) and STARBURST GALAXIES.

Gould, Benjamin Apthorp (1824–96)

Astronomer, born in Boston, MA, his early work in Germany was on the observation and motion of comets and asteroids. His greatest work was his mapping of the stars of the southern skies. He helped found the National Observatory in Cordoba, Argentina, and was its director as it compiled a catalog of stars using recently developed photometric methods. On returning to the USA, he spent his final years measuring the star clusters he had photographed in Argentina, and published the results as *Uranometry of the Southern Heavens*. He founded the *Astronomical Journal*.

Graham, George (*c.* 1674–1751)

Instrument-maker, born in Hethersgill, Cumberland, England. Employee, partner, and by virtue of marriage to the niece of clock-maker THOMAS TOMPION, his heir. With TOMPION he made an *orrery*, the original one from which the name comes, for the Earl of Orrery; in fact he may have invented the instrument (which is a mechanical model for demonstrating the relative positions and motions of the planets). He invented improvements to precision clock mechanisms such as the deadbeat escapement, the mercury compensated pendulum and the cylinder escapement for watches, and he used clocks he had made to measure the exact shape of the Earth, correcting NEWTON'S figures. He made instruments for HALLEY (an 8 foot quadrant with vernier) and BRADLEY (a 12.5 foot zenith sector with a micrometer screw with which Bradley discovered the aberration of light). He also made the apparatus used for the measurement of a degree of the meridian by the French Académie des Sciences in its northern expedition.

Grand Unified Theory

A theory that attempts to show that the strong nuclear force, the weak nuclear force and the electromagnetic force are different manifestations of a single, unified, fundamental force.

Each of these forces may be described by quantum field theories, which imply that forces are communicated ('mediated') between real particles by means of virtual particles (particles that cannot be observed directly but which are permitted brief existence by the Heisenberg uncertainty principle). The electromagnetic force is conveyed by virtual photons, the weak nuclear force by massive 'W' and 'Z' particles (intermediate vector bosons) and the strong nuclear force between nucleons, by virtual mesons, and between quarks, by 'gluons'. Particles that are acted on by the strong nuclear force are called hadrons (hadrons, of which protons and neutrons are examples, are composed of quarks), those which do not experience the strong force are called leptons. In the present, low-energy ('cool') phase of the universe, the four fundamental forces (gravitation is the fourth force) are separate and distinct, and have markedly different strengths. Grand unified theories (or 'GUTs') attempt to unify the weak, strong and electromagnetic interactions. Many physicists believe that a more comprehensive theory (a 'theory of everything') that unifies all four forces will eventually be found.

The first step towards unification was achieved by the Weinberg–Salam–Glashow theory of the electroweak force, published in 1967, which predicted that at particle energies greater than 100 GeV (10^{11} eV), the electromagnetic and weak nuclear interactions become indistinguishable from each other (force-carrying W and Z particles would behave in the same way as virtual photons) and act as a unified force. The theory received strong confirmation through the discovery, in 1983, of the predicted W and Z bosons. Grand unified theories predict that at much higher energies, around 10^{15} GeV (10^{24} eV), the electroweak and strong interactions lose their separate identities and behave as a single, unified 'superforce'. Such energies far exceed the capabilities of terrestrial particle accelerators but, according to the Big Bang model, would have existed throughout the universe during the first 10^{-35} s of its existence, when the temperature everywhere was in excess of 10^{28} K. Thereafter, as the universe expanded and cooled, the unified force would have split into the strong and electroweak forces (the 'symmetry' between the forces was broken). About 10^{-11} s later, when the temperature had dropped to around 10^{15} K, the electroweak force would have separated out into the electromagnetic and weak nuclear forces.

The simplest grand unified theory, proposed in 1974 by Sheldon Glashow and Howard Georgi, requires the existence of a set of supermassive particles ('X-particles') that can transform quarks into leptons and leptons into quarks (the unified force then acts equally on both kinds of particle). Because quarks are the basic constituents of protons (and of all the hadrons), the theory predicts that protons themselves must eventually decay into leptons and photons (proton decay would occur if two of the constituent quarks inside a proton came sufficiently close to enable a virtual X-particle to be exchanged between them). The mean lifetime of a proton is expected to be at least 10^{32} years but, given a large enough sample of protons, the occasional decay ought to be detectable at the present time. This is being attempted by the Kamio Kande detector. Experiments have not yet detected such an event, but if the theory is confirmed, then it implies the eventual demise of matter as we know it.

Granulation

The mottled structure exhibited by the visible surface of the Sun, in other words the photosphere, when it is observed under good conditions. Due to convection hot gas is rising and cooler gas descending in the outer layers of the Sun, and this gives rise to the visible granules, typically 1200 km in diameter, which are about 100 K hotter than the duller regions which separate them.

Gravitation

One of the four fundamental forces, gravitation is the force of mutual attraction that is exerted between massive bodies and between particles that have mass. Although gravitation is far weaker than the other three forces (the electromagnetic force and the weak and strong nuclear forces) over short ranges, it is the dominant force on large scales because its range of influence is far greater than that of the nuclear forces and because, unlike electrical charges (which can be positive or negative), all mass is positive (and mutually attractive). Because like charges repel and opposite charges attract, and matter on the large scale is electrically neutral (there are equal numbers of negative and positive charges in the universe), the electromagnetic force does not play a major role in the overall dynamics of the universe. Consequently, gravitation alone determines the motions of, and mutual interactions between, planets, stars and galaxies, and dominates the overall dynamics of the universe.

In 1687 Isaac Newton (1642–1727) published his law of universal gravitation in his book, *De Philosophiae Naturalis Principia Mathematica* (The Mathematical Principles of Natural Philosophy). It stated that the force of attraction between any two masses is directly proportional to the product of their masses and inversely proportional to the square of the distance between them. For two bodies, with masses m_1 and m_2, separated by distance, r, the mutual force of attraction, F, is given by $F = Gm_1m_2/r^2$, where G is the universal gravitational constant ($=6.670 \times 10^{-11}$ N m^2 kg^{-2}). An equal and opposite force acts on each of the masses; thus the force exerted on m_1 is equal in magnitude but opposite in direction to the force exerted on m_2.

According to Newtonian theory, gravity is a force that acts, instantaneously, directly between individual bodies and particles (a process that is called 'action at a distance'). Although, for most purposes, Newtonian gravitation gives a perfectly satisfactory description of the motions of, for example, projectiles, planets, stars and galaxies, in certain situations (for example, where gravitation is very strong, as in the vicinity of a black hole, or when dealing with the structure and dynamics of the universe as a whole), the theory is inadequate. The best current theory of gravitation is Einstein's general theory of relativity, according to which mass distorts the geometry of space (or, strictly, four-dimensional spacetime) and the paths followed by material particles, or rays of light, in the neighborhood of massive bodies are determined by these local distortions of space.

Gravitational Lensing

Gravity bends light rays in a way analogous to, but quantitatively different from, the way it bends trajectories of passing particles. If light from some bright object passes close enough to some foreground mass, that object's image will be altered. The effect is more like a piece of bathroom glass in the sky than a precision-ground and well-focused lens, but the terms 'gravitational lensing' or simply 'lensing' have stuck. The observable effect varies, depending on the mass of the lens and the relative positions of lens and background source. 'Weak lensing' produces a shape change in the image, typically a stretching along one direction; for very weak lensing such stretching is imperceptible in images of individual sources but statistically measurable from images of many sources close together on the sky. 'Strong lensing' produces multiple images of the same source, one or more being brighter than the unlensed source would have been, and typically all having very distorted shapes.

The bending of light by the Sun can be measured directly, but apart from this all known examples of lensing involve very distant objects. (A peculiar feature of the physics of lensing is that lensing becomes easier to find as one observes more distant objects.) Lensing of stars in the Milky Way and its environs by foreground stellar-sized masses is now routinely observed; this requires very large surveys because of order 1 in 10^6 stars is being strongly lensed. Lensing by foreground galaxies of quasars is proportionately much more common—of order 1 in 10^3 quasars is strongly lensed. GRAVITATIONAL LENSING BY CLUSTERS OF GALAXIES is ubiquitous—a long-exposure image of any rich cluster of galaxies at cosmological distance will show obvious weak lensing and possibly also strong lensing.

What makes lensing particularly attractive is that it depends only on gravity and geometrical things such as source and lens positions; the effects of lensing do not come mixed up with other (possibly poorly understood) physical effects. Thus astrophysical inferences made from lensing will hopefully be particularly robust. Lensing is astrophysically most important as a probe of dark matter (see DARK MATTER: ITS NATURE). However, it has other, sometimes surprising, uses too.

The main part of this article is based on physical arguments. Mathematical material is confined to sections indicated between ♢ and ♦, and these may be skipped.

Basic physics of lensing

Photons are affected by a gravitational field, but not in the same way as massive particles are. For the details one needs general relativity, and because of this lensing was considered a very difficult subject for a long time (see GENERAL RELATIVITY AND GRAVITATION). However, in astrophysical situations some useful approximations apply, and these make the physics very much simpler than in full general relativity. If anything, lensing is easier than the astrophysical applications of Newtonian dynamics.

There are several ways of expressing the effect of gravity on light, in the context of lensing. Perhaps the most intuitive is through the wavefront. A wavefront is the locus of points with a given light travel time from the source. When a wavefront crosses an observer, they see an image of the source in the direction normal to the wavefront. Normally a wavefront is an expanding sphere, and light travels in straight lines. The effect of a gravitational field is to delay the part of the wavefront that passes through it. This naturally changes the shape of the wavefront and hence the direction normal to it, i.e. the position of the image, which is equivalent to saying that the light ray is bent. Figure 1 illustrates this. Note that if the gravitational delay is large enough, the wavefront can double in on itself, producing multiple images (strong lensing). A good way to gain some intuition about the wavefront is to take a plastic transparency with a blank piece of paper behind it and look at the reflections of a lightbulb. The shape of the plastic produces delays in the lightbulb's wavefront analogous to the gravitational time delays. Notice how changing the shape of the plastic causes images to merge and split, and the appearance of grotesquely stretched images at these transitions. Images of galaxies lensed by clusters show just such effects.

The wavefront formulation is not in practice the most useful because it works in terms of a single source and many observers, whereas in astrophysics one is usually interested in many sources and a single observer. So lensing work generally uses two other formulations and some standard approximations.

The standard approximations are the following. First, the gravitational fields are weak enough that massive particles simply follow Newtonian dynamics. (Weak gravitational fields should not be confused with weak lensing—strong lensing can still happen.) Second, the extent of the lens masses along the line of sight is negligible compared with the distances between source and lens and observer. Then a lens behaves as if its mass had been squashed along the line of sight into a sheet of mass. The mass distribution transverse to the line of sight is still important, however. Third, the lens and source are nearly aligned along the line of sight, in the sense that the angular separation (say θ) on the sky between the lens and source is such that $\sin\theta \simeq \theta$. Fourth, diffraction effects are negligible, because even for radio waves the wavelengths are too small.

With these approximations, the effect of gravity on photons can be described by adopting the following result from general relativity. A point mass M at perpendicular distance R from a light ray bends the light towards it by an angular amount

$$\frac{4GM}{c^2R}$$

where G is the gravitational constant and c the speed of light. For the weak field approximation to apply R must be much larger than $2GM/c^2$ (the Schwarzschild radius), but this condition is easily satisfied because Schwarzschild radii are at most a few km for stars, <1 pc

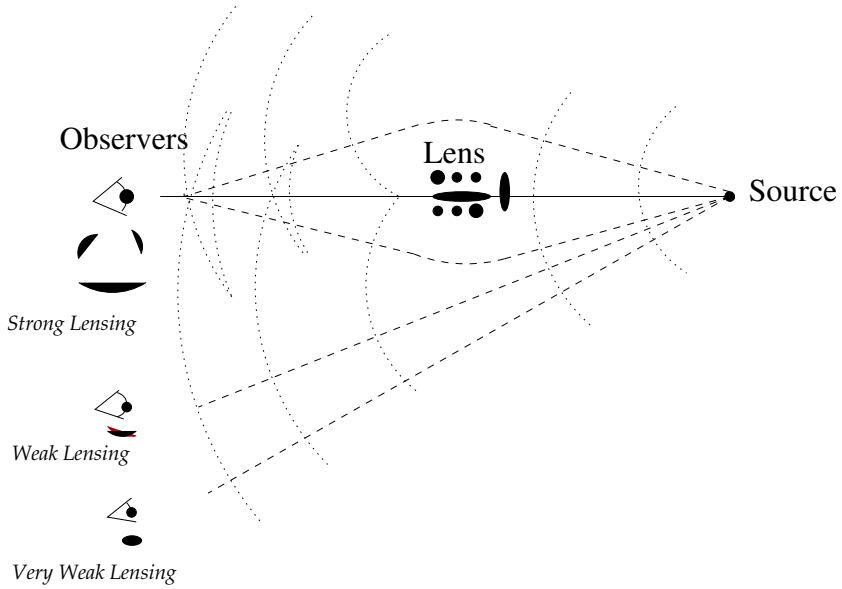

Figure 1. Schematic illustration of the wavefront. Observers see images of the source in the direction normal to the wavefront where the wavefront crosses them. If delayed enough by the lens, part of the wavefront can double in on itself, producing multiple images for some observers (strong lensing); other observers see single images (weak lensing). Images usually experience size and shape changes.

for a galaxy and $\lesssim 10^3$ pc for a cluster of galaxies. (The bending angle of $4GM/c^2R$ was the first prediction of general relativity; Newtonian dynamics would predict half that value. Measurement of the bending angle for the Sun demonstrated that the dynamics of photons is not Newtonian, and was the first test of general relativity.)

Alternatively, one can proceed from another result from general relativity, which is that a photon passing by a point mass M and then reaching an observer from a direction θ relative to the mass will have had its arrival time been delayed by

$$-\frac{4GM}{c^3}\ln\theta$$

by the mass. (Here θ will be very small, so the logarithm will be negative; hence the minus sign.) Now Fermat's principle is that photons take paths which make the arrival time a maximum, minimum or saddle point. In the absence of special delays photons simply minimize the arrival time, i.e. they follow straight lines. However, with a gravitational time delay, photons will follow a different path; this path will be such that the new arrival time (considering both the increased path length and the gravitational delay) is still a maximum, minimum or saddle point. It is often useful to consider the arrival time as a function of the arrival direction of photons from a particular source past some lens: this is known as the 'arrival time surface'. It is related to the wavefront, but is not quite the same thing, for the wavefront is a surface in real space whereas the arrival time surface is a more abstract entity.

The bending angle and arrival time formulations are equivalent. In both cases the effect of a distributed mass (rather than a point mass) is simply the sum of contributions from all points making up the mass distribution.

◊ *Derivation of the arrival time*

Consider a situation as in figure 2, where an observer is viewing a source at distance $D_{\rm S}$, with a lens (a mass screen) intervening at distance $D_{\rm L}$; $D_{\rm LS}$ is the distance from lens to the source. On galactic scales $D_{\rm L}$, $D_{\rm S}$, $D_{\rm LS}$ are ordinary distances, but on cosmological scales they must be understood as angular diameter distances, and $D_{\rm S} \neq D_{\rm L} + D_{\rm LS}$. (The reason for this complication is that the universe expands significantly over the light travel time.) We use angular coordinates for the transverse position; $\boldsymbol{\theta}_{\rm S}$ is the position of the source and $\boldsymbol{\theta}$ is its observed position after being lensed. Let $\Sigma(\boldsymbol{\theta})$ be the lens's surface mass density, i.e. mass per unit solid angle. (An important notational point: $\Sigma(\boldsymbol{\theta})$ is often defined as mass per unit physical area, i.e. $D_{\rm L}^{-2}$ times the convention in this article.) Let $\boldsymbol{\alpha}(\boldsymbol{\theta})$ be the deflection angle. Then, comparing vectors in the source plane, we obtain

$$D_{\rm S}\boldsymbol{\theta} = D_{\rm S}\boldsymbol{\theta}_{\rm S} + D_{\rm LS}\boldsymbol{\alpha}. \tag{1}$$

(By convention, $\boldsymbol{\alpha}$ is directed outwards from the deflecting mass rather than towards it.) Using $4GM/c^2R$ for the deflection from a point mass, we obtain

$$\boldsymbol{\theta} = \boldsymbol{\theta}_{\rm S} + \frac{D_{\rm LS}}{D_{\rm S}}\boldsymbol{\alpha}(\boldsymbol{\theta}) \qquad \boldsymbol{\alpha}(\boldsymbol{\theta}) = \frac{4G}{c^2 D_{\rm L}}\int \frac{\Sigma(\boldsymbol{\theta}')(\boldsymbol{\theta}-\boldsymbol{\theta}')\,{\rm d}^2\boldsymbol{\theta}'}{|\boldsymbol{\theta}-\boldsymbol{\theta}'|^2} \tag{2}$$

This is known as the lens equation. It gives $\boldsymbol{\theta}_{\rm S}$ as an explicit function of $\boldsymbol{\theta}$, but $\boldsymbol{\theta}$ as an implicit function of $\boldsymbol{\theta}_{\rm S}$. Moreover,

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

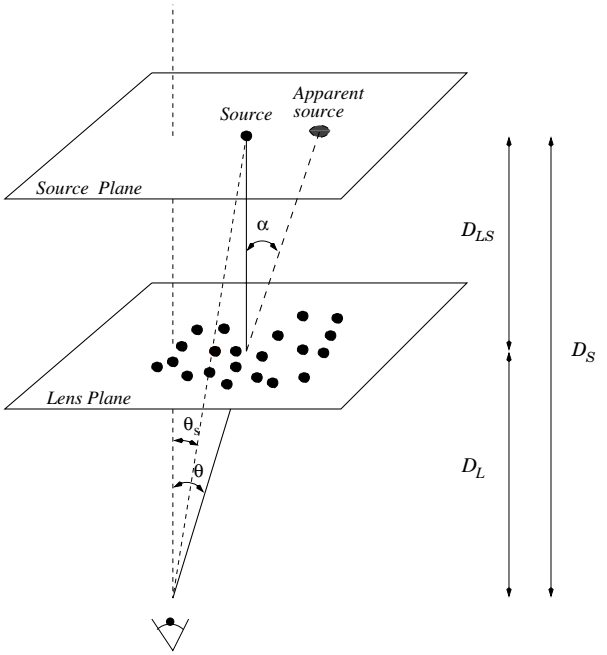

Figure 2. The geometrical meanings of the various distances and angles used in lensing work.

$\boldsymbol{\theta}(\boldsymbol{\theta}_{\rm S})$ need not be single valued, so sources can be multiply imaged.

We can change from this bending-angle formalism to the arrival time formalism by noting that the lens equation 2 amounts to equating a gradient to zero:

$$\boldsymbol{\nabla} T(\boldsymbol{\theta}) = 0 \qquad T(\boldsymbol{\theta}) = \tfrac{1}{2} T_0 (\boldsymbol{\theta} - \boldsymbol{\theta}_{\rm S})^2 - \Psi(\boldsymbol{\theta})$$

$$\Psi(\boldsymbol{\theta}) = (1 + z_{\rm L}) \frac{4G}{c^3} \int \Sigma(\boldsymbol{\theta}') \ln |\boldsymbol{\theta} - \boldsymbol{\theta}'| \, {\rm d}^2\boldsymbol{\theta}'$$

$$T_0 = (1 + z_{\rm L}) \frac{D_{\rm L} D_{\rm S}}{c D_{\rm LS}}. \tag{3}$$

Here $T(\boldsymbol{\theta})$ is of course the arrival time, up to an irrelevant constant, for arbitrary deflections: the first term in it is the change in light travel from geometrical considerations alone; the second term is the gravitational time delay (the factor of $1 + z_{\rm L}$ comes because everything that happens in the lens plane is observed redshifted, and that goes for time delays too). The deflections that actually occur are those that make $T(\boldsymbol{\theta})$ stationary; this is Fermat's principle. Later on, we will rearrange equation (3) to show the dimensions involved a little better. ♦

The Einstein radius

In the absence of lensing the wavefront is spherical. However, in lensing we are always only interested in very small regions of the wavefront, and over a small enough angular region a sphere is indistinguishable from a parabola. Similarly, in the absence of lensing the relevant part of the arrival time surface is also parabolic, with the image of course at the bottom.

Now consider what happens if a point lens is interposed exactly along the line of sight to the source. The arrival time surface will be raised according to the lens's time delay, and if the lens is strong enough the bottom of the parabola will become a dimple. The old minimum will now become a maximum, and the whole edge of the dimple will become a minimum. Observationally, the dimple edge corresponds to a spectacular ring image, called an Einstein ring. Its radius is known as the Einstein radius, say $\theta_{\rm E}$; if the source is much further away than the lens

$$\theta_{\rm E} \simeq 0.1 \text{ arcsec} \times \left(\frac{M \text{ in } M_\odot}{\text{lens distance in parsecs}} \right)^{1/2}$$

where $M_\odot$ denotes the solar mass.

Actually the lens need not be a point mass. Just as in Newtonian gravity a sphere attracts externally as if it were a point mass, a circular lens affects light outside the circle as if it were a point mass. So any circular mass can produce an Einstein ring, provided that the Einstein ring is 'outside the mass'. In other words the mass needs to be smaller than a length that projects to $\theta_{\rm E}$; this length, which we may denote by $R_{\rm E}$ ($=\theta_{\rm E} \times$ lens distance) is also called the Einstein radius. (Whether one means $\theta_{\rm E}$ or $R_{\rm E}$ will always be clear from context.) It turns out that $R_{\rm E}$ is roughly the geometric mean of the Schwarzschild radius and the lens distance. Thus for the ANDROMEDA GALAXY, $R_{\rm E}$ is some tens of parsecs—much smaller than the galaxy itself. However, a similar galaxy at cosmological distances will have $R_{\rm E}$ comparable with or bigger than its own size, and thus can produce strong lensing. Masses that are smaller than their $R_{\rm E}$ are said to be 'compact' to lensing.

In practice, Einstein rings are rarely observed. The reason is that the above scenario for forming one requires a perfectly circular lens and a perfectly aligned source. These improbable requirements relax a little if the source is very broad, however, and a few examples have been observed. Nevertheless, the *concept* of an Einstein ring is very important, because even if there is no Einstein ring the interesting strong lensing behavior all happens over a scale of $\theta_{\rm E}$. The larger $\theta_{\rm E}$, the likelier it is that there are some background sources to strongly lens. Thus from the above expression for $\theta_{\rm E}$ one can easily infer that lensing by massive galaxies ($M \sim 10^{12} M_\odot$ and $\theta_{\rm E}$ perhaps $\sim$1 arcsec) is much likelier than lensing by nearby stars (where $\theta_{\rm E} \ll 1$ arcsec), while rich clusters of galaxies (with $M \gtrsim 10^{14} M_\odot$ and $\theta_{\rm E} \sim 10$ arcsec) are even more favorable for lensing.

◊ *The Einstein radius and other scales*

Expressions for $\theta_{\rm E}$ and $R_{\rm E}$ are easily derived by considering the lens equation for a collinear point mass and source, i.e. $\boldsymbol{\theta}_{\rm S} = 0$ and $\Sigma(\boldsymbol{\theta}) = M\delta(\boldsymbol{\theta})$. The lens equation is trivially solved by $\theta = \theta_{\rm E}$, with

$$\theta_{\rm E}^2 = \frac{4GM}{c^2} \frac{D_{\rm LS}}{D_{\rm L} D_{\rm S}} \qquad R_{\rm E}^2 = \frac{4GM}{c^2} \frac{D_{\rm L} D_{\rm LS}}{D_{\rm S}}. \tag{4}$$

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

As mentioned in the previous section

$$R_{\rm E} \sim (\text{Schwarzschild radius} \times D_{\rm L})^{1/2}. \qquad (5)$$

By a Gauss law type argument, for any circular mass distribution $\Sigma(\theta_r)$, $\Psi(\boldsymbol{\theta})$ and $\boldsymbol{\alpha}(\boldsymbol{\theta})$ will be influenced only by interior mass. So any circular distribution of the mass M, *provided that it fits within an Einstein radius*, can produce an Einstein ring.

For given $D_{\rm L}$, $D_{\rm S}$, to obtain a compact object one needs to pack a mass (in projection) into a circle of radius $\theta_{\rm E}$, but the area of the circle is proportional to the mass. It follows that there is a critical density, say $\Sigma_{\rm crit}$, such that if $\Sigma \geq \Sigma_{\rm crit}$ somewhere then there is a compact (sub)object. Working out the algebra we easily find

$$\Sigma_{\rm crit} = \frac{D_{\rm L} D_{\rm S}}{D_{\rm LS}} \frac{c^2}{4\pi G}. \qquad (6)$$

If now we define κ as the projected mass density in units of the critical density, equation (3) can be rewritten as

$$\boldsymbol{\nabla}\tau(\boldsymbol{\theta}) = 0 \qquad \tau(\boldsymbol{\theta}) = \tfrac{1}{2}(\boldsymbol{\theta} - \boldsymbol{\theta}_{\rm S})^2 - \psi(\boldsymbol{\theta})$$

$$\psi(\boldsymbol{\theta}) = \frac{1}{\pi} \int \kappa(\boldsymbol{\theta}') \ln|\boldsymbol{\theta} - \boldsymbol{\theta}'| \, {\rm d}^2\boldsymbol{\theta}'$$

$$T(\boldsymbol{\theta}) = (1 + z_{\rm L}) \frac{D_{\rm L} D_{\rm S}}{c D_{\rm LS}} \tau(\boldsymbol{\theta}). \qquad (7)$$

From the second line of equation (7) it should be evident that ψ satisfies a two-dimensional Poisson equation

$$\nabla^2 \psi = 2\kappa. \qquad (8)$$

Note that the first two lines in equation (7) involve only dimensionless quantities and the scale of $T(\boldsymbol{\theta})$ is set entirely by the distances and lens redshift. ♦

On images and magnification

Let us now see what can happen to the arrival time surface from masses of arbitrary shape. For small masses, the shape changes slightly from being a parabola and the mininum moves a little. However, for large enough mass, a qualitative change occurs, in that a contour of constant arrival time becomes self-crossing. There are two ways in which a self-crossing can develop: as a kink on the outside of a contour line or a kink on the inside. These are illustrated in figure 3. The outer-kink type is topologically a lemniscate and the inner-kink type a limaçon. If the original contour loop enclosed a minimum then a lemniscate produces another minimum, plus a saddle-point at the self-crossing, while a limaçon produces a new maximum plus a saddle point. (Interchange maximum and minimum in the previous sentence if the original loop enclosed a maximum.) The process of contour self-crossing can then repeat around any of the new maxima and minima, producing more and more new images, but always satisfying

$$\text{maxima} + \text{minima} = \text{saddle points} + 1.$$

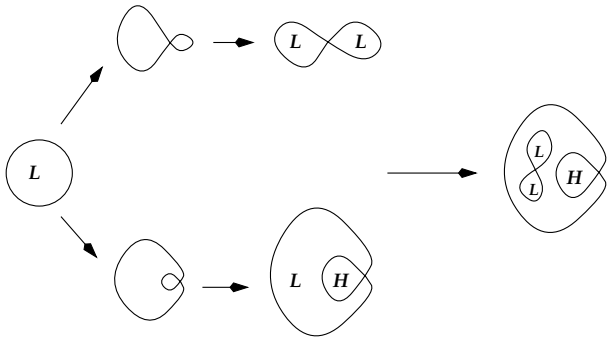

Figure 3. Multiple images via self-crossing contours in the arrival time surface. Here L marks minima and H marks maxima.

The rightmost part of figure 3 shows a typical configuration in observed systems.

Multiple images are not all equally bright. It turns out that each image is magnified by an amount equal to the inverse of the curvature of the arrival time surface. This curvature need not be the same in all directions. Very stretched images (of which an Einstein ring is an extreme example) correspond to very small curvature in one direction with larger curvature in the perpendicular direction. The standard way of quantifying lensing magnification (also called amplification in the literature) is through the 'convergence' which is total change in brightness and the 'shear' which is the amount and direction of stretching.

If the lens's mass density is infinite anywhere (as for any point mass, or say a galaxy with a central BLACK HOLE) the arrival time surface is going to have a needle-sharp but infinitely high maximum at that point, and, while this will formally be an image, because of the needle-sharp curvature the image will be (de)magnified to nothing. For example the five-image configuration in figure 3 is always in practice a four-image system, with the maximum completely demagnified by a very high central density in the lens.

Surface brightness (photon flux per unit sky area per unit telescope area) is conserved by lensing. Magnification changes only angular sizes on the sky. Thus a constant surface brightness sheet stays a constant brightness sheet when lensed. If this were not the case, the microwave background would be wildly lensed by large-scale structure. Polarization of light is also unaffected by lensing.

For unresolved sources, magnification is not observed directly; only their total luminosity changes under lensing. This leads to an interesting effect known as magnification (or amplification) bias. Imagine an unlensed patch of sky that has been surveyed down to some brightness limit for some type of unresolved objects. Now imagine the same patch lensed with some magnification factor A, for definiteness say $A > 1$. This magnification will increase the area of the patch by A, and if the survey area stays

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the same the source area will be reduced by A. Thus the number of objects available will also be reduced by A. However, at the same time all the objects will be brightened by A, so some objects that were originally below the survey brightness limit will now climb above it. The net effect depends on the luminosity function: if going fainter leads to enough new objects (a steep luminosity function) then the net effect will be an increase in the number of sources detected, otherwise there will be a net decrease.

Magnification

Magnification is formalized as the derivative of the image position with respect to the source position. It is a tensor, which we denote by $\mathbf{M}$. We have

$$\mathbf{M}^{-1} = \frac{\partial \boldsymbol{\theta}_{\rm S}}{\partial \boldsymbol{\theta}} = \frac{\partial^2}{\partial \boldsymbol{\theta}^2} T(\boldsymbol{\theta}). \tag{9}$$

In Cartesian coordinates

$$\mathbf{M}^{-1} = \begin{bmatrix} 1 - \dfrac{\partial^2 \psi}{\partial \theta_x^2} & \dfrac{\partial^2 \psi}{\partial \theta_x \partial \theta_y} \\ \dfrac{\partial^2 \psi}{\partial \theta_y \partial \theta_x} & 1 - \dfrac{\partial^2 \psi}{\partial \theta_y^2} \end{bmatrix} \tag{10}$$

It is helpful to write $\mathbf{M}^{-1}$ in terms of its eigenvalues, and the usual form is like

$$\mathbf{M}^{-1} = (1-\kappa) \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} - \gamma \begin{pmatrix} \cos 2\phi & \sin 2\phi \\ \sin 2\phi & -\cos 2\phi \end{pmatrix}. \tag{11}$$

The first term in equation (1) is the trace part—and comparing equations (10) and (8) shows that it must be κ—while the second term is traceless. The κ part produces an isotropic expansion or contraction, while the γ part produces a stretching in the ϕ direction and a shrinking in the perpendicular direction; κ is known as 'convergence' and γ as 'shear'.

The determinant of $\mathbf{M}$ can be thought of as a scalar magnification:

$$|\mathbf{M}| = [(1-\kappa)^2 - \gamma^2]^{-1}. \tag{12}$$

The places where one of the eigenvalues of $\mathbf{M}^{-1}$ becomes zero (and in consequence $|\mathbf{M}|$ is infinite) are in general curves and are known as critical curves. When critical curves are mapped onto the source plane through the lens equation, they give caustics; a point source lying on a caustic is infinitely magnified. Some straightforward algebra shows that for a point mass

$$|\mathbf{M}|^{-1} = 1 - \frac{\theta_{\rm E}^4}{\theta_r^4} \tag{13}$$

and that for a circular mass distribution $\Sigma \propto \theta_r^{-1}$

$$|\mathbf{M}|^{-1} = 1 - \frac{\theta_{\rm E}}{\theta_r}. \tag{14}$$

The latter case is known as the 'isothermal lens' after the isothermal sphere in stellar dynamics.

One way of proving that surface brightness is conserved by lensing is by setting up a correspondence with Hamiltonian dynamics. Let us write z for the axial coordinate in figure 2, and $\boldsymbol{w}$ for the transverse coordinates, and allow for observers at arbitrary $\boldsymbol{w}$, z. A photon trajectory can be expressed as $\boldsymbol{w}(z)$, and an observer at $\boldsymbol{w}$, z sees the photon coming from direction $\boldsymbol{\theta} = \mathrm{d}\boldsymbol{w}/\mathrm{d}z$ (in the small-angle regime). In these coordinates the lens equation $\boldsymbol{\theta}_{\rm S} = \boldsymbol{\theta} - \boldsymbol{\nabla}\psi(\boldsymbol{\theta})$ becomes

$$\begin{aligned} &\boldsymbol{\theta}(\boldsymbol{w}_{\rm obs}, z_{\rm obs}) - \boldsymbol{\theta}(\boldsymbol{w}_{\rm source}, z_{\rm source}) \\ &\qquad = (z_{\rm obs} - z_{\rm lens}) \frac{\partial}{\partial \boldsymbol{w}} \psi \left(\frac{\boldsymbol{w}_{\rm lens}}{z_{\rm obs} - z_{\rm lens}} \right). \end{aligned} \tag{15}$$

However, this is a solution of Hamilton's equations for the Hamiltonian

$$H = \tfrac{1}{2}\boldsymbol{\theta}\cdot\boldsymbol{\theta} - (z_{\rm obs} - z_{\rm lens}) \psi \left(\frac{\boldsymbol{w}_{\rm lens}}{z_{\rm obs} - z_{\rm lens}} \right) \delta(z - z_{\rm lens}) \tag{16}$$

with z as a formal time variable and $\boldsymbol{\theta} = \mathrm{d}\boldsymbol{w}/\mathrm{d}z$ identified as the momentum. By Liouville's theorem (or equivalently the collisionless Boltzmann equation), the photon density (say f) in the phase space of ($\boldsymbol{w}$, $\boldsymbol{\theta}$) space is conserved along photon trajectories. This f must be conserved by the act of placing the lens there too—think of f before and after going through the lens. In fact f is nothing but the surface brightness, because θ corresponds to sky area and $\boldsymbol{w}$ to telescope area. This proves surface brightness conservation, although we must be careful with two things about interpretation. First, because the result is 'along photon trajectories' we must always be looking at photons from the same source; so if the image is moved in the sky by lensing we must follow it when we measure surface brightness. Second, z here is just a formal variable and is neither time nor REDSHIFT, so the above does not imply that surface brightness is independent of redshift.

Lensing in the Milky Way

The Einstein radius for lensing of a Milky Way star by another star or a brown dwarf is, for typical distances, only ~1 AU for $R_{\rm E}$ and <1 marcsec for $\theta_{\rm E}$. Nevertheless, because of stellar motions, stars do occasionally manage to come within an Einstein radius (in projection of course) of lenses in the Milky Way. The fraction of source stars in a field that are doing this at a given time is known as the microlensing optical depth, and it is of order 10^{-6} in the Milky Way. ('Microlensing' is a term used when stellar-mass lenses are important.) As the source enters and then exits the Einstein radius of the lens, the image brightens and then dims again in a characteristic way, over timescales of weeks to months. Such lensing is now being detected by large surveys that monitor ~10^7 stars, searching for the characteristic behavior of the brightness. The aim of these surveys is to measure the optical depth in different directions and thence infer something about the mass density in compact objects in the Milky Way.

Microlensing optical depth

Approximating a star or a brown dwarf as a point lens, there will be two images, at

$$|\boldsymbol{\theta}| = \tfrac{1}{2}[|\boldsymbol{\theta}_S| \pm (|\boldsymbol{\theta}_S|^2 + 4\theta_E^2)^{1/2}]. \quad (17)$$

The image separation is too small to resolve. What will be observed is a brightening equal to the combined magnification of both images. Using equation (13) for the magnification, and adding the absolute values of $|\mathbf{M}|$ at the two image positions, we obtain the total brightness amplification

$$A_{\rm tot} = \frac{u^2+2}{u(u^2+4)^{1/2}} \qquad u = \frac{|\boldsymbol{\theta}_S|}{\theta_E}. \quad (18)$$

If the background source star has impact parameter b and velocity v (projected onto the lens plane) with respect to the lens, then

$$u = \frac{(b^2 + v^2t^2)^{1/2}}{R_E}. \quad (19)$$

Inserting equation (19) into (18) gives us $A_{\rm tot}(u)$, i.e. the light curve, plotted for three different b in figure 4. The height of a measured light curve immediately gives R_E/b, and the width gives R_E/v.

We can express the microlensing optical depth (usually denoted by τ) as follows. Using equation (4) for R_E, the total area covered by the Einstein rings of lenses at distances between D_L and $D_L + \mathrm{d}D_L$ in a patch of sky is

$$\frac{4\pi GM}{c^2 D_S} D_L D_{LS} \rho(D_L)\,\mathrm{d}D_L \times \langle \text{area of patch} \rangle. \quad (20)$$

To obtain the fraction of sky covered by Einstein rings, we divide equation (20) by the area and integrate over D_L, giving

$$\tau = \frac{4\pi G}{c^2 D_S} \int_0^{D_S} D_L D_{LS} \rho(D_L)\,\mathrm{d}D_L. \quad (21)$$

The really nice thing about this formula is that it does not depend on the mass distribution of the lenses, as long as each mass fits within its own Einstein radius (diffuse gas clouds do not count, nor does any kind of diffuse dark matter). So τ estimated from light curve monitoring could be used to make inferences about ρ.

Although trying to resolve the images in microlensing seems hopeless with foreseeable technology, it may be possible to track the moving double image indirectly. By combining the positions and magnifications of the two images, we have for the centroid

$$\theta_{\rm cen} = \frac{u(3+u^2)}{2+u^2}\theta_E. \quad (22)$$

Since images can be centroided much better (10^2–10^3 times more precisely) than they can be resolved, measuring the proper motion of the centroid seems a realistic prospect.

Lensing by galaxy clusters

At the other end of the lensing scale, we have clusters of galaxies, which are the most effective lensers of all. A rich cluster at cosmological distance will be effective for lensing over a large enough patch of sky to include plenty of background objects (faint blue galaxies) to lens. A number of clusters show all the regimes of lensing, with multiple-image systems in the inner region, arcs and arclets (highly stretched single images) outside of that and statistical stretching in the outer regions. Each of these regimes contributes different types of information about the mass distribution. Now galaxy clusters are generally not in dynamical equilibrium (there have not been enough crossing times since they formed), so their mass distributions tend to be more complicated than those of single galaxies. This makes it all the more important to have good ways of mapping cluster masses, and makes clusters particularly interesting to researchers in lensing.

Lensing constraints on clusters

There are several approaches in the literature to mass-mapping clusters from lensing data. The following sketches one approach.

Cluster lensing data provide three types of information:

(i) multiple image positions $\boldsymbol{\theta}_1$, $\boldsymbol{\theta}_2$ and so on;
(ii) relative brightnesses at $\boldsymbol{\theta}_1$, $\boldsymbol{\theta}_2$ and so on;
(iii) elongated images of sources may be obvious (arcs and arclets) or statistical (requiring a large number of background galaxies to measure).

Going back to equation (7), these can be translated into three types of constraints on $\kappa(\boldsymbol{\theta})$.

(i) Image positions imply $\boldsymbol{\nabla}\tau(\boldsymbol{\theta}_1) = \mathbf{0}$, $\boldsymbol{\nabla}\tau(\boldsymbol{\theta}_2) = 0$ and so on. From equation (7) these are clearly dimensionless linear constraints on $\boldsymbol{\theta}_S$ and $\kappa(\boldsymbol{\theta})$. (If there is more than one multiple-image system, there will be a separate $\boldsymbol{\theta}_S$ for each of these.)
(ii) Relative brightnesses are constraints of the type

$$\boldsymbol{\nabla}\boldsymbol{\nabla}\tau(\boldsymbol{\theta}_1) = \langle \text{measured number} \rangle \times \boldsymbol{\nabla}\boldsymbol{\nabla}\tau(\boldsymbol{\theta}_2).$$

(iii) Elongated images (whether arclets or statistical elongations) provide constraints of the type

$$k\frac{\partial^2}{\partial\theta_{x'}^2}\tau(\boldsymbol{\theta}_1) \le \frac{\partial^2}{\partial\theta_{y'}^2}\tau(\boldsymbol{\theta}_1)$$

where $\theta_{x'}$ and $\theta_{y'}$ are a coordinate system rotated to align with the observed direction of the elongation. This equation expresses the statement that the magnification along $\theta_{x'}$ is at least k times the magnification along the $\theta_{y'}$ direction. Provided that the elongation direction is well-measured, the constraint is linear in $\kappa(\boldsymbol{\theta})$.

Types (i) and (ii) are strong lensing constraints and available only in the inner regions of rich clusters. Type (iii)

constraints apply also in the the weak lensing regime and can be extracted over a much larger area (∼5 times further out).

Expressed as above, cluster mass reconstruction becomes an underdetermined problem with linear, plus possibly some quadratic, constraints in both strong and weak lensing regimes. It is thus a relative of image reconstruction problems. The standard way of proceeding to derive an image (or a mass map in this case) would be to pixellate $\kappa(\boldsymbol{\theta})$, select some figure of merit on κ such as smoothness or entropy and then optimize it subject to the data constraints.

Multiple-image quasars

These occur when a QUASAR (or other small but very bright object) is strongly lensed by a foreground galaxy and produces two or four images with arcsec order separations. (A third or fifth image is invariably demagnified to undetectability by the lens's high-density core.) These are of some interest for constraining the masses of the lensing galaxies, but they are perhaps much more interesting to astrophysicists for two other reasons.

The first is that since quasars are often very time variable and the different images have different arrival times, the images will show the same time variability, but with offsets. These offsets, or differences in arrival times, are unique among lensing observables, because they are dimensional. All other lensing observables, i.e. image positions and magnifications, are dimensionless. Measuring a dimensional quantity immediately sets a scale for the system. That scale is the distance scale, which in a cosmological context amounts to HUBBLE'S CONSTANT. Unfortunately, an accurate measurement of variability offsets does not immediately give an accurate determination of Hubble's constant, because the offsets also depend on the distribution of mass in the lens plane; the latter still needs to be determined or modelled somehow. Still, the prospect of measuring Hubble's constant from lensing is attractive because it involves no extra physics apart from gravitation, thus hopefully leaving less room for the sort of systematic errors that plague Hubble constant estimates.

The second has to do with the extremely small size of quasars in optical continuum. Now the mass distribution of a galaxy is not perfectly smooth; it becomes granular on the scale of individual stars. This produces a very complicated network of critical lines (in the lens plane), and a corresponding complicated network of caustics in the source plane (like the pattern at the bottom of a swimming pool). The optical continuum emitting regions of quasars are small enough to fit between the caustics, but the line emitting regions straddle several caustics. As proper motions move the caustic network, the continuum region will sometimes cross a caustic, and show a sudden change in brightness; the time taken for the brightness to change is the time it take to cross the caustic. This is the phenomenon of quasar microlensing: continuum shows it but lines do not. (It is just the gravitational version of stars twinkling and planets not twinkling.) This has been observed, and modelling the caustic network and putting in plausible values for the proper motion leads to an estimate of the intrinsic size of the continuum source. The conclusion is that the optical continuum regions of a quasar—the heart that emits much more light than the entire host galaxy—cannot be much larger than the solar system.

Arrival times and Hubble's constant

In equation (7) $\tau(\boldsymbol{\theta})$ is dimensionless while $T(\boldsymbol{\theta})$ has dimensions of time, and the factor relating them is $\propto H_0^{-1}$. (This factor actually depends on Ω and Λ as well, but a case such as $z_{\rm L} < 0.5$, $z_{\rm S} > 2$, the Ω and Λ dependences are very weak.) So if we can measure the arrival time difference $T(\boldsymbol{\theta}_1) - T(\boldsymbol{\theta}_2)$ between two images (and accurate measurements are now starting to appear) and we know $\kappa(\boldsymbol{\theta})$, we can determine H_0.

The difficulty here is that we need to know $\kappa(\boldsymbol{\theta})$, because for a given $T(\boldsymbol{\theta}_1) - T(\boldsymbol{\theta}_2)$ the inferred H_0 can vary by a factor of several depending on the $\kappa(\boldsymbol{\theta})$ assumed. However, naturally, we can use the lensing data

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

themselves to help constrain $\kappa(\boldsymbol{\theta})$. The constraints (i) and (ii) from the cluster lensing case are available here also, since we have a multiple-image system. Constraints of the type (iii) may possibly be available. If there are more than two images then a fourth type of constraint exists, which comes from the ratio of arrival time differences between different pairs of images, i.e.

$$T(\boldsymbol{\theta}_1) - T(\boldsymbol{\theta}_2) = \langle \text{measured number} \rangle \times [T(\boldsymbol{\theta}_2) - T(\boldsymbol{\theta}_3)].$$

Some algebra from equation (7) shows that this is a dimensionless linear constraint on $\boldsymbol{\theta}_S$ and $\kappa(\boldsymbol{\theta})$.

That the lensing constraints are mostly linear and at worst quadratic is a useful simplification, but still the number of constraints possible is small and leaves $\kappa(\boldsymbol{\theta})$ underdetermined, implying some residual uncertainty in H_0 even for perfect lensing data. Hopefully this uncertainty can be reduced by well-motivated modelling or other observations constraining $\kappa(\boldsymbol{\theta})$. However, whether the residual uncertainty in H_0 for any system can be made small enough to be interesting is at present an unanswered question.

Bibliography

The lensing literature being as large as it now is, the following cannot hope to be comprehensive. However, here are pointers to a number of key papers in the development of the field, and to some recent surveys of research in the field.

The first person to take gravitational lensing seriously as an observational prospect appears to have been Zwicky, in

Zwicky F 1937 *Phys. Rev.* **51** 290, 679

It is interesting to compare these papers with

Einstein A 1936 *Science* **84** 506

Einstein sounds almost apologetic for publishing the results for a point lens, because stellar lenses seemed improbable to observe. Zwicky, writing the following year, points out that for galaxies and clusters of galaxies the situation is very different, and lensing becomes 'virtually a certainty'.

Discoveries of the first two lensed systems (both multiply imaged quasars) appeared in

Walsh D, Carswell R F and Weymann R J 1979 *Nature* **279** 381
Weymann R J, Latham D, Angel J R P, Green R F, Liebert J W, Turnshek D A, Turnshek D E and Tyson J A 1980 *Nature* **285** 641

The first arcs in clusters were reported in

Soucail G, Fort B, Mellier Y and Picat J P 1987 *Astron. Astrophys.* **172** L14
Lynds R and Petrosian V 1987 *Bull. Am. Astron. Soc.* **18** 1014

The study of statistical weak lensing by clusters was initiated by

Tyson J A, Wenk R A and Valdes F 1990 *Astrophys. J.* **349** L1

The first quasar microlensing event is in

Irwin M J, Webster R L, Hewett P C, Corrigan R T and Jedrzejewski R I 1989 *Astron. J.* **98** 1989

The first galactic microlenses were published in

Alcock C *et al* 1993 *Nature* **365** 621
Aubourg E *et al* 1993 *Nature* **365** 623
Udalski A *et al* 1993 *Acta Astron.* **43** 289

Our present understanding of lensing theory is due very largely to Sjur Refsdal. The now-standard approximations and basic methods of calculation, and the relation between time delays and Hubble's constant, are set out in

Refsdal S 1964 *Mon. Not. R. Astron. Soc.* **128** 295
Refsdal S 1964 *Mon. Not. R. Astron. Soc.* **128** 307

These long preceded the discovery of the first lens. Quickly following the discovery of the first lensed system

Chang K and Refsdal S 1979 *Nature* **282** 561

predicted microlensing in lensed quasars. Further developments of the formalism appeared in

Kayser R and Refsdal S 1983 *Astron. Astrophys.* **128** 156

introducing the wavefront picture, and

Blandford R D and Narayan R 1986 *Astrophys. J.* **310** 568
Schneider P 1985 *Astron. Astrophys.* **143** 413

which introduce Fermat's principle by very different routes.

The most comprehensive book on lensing is

Schneider P, Ehlers J A and Falco E E 1992 *Gravitational Lenses* (Berlin: Springer)

The most recent conference proceedings covering all aspects of lensing is

Brainerd T G and Kochanek C S (ed) 2000 Gravitational lensing: recent progress and future goals *ASP Conference Series*

For eight unsolved problems in gravitational lensing, see

Blandford R D 1997 *Unsolved Problems in Astrophysics* ed J N Bahcall and J P Ostriker (Princeton, NJ: Princeton University Press)

Gravitational Lensing by Clusters of Galaxies

CLUSTERS OF GALAXIES are massive and relatively rare objects containing hundreds of galaxies. Their huge mass—dominated by DARK MATTER—bends light from all background objects, systematically distorting the images of thousands of distant galaxies (shear). This observed gravitational lens distortion can be inverted to produce an 'image' of the mass in the foreground cluster of galaxies. Most of the mass in clusters of galaxies is dark matter, not the stars, gas and dust associated with the galaxies in the cluster. This dark matter outweighs ordinary matter by at least 10:1, and GRAVITATIONAL LENSING studies of the dark matter distribution around clusters promise a deeper understanding of the nature of dark matter and the scenario of structure formation.

The most direct method currently available to determine the entire mass distribution of a galaxy cluster is gravitational lensing. How does one get from the observed distorted forest of background galaxies to a map of the mass responsible for the distortion? The optimal method of inverting the observed galaxy distortions to obtain the projected mass map depends on the number of observational constraints. In turn, the resolution of the mass map will be proportional to the density of constraints on the plane of the sky. Strong lensing (multiple resolved images of a single source) can offer high mass resolution near the source image positions, but the resolution degrades far from these positions. Weak lensing (single distorted images of each resolved source) is ubiquitous since there are nearly a million background galaxies per square degree anywhere on the sky, and can yield moderate resolution maps of projected mass over wide areas. Figure 1 shows a good example of gravitational lensing (both strong and weak) by a cluster of galaxies.

The properties of clusters are functions both of the dynamical processes operating within them and of the underlying cosmology. While the present epoch mass function gives the parameters of the mass fluctuation spectrum on cluster scales, changes measured at higher REDSHIFT depend on cosmological parameters. Previous work has used the temperature (or equivalently the cluster velocity dispersion) distribution as a proxy for the mass. The average matter density of the universe Ω_m has been estimated by extrapolating observations of cluster luminosities to the rest of the universe and assuming the mass-to-luminosity ratio is the same for clusters and the universe as a whole. If we could explore mass structure and pin down Ω_m via direct observations of mass, this would significantly clarify cosmology. Recently, the first steps have been taken toward addressing three fundamental questions: what is the total mass of clusters, how is the mass distributed within clusters, and how does the cluster's mass evolve over time? Comparisons of the cluster mass spectrum, particularly its evolution over cosmic time, with N-body simulations of dark matter structure formation for different cosmological models can in principle be used to distinguish among these models.

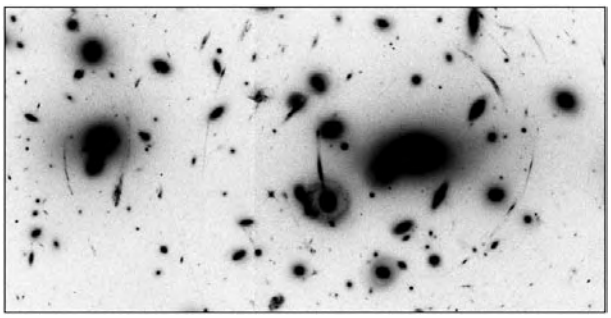

Figure 1. A Hubble Space Telescope image of the cluster of galaxies A2218, showing multiple 'arcs': lens-distorted images of background galaxies. The mass of the dark matter in the cluster is far greater than the mass of all the stars. This mass bends light rays from distant galaxies, causing a tangential 'stretching' of the images of the background galaxies. Courtesy W Couch (University of New South Wales), R Ellis (Cambridge University), and NASA.

Background sources

Observations of distant GALAXIES AT HIGH REDSHIFT suggest that we are seeing these galaxies at the epoch of formation of much of their stellar content. The resulting UV-bright spectrum, when redshifted to redshifts of 1–3, would produce the observed blue spectral shape. This backdrop of distant galaxies may be used as a tool for studying foreground mass concentrations. Their unusual spectral shape makes it particularly easy to distinguish them from red cluster galaxies which have been swept of most of their gas and thus are not undergoing STAR FORMATION. Light from the forest of distant galaxies passes by and through a foreground cluster of galaxies. For small impact parameters, close to the cluster center, gravitational lensing of a chance projection of one of these distant galaxies is strong enough to produce multiple images (strong lensing). Farther out, lensing distorts the shape of all distant galaxies (weak lensing).

Gravitational lensing studies of clusters of galaxies present an opportunity to learn about the properties of dark matter via its clustering properties on a variety of spatial scales. Of interest is the mass profile near the center (from strong lensing observations) to probe dark matter at peak densities, the mass profile at large distance from the cluster to probe the nature of structure formation (from weak-lensing observations), the correlation with luminosity, and mass segregation between galaxies and the totally dark component. Using mosaics of CCDs, wide-field weak-lensing studies can now map the mass out towards the linear regime beyond 2 Mpc radius. Both observations and N-body cold dark matter (CDM) simulations show a steep mass drop-off at large radii in clusters.

Strong lensing

A single background galaxy, if placed by chance directly behind the cluster lens, is heavily distorted into one or more long arcs concentric with the mass centroid of the cluster. This type of strong lensing forms the basis of the highest resolution mass maps. In cases where multiple images of a source are created by the lens, the details of the position and distortion of these sub-images are highly sensitive to the projected 2-dimensional mass distribution within the lens. Parametric models of the lens mass can then be used to first unlens the sub-images to get an image of the source, and then ray trace light from this source past the lens in an iterative fit in the image plane for the lens mass parameters.

As an example, figure 2 shows a high-resolution mass map of the cluster 0024 + 1654, some three billion light-years distant, based on parametric inversion of the associated gravitational lens. This lens creates eight well resolved whole or partial sub-images of a background galaxy, seen in deep imaging with the HUBBLE SPACE TELESCOPE. Excluding mass concentrations centered on visible galaxies, more than 98% of the remaining mass is represented by a smooth concentration of dark matter centered near the brightest cluster galaxies, with a 50 kpc soft core (throughout we use Hubble constant $H_0 = 70$ km s^{-1} Mpc^{-1}). The dark matter distribution we observe in CL0024 is far more smooth, symmetric, and nonsingular than in typical simulated clusters using the CDM model. Inside 160 kpc radius, the rest-frame mass-to-light ratio is 170 times the solar value, rising with radius. Because galaxies were brighter in the past, this translates to a current mass-to-light ratio of 280. For scale, we would need around 1400 for an average cluster to extrapolate to a closed universe.

The mass core radius is smaller than most observed x-ray core radii in nearby clusters, suggesting that the x-ray gas may be less relaxed dynamically than the dark matter. Recent high resolution N-body simulations of dark matter clustering develop mass cores much smaller than the observed mass cores. Perhaps there are other physical mechanisms at work in the cores of clusters, beyond gravitational instability and merging of dark matter halos, which are capable of damping the buildup of the mass at the center. But strong lensing events like this are rare. The large mass associated with rich clusters of galaxies distorts background galaxy images over a large area of the sky. To accurately measure this effect, deep multi-wavelength imaging to 29th magnitude over a wide field must be obtained.

(*b*)

Figure 2. (*a*) A Hubble Space Telescope image of the redshift 0.4 cluster CL0024+1654. Multiple images (A–E) of a $z = 1.6$ background galaxy may be seen. **This figure is reproduced as Color Plate 17.** (*b*) A contour map of the projected mass density in CL0024+1654, obtained by fitting the observed distorted images of the source galaxy. The concentrated dark matter halos of individual cluster galaxies can be seen. However, most of the mass in the cluster is in a smooth non-singular distribution.

Statistical weak lensing

Foreground GALAXY CLUSTERS at redshifts 0.2–0.5 with radial velocity dispersions above 700 km s^{-1} have sufficient mass density to significantly distort background galaxies of redshift greater than 0.4–1. Lensing preserves the surface brightness and spectrum of the source, so that most lensed sources have the very faint surface brightness and blue color of the faint blue galaxies.

Since there are roughly 100 independent resolved sources per square arcminute, this enables a different kind of solution to the inverse problem, called 'statistical weak lensing'. This method has the advantage that it is generally applicable, and gives good signal-to-noise inversions in regions of low shear which are much more representative of random regions. In statistical weak

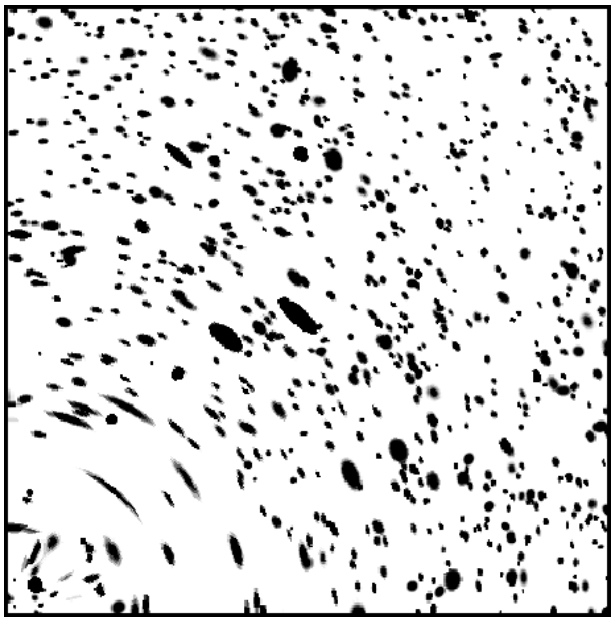

Figure 3. A simulated field, several arcminutes wide, looking through the forest of galaxies out to redshift 3. The effects of a dark matter concentration of the type found in a massive cluster centered at lower left are shown.

lensing it is necessary to average over the apparent orientation of many sources for each mass resolution element; this is why weak-lens statistical inversion uses tens of thousands of distorted background galaxies over a wide field. The largest source of noise in weak-lens inversion of deep optical images is the ellipticity noise of the source population itself; galaxies are not round and they come in all orientations. A number of non-parametric, regularized algorithms have been developed for inverting the distortion field represented by the observed distorted source galaxy images. A simulation of both weak and strong lensing is shown in figure 3. First, a long cone is populated with galaxies of appropriate size and luminosity, out to redshift 3. Then a cluster mass is placed at redshift 0.3, distorting the images of these background galaxies.

To construct a map of the gravitational lens projected mass distribution, we need to estimate the distortion at each point in the field. Start with the (r, θ) principal-axis transformed second moments of the intensity I (the tangential and radial components of the major axis a and minor axis b) for each background galaxy image g about some point on the sky (x, y). The excess tangential alignment about that point is then given by the distortion statistic

$$T_g(x, y) \;=\; (a^2 - b^2)/(a^2 + b^2)$$

For example, about position (0,0) in figure 3 this tangential alignment is high. In the weak-lensing limit it can be shown that the integral of the tangential alignment T around a circle of radius r about the point (x_0, y_0) is a measure of the mass contrast interior:

$$\int_c T(\vec{r}, x_0, y_0)\, \mathrm{d}^2 r \;=\; 2\,[\Sigma_{\mathrm{av}}(< r) - \Sigma(r)]\;\Sigma_c^{-1},$$

where Σ_c is the critical mass density for lensing the source onto the observer. A typical value for Σ_c for lenses at moderate redshift is 1 g cm^{-2}. To construct an image of the gravitational lens projected mass distribution, the distortion statistic $T(x, y)$ may be computed over a grid of positions as candidate lens centers. The average projected mass density at point (x, y) on the sky, with resolution rmin, is given by

$$\bar{\Sigma}(x, y) \;=\; \Sigma_0 \int \frac{G(r)}{r^2} T(\vec{r}, x, y)\, \mathrm{d}^2 r \;+\; \bar{\Sigma}_{\mathrm{outer}},$$

where Σ_0(rmin, rmax, zs, zl) is a function of the source and lens redshifts and is calibrated with strong lensing cluster test masses, G(r, rmin, rmax) is an apodizing filter which smoothly cuts on at rmin and off at rmax, and $\bar{\Sigma}_{\mathrm{outer}}$(rmin, rmax) is the average density in the annulus between rmin and rmax. $\bar{\Sigma}(x, y)$ is a direct map of the projected mass density.

In practice, a catalog of faint blue galaxy positions, total magnitudes, and second moments of flux is passed to the lens arclet inversion software. Currently there are more than 30 clusters with weak-lensing mass estimates. The center of (lensing) mass corresponds well to the center of optical light. The lens projected mass overdensity (see second equation above) as a function of radius from the centroid of the mass distribution may be compared to the lens cluster light (baryonic) distribution. The smoothed optical light distribution traces the (lensing) mass well. Despite earlier indications that the x-ray derived mass disagreed with the lensing mass inside 200–300 kpc, recent measurements of both quantities out to 1 Mpc radius show that the two methods are in closer agreement inside this larger radius. This suggests that the assumptions of pressure support and isothermality for the x-ray gas break down inside $\sim$ 300 kpc. This has been resolved, in large part due to wide-field imaging of cluster lenses. Until recently, observations of lensing, x-rays, and galaxy velocities (i.e. virial mass) were often made on very different physical scales and this appears to have contributed to the confusion in the literature as to which of the three independent mass estimates for a given cluster was correct. As multiband deep imaging becomes more common in lensing work, color-redshifts will enable weak-lens studies of clusters at high redshift.

Mass and light in typical clusters

Many clusters studied in this way have been chosen for their high x-ray luminosity. This may bias the statistics of mass in clusters. A recent weak-lensing survey studied ten x-ray selected 'normal' clusters of galaxies with a wide-field CCD mosaic camera. Mass and light in a sample of clusters of galaxies of typical x-ray luminosity at redshifts ($z = 0.15$–0.25) were studied. These clusters

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

are more representative of cluster mass distribution than the rare x-ray luminous rich clusters studied so far. Out to 3 Mpc radius, mass generally traces light. Some of the cluster mass profiles are flatter than isothermal in a central region, with downturns at radii beyond 2 Mpc. Outside the core, these profiles are well-fit by N-body cold dark matter clustering simulations. Mass-to-light ratios at red wavelengths in the cluster rest frame scatter around 350, with no systematic trend with mass. Scaling the average M/L by the luminosity density leads to an estimate for the mean mass density of $\Omega_{\rm m} = 0.2$. But there may be low mass density regions in the huge volume outside clusters. Taking all the clusters observed to date (both high and low x-ray luminosity), lensing-inferred mass to light ratios bracket a broad range, from $200h$ to $800h$ (in solar units), with most of the clusters being in the low to middle part of this range (Here, $h = H_0/100$.)

Beyond clusters

Weak lensing is a tool which may be applied anywhere on the sky. One may even search for mass overdensities comparable to clusters without first knowing a cluster is there. Some clusters have already been found via their mass in this way. More importantly for our understanding of cosmology, weak lensing may be used to directly investigate the evolution of mass structures over cosmic time, and surveys are currently under way. Figure 4 shows a mass map of a 0.8 degree wide field, revealing several mass concentrations. If the shear pattern of sufficiently distant galaxies is measured over a wide field, then intervening mass overdensities over a wide range of redshift are revealed.

In different cosmologies mass structure develops differently; this leads to a weak-lens cosmological diagnostic. Generally, the net effect of all intervening mass overdensities is a correlation of orientations of faint galaxies separated by some angle on the sky. A direct probe of the development of mass structures, this 'cosmic shear' has recently been detected. Meaningful tests of cosmological models will result from the comparison of what is found for this cosmic shear (as well as counts of discrete clusters found via weak lensing) with theoretical models for the evolution of large scale structure. Comparing mass maps from deep weak-lensing observations with data from upcoming satellite COSMIC MICROWAVE BACKGROUND anisotropy missions will lead to a precision test of the nature of cosmic mass-energy, probing the basic theory of structure formation in our universe.

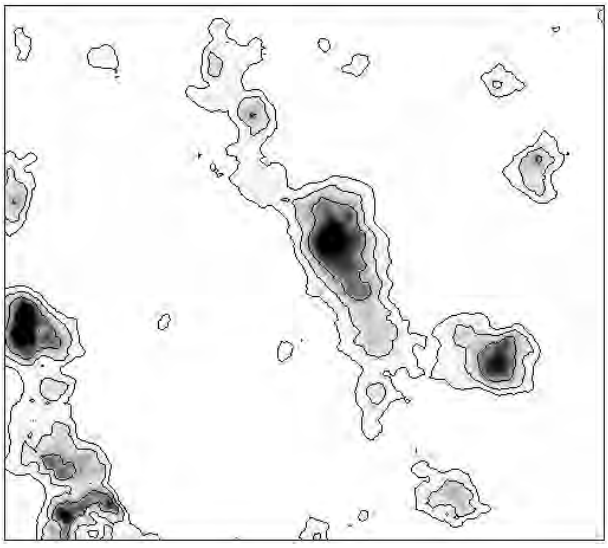

Figure 4. The ellipticities of over 50 000 faint galaxies can be inverted to reconstruct a map of the intervening mass distribution. Several projected mass concentrations are seen in this weak-lensing mass map covering 0.8 degrees of the sky. One of these structures spans 6 Mpc, twelve times the size of the map shown in figure 2. At the center of the mass structure is a cluster of galaxies.

Gravitational Radiation

Gravity is one of the fundamental forces of nature, and it is the dominant force in most astronomical systems. In common with all other phenomena, gravity must obey the principles of SPECIAL RELATIVITY. In particular, gravitational forces must not be transmitted or communicated faster than light. This means that, when the gravitational field of an object changes, the changes ripple outwards through space and take a finite time to reach other objects. These ripples are called gravitational radiation or gravitational waves[1].

In Einstein's theory of gravitation (see GENERAL RELATIVITY AND GRAVITATION), as in many other modern theories of gravity, gravitational waves travel at exactly the speed of light. Different theories make different predictions, however, about details, such as their strength and polarization. There is strong indirect observational evidence (see GENERAL RELATIVITY TESTS: BINARY PULSARS) that gravitational waves follow the predictions of general relativity, and instruments now under construction are expected to make the first direct detections of them in the first years of the 21st century.

These instruments and plans for future instruments in space are described in the article GRAVITATIONAL RADIATION DETECTORS ON EARTH AND IN SPACE. Detectors must look for gravitational radiation from astronomical systems, because it is not possible to generate detectable levels of radiation in the laboratory. It follows that gravitational wave detection is also a branch of observational astronomy.

The most striking aspect of gravitational waves is their weakness. A comparison with the energy in light will illustrate this. The human eye has no trouble sensing the light from the planet Jupiter: the amount of energy that passes through the iris of the eye is far more than the minimum the eye can detect. Yet several times a week a gravitational wave, generated in a far distant galaxy, carries a similar amount of energy into the eye, and we do not notice it.

The reason is that gravity is the weakest of the fundamental forces, and the disturbance created by even such an energetic wave is so tiny that no man-made instrument has so far registered it. While all the energy in the light from Jupiter that enters the eye is absorbed in the eye, the gravitational wave passes right through, leaving behind almost none of its energy. All the matter in the present universe is similarly transparent to gravitational waves.

Gravitational radiation is today one of the last unopened windows into the universe. There are at least five reasons motivating scientists to develop gravitational wave astronomy.

- The weakness with which gravitational waves interact with matter is a great advantage for astronomy. It means that gravitational waves arrive unaffected by any intervening matter they may have encountered since being generated. There is no significant scattering or absorption, although they will be deflected by GRAVITATIONAL LENSING in the same way as light. Gravitational waves carry uncorrupted information even if they come from the most distant parts of the universe or from its most hidden regions, like the interiors of SUPERNOVAE.
- Gravitational waves are emitted by the bulk motions of their sources, not by individual atoms or electrons, as is normally the case for electromagnetic waves. They therefore carry a completely different kind of information about their sources from that which is normally available in observations of binary stars (see BINARY STARS: OVERVIEW), supernovae and NEUTRON STARS.
- Gravitational waves can be emitted by black holes, which are described in the article GRAVITATIONAL RADIATION DETECTORS ON EARTH AND IN SPACE. Indeed, gravitational waves provide the only way to make direct observations of these objects. Since there is now strong indirect evidence that giant black holes inhabit the centers of many (or even most) galaxies (see SUPERMASSIVE BLACK HOLES IN AGN), and since smaller ones are common in the Galaxy (see BLACK HOLE CANDIDATES IN X-RAY BINARIES), there is great interest in making direct observations of them.
- Gravitational waves can come from extraordinarily early in the history of the universe. The electromagnetic radiation from the big bang is called the COSMIC MICROWAVE BACKGROUND. Observations of it describe the universe at it was about 10^5 yr after the big bang. Studies of cosmological NUCLEOSYNTHESIS give information about what the universe was like as little as 3 min after the big bang. Gravitational waves, if they can be detected, would picture the universe when it was only perhaps 10^{-24} s old, just at the end of INFLATION.
- Gravitational radiation is the last fundamental prediction of Einstein's general relativity that has not yet been directly verified. If another theory of gravity is correct, then differences could in principle show up in the properties of gravitational waves, such as their polarization. In principle, there must be a better theory of gravity, since general relativity is not a quantum theory, a deficiency that theoretical physicists today are working hard to remedy. The majority belief today is that there should be a unified theory of the fundamental forces, in which gravitation is related to the other forces. Evidence for the nature of this relation could show up in observations of gravitational waves, particularly those from the big bang.

These motivations and their implications are developed in the following sections. Each section begins with an introduction to the physical ideas and then develops some of the mathematical details.

[1] They are also sometimes referred to as *gravity waves*, but since this term has a different meaning in meteorology and stellar hydrodynamics, we will avoid it here. See SOLAR INTERIOR: HELIOSEISMOLOGY.

The physics of gravitational radiation: weakness and strength

The starting point for understanding gravitational radiation is Newtonian gravity. The weakness of gravity is evident. If a child picks up a book, she defeats the cumulative gravitational pull of the entire planet Earth on the book. The strength to do this comes from the chemical forces in her muscles, which come from electromagnetic interactions.

In fact, the electromagnetic force between the electron and the proton in a hydrogen atom is 2×10^{39} times bigger than the gravitational force between them. The reason that gravity can nevertheless dominate on the cosmic scale is that opposite electrical charges cancel each other, while the gravitational forces of all the particles add.

Another fact about gravity that was known to Newton is what is now called the equivalence principle. This is the principle that all bodies accelerate in the same way in a gravitational field, so that the trajectory that a freely falling body (a body influenced only by gravity) follows in a given gravitational field depends only on its starting position and velocity, not on what it is made of.

Imagine now a machine made in some way to detect gravitational waves. Whatever the method of detection, a wave needs somehow to alter the internal state of the detector. If the wave carries a gravitational field that is completely uniform across the detector, then by the equivalence principle all of the parts of the detector will accelerate together, and its state will not change at all. To detect a gravitational wave, the machine must measure the non-uniformities of the gravitational field across a detector.

These non-uniformities are called tidal forces, because they produce the stretching effects that raise tides on the Earth. Gravitational waves are traveling tidal forces.

Newton's theory of gravity had no gravitational waves. For Newton, if a gravitational field changed in some way, that change took place instantaneously everywhere in space. This is not a wave. Let us consider what we mean by the term 'wave' in ordinary language.

Imagine a child's rubber duck floating in a bath tub half full of water. If a child presses down on the duck very gently, until is is nearly submerged, then the level of the water will rise everywhere in a nearly uniform way, and this is not called a wave. If instead he drops the duck, then the disturbance rises around the base of the duck rapidly, moves away from it and eventually reaches the walls. This is a wave. Wave motion requires a finite speed for the propagation of disturbances. If the disturbance is very slow, as for the floating duck, then the wavelength is very long, and near the site of the disturbance the wave motion is not noticeable. We say we are in the 'near zone'. However, when we are more than a wavelength away, then we see waves, and this is the 'wave zone' or 'far zone'. For the dropped duck, we see the waves because their wavelengths are shorter than the size of the bath. In general relativity, the speed of gravity is the speed of light. Because of this finite speed, gravity must exhibit wave effects.

Many of Newton's contemporaries were unhappy that his theory of gravity was based on instantaneous 'action at a distance', but Newton's theory fitted the observational facts. If gravity had a finite speed of propagation, there was no evidence for it in the solar system. Interestingly, the brilliant 18th century French mathematician and physicist Laplace tried out a variation on Newton's theory in which gravity was represented by something 'flowing' out of its source with a finite speed. He reasoned that a planet like the Earth, moving through this fluid of gravity, would experience friction and gradually spiral in towards the Sun.

Laplace could show that the observational limits on this in-spiral even in his day were so stringent that the speed of gravity in his model needed to be huge compared with the speed of light. He did not find this result attractive and took the theory no further. (Laplace also explored the notion of what we now call a black hole, which for him was a region where gravity was strong enough to trap light.)

It is interesting that, today, observations of the two neutron stars in the binary system PSR1913 + 16 spiraling together as they orbit one another provide the most convincing evidence that gravitational waves exist and are as described in general relativity (see below). Laplace had the right effect, but the wrong theory. This evidence is described in the next section.

In general relativity, Einstein used the principle of equivalence as the basis for a geometrical description of gravity. In the four-dimensional world of space–time, the trajectory of a particle falling freely in a gravitational field is a certain fixed curve. Its direction at any point depends on the velocity of the particle. The equivalence principle implies that there is a preferred set of curves in space–time: at any point, pick any direction, and there is a unique curve in that direction that will be the trajectory of any particle starting with that velocity. These trajectories are thus properties of space–time itself.

Moreover, if there were no gravitational field, the trajectories would be simple straight lines. Even in a gravitational field, a small freely falling particle does not 'feel' any acceleration: its internal state is the same as if there were no gravity. Therefore Einstein postulated that a gravitational field made space–time curved, and that the preferred trajectories were locally straight lines that simply changed direction as they moved through the curved space–time, in much the same way as a great circle on a sphere changes direction relative to other great circles as one goes along it. For weak gravitational fields of slowly moving bodies, Einstein's theory reduces to Newton's in the first approximation.

For gravitational waves, one could make a very simple detector just by monitoring the distance between two nearby freely falling particles. If they are genuinely free, then any changes in their separations would indicate the passage of a gravitational wave. Because this measures a tidal effect, the bigger the separation of the particles,

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the bigger will be the change in their separation, at least for particles that are separated by less than a gravitational wavelength. Most modern gravitational wave detectors are designed to be as big as cost and practicality allows.

Although gravitational radiation is well understood in theoretical terms in general relativity, the complexity and non-linearity of Einstein's equations means that calculations are often difficult. In the historical development of general relativity, between 1915 and the 1950s and 1960s, these mathematical difficulties created confusion over the physical nature of gravitational radiation, and in particular over whether it carried energy away from the source. Improved mathematical techniques finally resolved the matter in favor of the simple physical picture presented here, but this picture would not be complete without the strong mathematical underpinning that now exists.

The question of energy in gravitational waves is still a delicate one. There is no question that waves carry energy (and momentum) away from their sources. Nevertheless, it is not possible in general relativity to localize the energy in the radiation to regions smaller than about a wavelength. Indeed the equivalence principle shows that 'point' particles feel nothing, no matter how strong the wave. The wave only acts by stretching space–time, producing a tidal distortion in the separations between particles (see the discussion of polarization below).

For this reason, energy is localized only in regions, not at points. It is nevertheless real energy: the non-linearity of general relativity allows waves to create gravitation themselves. Recent numerical simulations have shown that focussed gravitational waves can actually form black holes, trapping themselves. If the waves are weak, they enter the focussing region and re-emerge. If they are strong enough, they enter and never leave.

Gravitational waves in a quasi-Newtonian model

It is possible to calculate the approximate size of the effect of a given gravitational wave by beginning with Newtonian gravity and adding waves to it. In Newtonian gravity the gravitational field produced by a mass M at a distance r is given by

$$\phi = -GM/r \tag{1}$$

where G is Newton's gravitational constant. The field of a gravitational wave must be a ripple on this, which means a small change that oscillates in space and time. A suitable form for a change that propagates at the speed of light in the z-direction with an angular frequency ω is:

$$\delta\phi = -\epsilon\frac{GM}{r}\sin[\omega(z/c - t)] \tag{2}$$

where ϵ is a dimensionless number that would be expected to be small compared with 1. Its size is the subject of the next main section.

The field $\delta\phi$ produces an acceleration in the z-direction that depends on its z-derivative. Both $1/r$ and the sin() term depend on z. The derivative of $1/r$ will be proportional to $1/r^2$, which is how the acceleration falls off in Newton's theory (where ϕ is the only field). However, the derivative of the sin() term does not change the $1/r$; rather, it essentially just multiplies $\delta\phi$ by ω/c. At sufficiently large distances from the source, this term will dominate the $1/r^2$ term and the acceleration produced by the wave will be

$$\delta a_z = -\epsilon\omega\frac{GM}{rc}\cos[\omega(z/c - t)]. \tag{3}$$

Note that this term would not be present in the x- and y-derivatives, so these components of the acceleration are much smaller in this quasi-Newtonian model of a gravitational wave.

Effect on a simple detector

The tidal part of this acceleration, for a detector that has size ℓ in the z-direction, is to a first approximation

$$\ell\frac{\mathrm{d}}{\mathrm{d}z}\delta a_z = \epsilon\omega^2\ell\frac{GM}{rc^2}\sin[\omega(z/c - t)]. \tag{4}$$

If a detector consists of two freely falling particles with this relative acceleration, the equation of motion for their separation ℓ will be

$$\frac{\mathrm{d}^2\ell}{\mathrm{d}t^2}2 = \epsilon\omega^2\ell\frac{GM}{rc^2}\sin[\omega(z/c - t)]. \tag{5}$$

The dimensionless coefficient $\epsilon GM/rc^2$ is typically very small. Even if ϵ is of order 1, the other number is, with reasonable values for M and R,

$$\frac{GM}{rc^2} = 2.4\times10^{-21}\frac{M}{M_\odot}\left(\frac{r}{20\ \mathrm{Mpc}}\right)^{-1}.$$

The mass and distance scales here are those appropriate to a neutron star in the nearest large cluster of galaxies, the Virgo Cluster. (The distance unit is based on the astronomers' parsec, denoted pc, which is about 3×10^{16} m. The unit Mpc is a megaparsec.) It is believed that several neutron stars are formed in the Virgo Cluster each year in supernova explosions. Ever since the beginning of the development of gravitational wave detectors such events have been high on the list of possible sources of gravitational waves.

To solve equation (5), one takes r and z as constants and uses the smallness of the right-hand side, which implies that the changes in ℓ are tiny compared with ℓ itself. On the right-hand side one can therefore replace ℓ by ℓ_0, the initial value of ℓ, and then simply integrate twice in time to obtain (for an initial value $\mathrm{d}\ell/\mathrm{d}t = 0$)

$$\frac{\ell(t) - \ell_0}{\ell_0} = -\epsilon\frac{GM}{rc^2}\sin[\omega(z/c - t)]. \tag{6}$$

The right-hand side of equation (6) is identical to that of equation (2). This is an important conclusion which

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

fits neatly with Einstein's geometrical conception of gravity: the size of a gravitational wave gives directly the stretching of the distance between nearby free particles. It is conventional to call this $h/2$ and refer to h as the gravitational wave potential:

$$h := 2\frac{\ell(t) - \ell_0}{\ell_0} = 2\delta\phi. \tag{7}$$

The amplitude of the oscillations of h is

$$h \sim 2\epsilon\frac{GM}{rc^2}. \tag{8}$$

It is evident from this that a detector must be able to measure changes in its own size that are smaller than 1 part in 10^{21} to have a reasonable chance of making astronomical observations. The extraordinary smallness of this effect also explains why ordinary objects in the universe are transparent to gravitational waves. As the waves pass through them, they disturb them so little (parts per 10^{21} typically) that the transfer of energy to the object and any back-reaction effects of this on the wave are negligibly small.

Energy flux carried by waves

The *energy* in the waves can also be estimated from these equations and general physical principles. Quite generally, in classical field theories, the energy flux of a propagating sinusoidal plane wave is proportional to the square of the time-derivative of the fundamental field. In electromagnetism, the Poynting flux is proportional to the square of the time-derivative of the vector potential.

In general relativity, the flux is therefore proportional to the square of the time-derivative of $h(t)$. The proportionality constant must be built only out of c, G and pure numbers. To obtain the right units, it must be proportional to c^3/G: to obtain the pure number, a calculation in general relativity is required; $1/32\pi$ for a linearly polarized wave. (Polarization is described later.) This gives

$$F_{\rm gw} = \frac{1}{32\pi}\frac{c^3}{G}\left(\frac{{\rm d}h}{{\rm d}t}\right)^2$$

$$= 1.6\times10^{-5}\left(\frac{f}{100\ {\rm Hz}}\right)^2\left(\frac{h}{10^{-22}}\right)^2\ {\rm W\ m^{-2}} \tag{9}$$

for a wave with frequency $f = \omega/2\pi$. For comparison, reflected sunlight from Jupiter has a flux on Earth of 2.3×10^{-7} W m^{-2}, almost 100 times smaller than that of a gravitational wave with an amplitude of 10^{-22}.

Deficiencies of the quasi-Newtonian model

The calculation and equations in this section have been framed within a modified Newtonian model of gravity with a propagation speed of c, and one would expect some differences from general relativity. The most important difference is in the direction in which the tidal forces act. In the simple model, wave accelerations act in the z-direction, which was the direction of propagation of the wave. This is called a longitudinal wave.

In general relativity, gravitational waves are transverse waves: if the wave propagates in the z-direction then the tidal forces act only in the x–y-plane. We will discuss later the exact form that their action in this plane takes. Remarkably, the rest of the formulas above are good approximations even in general relativity, provided that ϵ is calculated correctly, as described in the next section.

The emission of gravitational waves

The previous section described the propagation of gravitational waves, their interaction with detectors and the energy they carry. This section deals with the strength with which waves are emitted by astronomical bodies.

In Newtonian gravity there is a fundamental theorem, proved by Newton, that the gravitational field outside a spherical body is not only spherical but the same as that of a point mass located at the origin of the body. It has the form given in equation (1). In particular, the field is independent of the size of the body, as long as we consider only points outside it. This is true even if the star pulsates in a spherical manner.

This theorem is essentially the same in general relativity, and is known as Birkhoff's theorem. Outside a spherical body the field is the same as that of a black hole of the same mass as the body (the Schwarzschild metric), even if the body is pulsating spherically. However, if the pulsation is non-spherical, then the outside field will change. In general relativity the changes generally propagate as a wave. So gravitational waves will be emitted by non-spherical motions.

In general the calculation of the emitted waves is extremely difficult, since the field equations of general relativity are a system of many coupled, non-linear, partial differential equations. However, in four circumstances the emission mechanisms are understood in some detail:

- Small-amplitude pulsations of relativistic stars and black holes. Normally gravitational radiation carries away energy and damps pulsations away, but in rotating stars the opposite may happen: the radiated loss of angular momentum may allow the star to spin down to an energetically more favored state, in which case the perturbation will grow, at least until non-linear effects intervene. Discovered by S Chandrasekhar and now called the Chandrasekhar–Friedman–Schutz (CFS) instability, it is thought to limit the rotation speed of *young* neutron stars (see below). Black holes also emit gravitational radiation when they are disturbed, *e.g.* by something falling into them, but they are not unstable: they always settle down into a steady state again.
- Radiation from 'test' objects orbiting black holes. If the mass of the object is small enough then the total gravitational field may be treated as a linear perturbation of the exactly known field of a

black hole (the Schwarzschild or, with rotation, the Kerr solution). These studies give insight into the general problem of gravitational radiation, and they also predict gravitational waveforms that might be observed by space-based observatories looking at compact stars falling into the giant black holes in the centers of galaxies (see below).

- Weak gravitational fields and slow motion. Such weakly relativistic sources are studied in the *post-Newtonian* approximation, which includes higher-order corrections to Newtonian gravity from general relativity. This is analogous to the slow-motion multipole approximation that is so powerful in the study of electromagnetic radiation. Most realistic gravitational-wave sources can be studied to some approximation this way.
- Collisions of black holes and neutron stars. These events, which are expected to be observed by gravitational wave detectors (see below), must be modeled by solving the full set of Einstein equations on a powerful computer. Techniques to do this are advancing rapidly, and simulations of realistic mergers of stars and black holes from in-spiraling orbits can be expected to yield useful results in the first years of the 21st century.

Quadrupole approximation

The post-Newtonian approximation has so far been the most powerful of these methods, and it yields the most insight into the emission mechanisms. Its fundamental result is the quadrupole formula, which gives the first approximation to the radiation emitted by a weakly relativistic system.

The quadrupole formula is analogous to the dipole formula of electromagnetism. In this language, monopole means spherical, which emits no radiation. This is also true in electromagnetism, where it is linked to conservation of charge. The 'monopole moment' in electromagnetism is the total charge of a system, and since that does not change, there can be no spherical radiation.

Again in electromagnetism, the dipole moment is defined as the integral

$$d_i = \int \rho x_i \, \mathrm{d}^3 x$$

where ρ is the charge density and x_i is a Cartesian coordinate. If this integral is time dependent, then the amplitude of the electromagnetic waves will be proportional to its first time-derivative $\mathrm{d}d_i/\mathrm{d}t$, and the radiated energy will be proportional (as we remarked earlier) to the square of the time derivative of this amplitude, *i.e.* to $\sum_i |\mathrm{d}^2 d_i/\mathrm{d}t^2|^2$.

In the post-Newtonian approximation to general relativity, the calculation goes remarkably similarly. The monopole moment is now the total mass–energy, which is the dominant source of the gravitational field for non-relativistic bodies, and which is constant as long as the radiation is weak. (Radiation will carry away energy, but in the post-Newtonian approximation that is a higher-order effect.) The dipole moment is given by the same equation as above, but with ρ interpreted as the density of mass–energy.

However, here general relativity departs from electromagnetism. The time-derivative of the dipole moment is, since the mass–energy is conserved, just the integral of the velocity v_i:

$$\dot{d}_i = \int \rho v_i \, \mathrm{d}^3 x. \tag{10}$$

However, this is the total momentum in the system, and (to lowest order) this is constant. Therefore, there is no energy radiated as a result of dipole effects in general relativity. The gravitational field far from the source does contain a dipole piece if $\dot{d}_i$ is non-zero, but this is constant because it reflects the fact that the source has non-zero total momentum and is therefore moving through space.

To find genuine radiation in general relativity one must go one step beyond the dipole approximation to the quadrupole terms. These are also studied in electromagnetism, and the analogy with relativity again is close. The fundamental quantity is the spatial tensor (matrix) Q_{jk}, the second moment of the mass (or charge) distribution:

$$Q_{jk} = \int \rho x_j x_k \, \mathrm{d}^3 x. \tag{11}$$

A gravitational wave in general relativity is represented by a matrix h_{jk} rather than a single scalar h, and its source (in the quadrupole approximation) is Q_{jk}.

As in electromagnetism, the amplitude of the radiation is proportional to the second time-derivative of Q_{jk}, and it falls off inversely with the distance r from the source. A factor of G/c^4 is needed in order to obtain a dimensionless amplitude h, and a factor of 2 to be consistent with the definition in equation (8). The result for h_{jk} is

$$h_{jk} = \frac{2G}{rc^4} \frac{\mathrm{d}^2 Q_{jk}}{\mathrm{d}t^2}. \tag{12}$$

General relativity describes waves with a matrix because gravity is geometry, and the effects of gravity are represented by the stretching of space–time. This matrix contains that distortion information. Here is the information about the transverse action of the waves that the quasi-Newtonian model of the last section did not get right.

Simple estimates

If the motion inside the source is highly non-spherical, then a typical component of $\mathrm{d}^2 Q_{jk}/\mathrm{d}t^2$ will (from equation (11)) have magnitude $M v_{\mathrm{NS}}^2$, where v_{NS}^2 is the non-spherical part of the squared velocity inside the source. So one way of approximating any component of equation (12) is

$$h \sim \frac{2GMv_{\mathrm{NS}}^2}{rc^4}. \tag{13}$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Comparing this with equation (8) we see that the ratio ϵ of the wave to the Newtonian potential is simply

$$\epsilon \sim \frac{v_{\rm NS}^2}{c^2}.$$

By the virial theorem for self-gravitating bodies, this will not be larger than

$$\epsilon < \phi_{\rm int}/c^2 \tag{14}$$

where $\phi_{\rm int}$ is the maximum value of the Newtonian gravitational potential *inside* the system. This provides a convenient bound in practice. It should not be taken to be more accurate than that.

For a neutron star source one has $\phi_{\rm int} \sim 0.2c^2$. If the star is in the Virgo cluster, then the upper limit on the amplitude of the radiation from such a source is 5×10^{-22}. This has been the goal of detector development for decades, to make detectors that can observe waves at or below an amplitude of 10^{-21}.

Polarization of gravitational waves

The matrix nature of the wave amplitude comes from general relativity and has no Newtonian analog. In order to find the effect of the waves on the separation of two free particles (the idealized detector), one has to start with h_{jk} as given by equation (12) or by any other calculation, and then do three things.

1. Project the matrix h_{jk} onto a plane perpendicular to the direction of travel of the wave. In the simple case considered above, where the wave was traveling in the z-direction, this means leaving the components $\{h_{xx}, h_{xy}, h_{yy}\}$ alone and setting the remaining components to zero. It is then a two-dimensional matrix in the transverse plane.
2. Remove the two-dimensional trace of the projected matrix. Call the resulting matrix $h_{jk}^{\rm TT}$, where TT stands for transverse–traceless. In the example this means subtracting $(h_{xx}+h_{yy})/2$ from both h_{xx} and h_{yy}. Then there are only two independent components left, $h_{xy}^{\rm TT} = h_{yx}^{\rm TT}$ and $h_{xx}^{\rm TT} = -h_{yy}^{\rm TT}$.
3. To find the change in the separation of two particles that have an initial separation given by the vector ℓ_k, let the matrix $h_{jk}^{\rm TT}$ act on it:

$$\delta\ell_j = \sum_k h_{jk}^{\rm TT}\ell_k. \tag{15}$$

It is clear that any longitudinal component of the separation ℓ_j between the particles is unaffected by the wave (in the example, this is the z-separation), and that there are two degrees of freedom (the two independent components of $h_{jk}^{\rm TT}$) to move particles in the plane perpendicular to the propagation direction. These two degrees of freedom are the two polarizations of the wave.

Figure 1 shows the conventional definition of the two independent polarizations, from which any other can be made by superposition. What is shown is the effect of a wave on a ring of free particles in a plane transverse to the wave. The first line shows a wave with $h_{xy} = 0$, conventionally called the '+' polarization. The bottom line shows a wave with $h_{xx} = 0$, the '×' polarization.

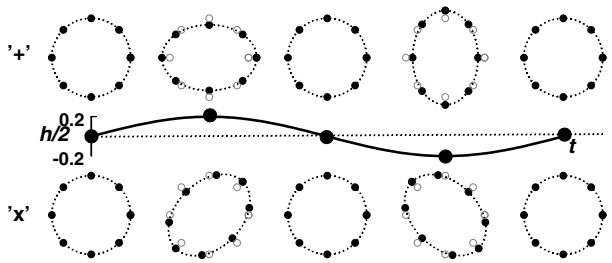

Figure 1. Polarization of gravitational waves. The center line gives the wave as a function of time, with an amplitude of $h = 0.2$, and the top and bottom lines show to scale the distortions produced by two polarizations with this amplitude.

Luminosity in gravitational waves

The energy carried by the gravitational wave must be proportional to the square of the time-derivative of the wave amplitude, so it will depend on the sum of the squares of the components d^3Q_{jk}/dt^3. The energy flux falls off as $1/r^2$, but when integrated over a sphere of radius r to obtain the total luminosity, the dependence on r goes away, as it should. The luminosity contains a factor G/c^5 on dimensional grounds, and a further factor of $1/5$ comes from a careful calculation in general relativity. The result is the gravitational wave luminosity in the quadrupole approximation:

$$L_{\rm gw} = \frac{G}{5c^5}\left(\sum_{j,k} \dddot{Q}_{jk}\,\dddot{Q}_{jk} - \frac{1}{3}\,\dddot{Q}^2\right) \tag{16}$$

where Q is the trace of the matrix Q_{jk}. Its squared third derivative must be subtracted in order to ensure that spherical motions do not radiate.

This equation will be used in the next section to estimate the back-reaction effect on a system that emits gravitational radiation.

Emission estimates

Until observations of gravitational waves are successfully made, one can only make intelligent guesses about most of the sources that will be seen. There are many that could be strong enough to be seen by the early detectors: binary stars, supernova explosions, neutron stars, the early universe. The estimates in this section are accurate only to within factors of order 1. The estimates correctly show how the important observables scale with the properties of the systems.

Man-made gravitational waves

One source can be ruled out: man-made gravitational radiation. Imagine creating a wave generator with the following extreme properties. It consists of two masses of 10^3 kg each (a small car) at opposite ends of a beam 10 m long. At its center the beam pivots about an axis. This centrifuge rotates 10 times per second. All the velocity is non-spherical, so v_{NS}^2 in equation (13) is about 10^5 m^2 s^{-2}. The frequency of the waves will actually be 20 Hz, since the

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

mass distribution of the system is periodic with a period of 0.05 s, only half the rotation period. The wavelength of the waves will therefore be 1.5×10^7 m, about the diameter of the earth. In order to detect gravitational waves, not near-zone Newtonian gravity, the detector must be at least one wavelength from the source. Then the amplitude h can be deduced from equation (13): $h \sim 5 \times 10^{-43}$. This is far too small to contemplate detecting.

Radiation from a spinning neutron star

Some likely gravitational wave sources behave like the centrifuge, only on a grander scale. Suppose a neutron star of radius R spins with a frequency f and has an irregularity, a bump of mass m on its otherwise axially symmetric shape. Then the bump will emit gravitational radiation (again at frequency $2f$ because it spins about its center of mass, so it actually has mass excesses on two sides of the star), and the non-spherical velocity will be just $v_{NS} = 2\pi Rf$. The radiation amplitude will be, from equation (13),

$$h_{\text{bump}} \sim 2(2\pi Rf/c)^2 Gm/rc^2 \tag{17}$$

and the luminosity, from equation (16) (assuming that roughly four comparable components of Q_{jk} contribute to the sum),

$$L_{\text{bump}} \sim (G/5c^5)(2\pi f)^6 m^2 R^4.$$

The radiated energy would presumably come from the rotational energy of the star. This would lead to a spindown of the star on a timescale

$$t_{\text{spindown}} = \frac{1}{2}mv^2/L_{\text{bump}} \sim \frac{5}{4\pi} f^{-1} \left(\frac{Gm}{Rc^2}\right)^{-1} \left(\frac{v}{c}\right)^{-3}.$$

It is felt that neutron star crusts are not strong enough to support asymmetries with a mass of more than about $m \sim 10^{-5} M_\odot$, and from this one can estimate the likelihood that the observed spindown timescales of PULSARS are due to gravitational radiation. In most cases, it seems that gravitational wave losses cannot be the main spindown mechanism.

However, lower levels of radiation would still be observable by detectors under construction, and this may be coming from a number of stars. In particular, there is a class of neutron stars in X-RAY BINARY STARS. They are accreting, and it is possible that accretion will create some kind of mass asymmetry (bump) or else lead to a rotational instability of the CFS type in the r-modes (see below). In either case, the stars could turn out be long-lived sources of gravitational waves.

Radiation from a binary star system

Another 'centrifuge' is a binary star system. Two stars of the same mass M in a circular orbit of radius R have $v_{\text{NS}}^2 = GM/4R$. The gravitational-wave amplitude from equation (13) can then be written

$$h_{\text{binary}} \sim \frac{1}{2}\frac{GM}{rc^2}\frac{GM}{Rc^2}. \tag{18}$$

Compare this with the implications of putting equation (14) into equation (8).

The gravitational-wave luminosity of such a system is, by a calculation analogous to that for bumps on neutron stars,

$$L_{\text{binary}} \sim \frac{1}{80}\frac{c^5}{G}\left(\frac{GM}{Rc^2}\right)^5.$$

In this equation there appears the important constant $c^5/G = 3.6\times^{52}$ W, a number with the dimensions of luminosity built only from fundamental constants. By comparison, the luminosity of the Sun is only 3.8×10^{26} W. Close binaries can therefore radiate more energy in gravitational waves than in light.

The radiation of energy by the orbital motion causes the orbit to shrink. The shrinking will make any observed gravitational waves increase in frequency with time. This is called a *chirp*. The timescale for this is

$$t_{\text{chirp}} = Mv^2/L_{\text{binary}} \sim \frac{20GM}{c^3}\left(\frac{GM}{Rc^2}\right)^{-4}. \tag{19}$$

The binary pulsar system—verifying gravitational waves

This orbital shrinking has already been observed in the HULSE–TAYLOR PULSAR system, containing the radio pulsar PSR1913 + 16 and an unseen neutron star in a binary orbit. Discovered in 1974 by R Hulse and J Taylor, it has established that gravitational radiation is correctly described by general relativity. For their discovery, Hulse and Taylor received the 1993 Nobel Prize for Physics.

The key to the importance of this binary system is that all of the important parameters of the system can be measured before one takes account of the orbital shrinking. This is because a number of post-Newtonian effects on the arrival time of pulses at the Earth, such as the precession of the position of the periastron and the time-dependent gravitational redshift of the pulsar period as it approaches and recedes from its companion, are measured in this system. They fully determine the masses and separation of the stars and the inclination and eccentricity of their orbit. From these numbers, without any free parameters, it is possible to compute the shrinking timescale predicted by general relativity. The observed rate matches the predicted rate to within the observational errors of less than 1%.

The stars are in an eccentric orbit ($e = 0.615$) and both have masses of $1.4M_\odot$. The orbital semimajor axis is about 7×8 m. Equation (19) assumes a circular orbit and gives a shrinking timescale of 6×10^{10} yr. This is an overestimate, however, partly because it is in any case a rough approximation, and partly because the timescale is very sensitive to eccentricity. With the observed eccentricity, a careful calculation shows that the expected shrinking timescale is around 4×10^8 yr, consistent with observations.

Chirping binaries

For a circular equal-mass binary, the orbital shrinking timescale and the frequency of the orbit determine both

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

M and R. If in addition a gravitational wave detector measures the wave amplitude $h_{\rm binary}$, then the *distance* r to the binary system can be determined.

Remarkably, this conclusion holds even for binaries with unequal masses. In such a case, the measurable mass is the chirp mass of the binary, defined as $\mathcal{M} := \mu^{3/5} M_{\rm T}^{2/5}$, where μ is the reduced mass of the binary system and $M_{\rm T}$ its total mass. Then the distance r is still measurable from the chirp rate, frequency, and amplitude. In other words, a chirping binary is a standard candle in astronomy. Post-Newtonian corrections to the orbit, if observed in the waveform, can determine the individual masses of the stars and even their spins.

Recognizing weak signals

For ground-based detectors, all expected signals have amplitudes that are close to or even below the instrumental noise level in the detector output. Such signals can nevertheless be detected with confidence if their waveform matches an expected waveform. The pattern recognition technique that will be used by detector scientists is called matched filtering.

Matched filtering works by multiplying the output of the detector by a function of time (called the template) that represents an expected waveform, and summing (integrating) the result. If there is a signal matching the waveform buried in the noise then the output of the filter will be higher than expected for pure noise.

A simple example of such a filter is the Fourier transform, which is a matched filter for a constant-frequency signal. The noise power in the data stream is spread out over the spectrum, while the power in the signal is concentrated in a single frequency. This makes the signal easier to recognize. The improvement of the signal-to-noise ratio for the amplitude of the signal is proportional to the square root of the number of cycles of the wave contained in the data. This is well known for the Fourier transform, and it is generally true for matched filtering.

Matched filtering can make big demands on computation, for several reasons. First, the arrival time of a short-duration signal is generally not known, so the template has to be multiplied into the data stream at each distinguishable arrival time. This is then a correlation of the template with the data stream. Normally this is done efficiently using fast Fourier transform methods.

Second, the expected signal usually depends on a number of unknown parameters. For example, the radiation from a binary system depends on the chirp mass $\mathcal{M}$, and it might arrive with an arbitrary phase. Therefore, many related templates must be separately applied to the data to cover the whole family of signals.

Third, matched filtering enhances the signal only if the template stays in phase with the signal for the whole data set. If they go out of phase, the method begins to reduce the signal-to-noise ratio. For long-duration signals, such as for low-mass neutron star coalescing binaries or continuous-wave signals from neutron stars (see below), this requires the analysis of large data sets and often forces the introduction of additional parameters to allow for small effects that can make the signal drift out of phase with the template. It also means that the method works well only if there is a good prediction of the form of the signal.

Because the first signals will be weak, matched filtering will be used wherever possible. As a simple rule of thumb, the detectability of a signal depends on its *effective* amplitude $h_{\rm eff}$, defined as

$$h_{\rm eff} = h N_{\rm cycles}^{1/2} \tag{20}$$

where $N_{\rm cycles}$ is the number of cycles in the waveform that are matched by the template.

For example, the effective amplitude of the radiation from a bump on a neutron star (equation (17)) will be $h_{\rm bump}(2fT_{\rm obs})^{1/2}$, where $T_{\rm obs}$ is the observation time. In order to detect this radiation, detectors may need to observe for long periods, say four months, during which they accumulate billions of cycles of the waveform. During this time, the star may spin down by a detectable amount, and the motion of the Earth introduces large changes in the apparent frequency of the signal, so matched filtering needs to be done with care and precision.

Another example is a binary system followed to coalescence, i.e. where the chirp time in equation (19) is less than the observing time. For neutron star binaries observed by ground-based detectors this will always be the case (see the next section), so the effective amplitude is roughly

$$h_{\rm chirp} \sim h_{\rm bin}(f_{\rm gw} t_{\rm chirp})^{1/2} \sim \frac{GM}{rc^2}\left(\frac{GM}{Rc^2}\right)^{-1/4} \tag{21}$$

where for $f_{\rm gw}$ one must use twice the orbital frequency $(GM/R^3)^{1/2}/4\pi$. This may seem a puzzling result, because it says that the effective amplitude of the signal gets *smaller* as the stars become closer. However, this just means that the signal will be more detectable if it is picked up earlier, since equation (21) assumes that the signal is followed right to coalescence. If one picks up the signal at earlier times, then there are more cycles of the waveform to filter for, and this naturally gives a better signal-to-noise ratio. This gives an advantage to detectors that can operate at lower frequencies. This has been an important consideration in the design of modern detectors.

In general, the sensitivity of detectors will be limited not just by detector technology but also by the duration of the observation, the quality of the signal predictions and even the availability of computer processing power for the data analysis.

Astronomical sources of gravitational waves

Estimating the frequency

The signals for which the best waveform predictions are available have narrowly defined frequencies. In some cases the frequency is dominated by an existing motion, such as the spin of a pulsar. However, in most cases the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

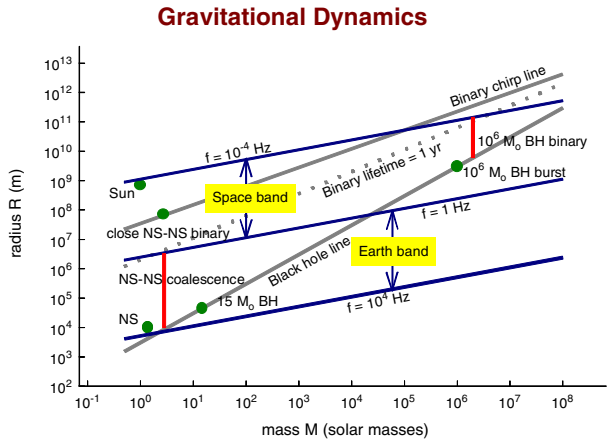

Figure 2. Mass–radius plot for gravitational wave sources.

frequency will be related to the natural frequency for a self-gravitating body, defined as

$$f_0 = (G\bar{\rho}/4\pi)^{1/2} \tag{22}$$

where $\bar{\rho}$ is the mean density of mass–energy in the source. This is of the same order as the binary orbital frequency and the fundamental pulsation frequency of the body.

The frequency is determined by the size R and mass M of the source, taking $\bar{\rho} = 3M/4\pi R^3$. For a neutron star of mass $1.4M_\odot$ and radius 10 km, the natural frequency is $f_0 = 1.9$ kHz. For a black hole of mass $10M_\odot$ and radius $2GM/c^2 = 30$ km, it is $f_0 = 1$ kHz. For a large black hole of mass $2.5 \times 10^6 M_\odot$, such as the one at the center of our Galaxy, this goes down in inverse proportion to the mass to $f_0 = 4$ mHz.

Figure 2 shows the mass–radius diagram for likely sources of gravitational waves. Three lines of constant natural frequency are plotted: $f_0 = 10^4$ Hz, $f_0 = 1$ Hz and $f_0 = 10^{-4}$ Hz. These are interesting frequencies from the point of view of observing techniques: gravitational waves between 1 and 10^4 Hz are accessible to ground-based detectors, while lower frequencies are observable only from space. Also shown is the line marking the black hole boundary. This has the equation $R = 2GM/c^2$. There are no objects below this line. This line cuts through the ground-based frequency band in such a way as to restrict ground-based instruments to looking at stellar-mass objects. Nothing over a mass of about $10^4 M_\odot$ can radiate above 1 Hz.

A number of typical relativistic objects are placed in the diagram: a neutron star, a binary pair of neutron stars that spiral together as they orbit, some black holes. Two other interesting lines are drawn. The lower (dotted) line is the 1 yr coalescence line, where the orbital shrinking timescale in equation (19) is less than one year. The upper (solid) line is the 1 yr chirp line: if a binary lies below this line then its orbit will shrink enough to make its orbital frequency increase by a measurable amount in 1 yr. (In a 1 yr observation one can in principle measure changes in frequency of 1 yr^{-1}, or 3×10^{-8} Hz.)

It is clear from the figure that any binary system that is observed from the ground will coalesce within an observing time of 1 yr. Since pulsar statistics suggest that this happens less than once every 10^5 yr in our Galaxy, ground-based detectors must be able to register these events in a volume of space containing at least 10^6 galaxies in order to have a hope of seeing occasional coalescences. When detectors reach this sensitivity (sometime in the first decade of the 21st century), then astronomers will be able to use the observed chirping binaries as standard candles to measure distance scales in the universe.

Radiation from neutron star normal modes

In figure 2 there is a dot for the typical neutron star. The corresponding frequency is the fundamental vibrational frequency of such an object. In fact, neutron stars have a rich spectrum of non-radial normal modes, which fall into several families: f-, g-, p-, w- and r-modes have all been studied. If their gravitational wave emissions can be detected, then the details of their spectra would be a sensitive probe of their structure and of the equation of state of neutron stars, in much the same way that HELIOSEISMOLOGY probes the interior of the Sun (see HIGH-ENERGY EQUATION OF STATE OF NEUTRON STARS). This is a challenge to ground-based detectors, which cannot yet make sensitive observations as high as 10 kHz.

Radiation from gravitational collapse

The event that forms a neutron star is the gravitational collapse that produces a supernova. It is difficult to predict the waveform or amplitude expected from this event, because we have no observational evidence about how non-spherical the collapse event might be in a typical supernova: the collapse is hidden deep within the star. So we can only guess. For example, a gravitational wave burst might be broad band, centered on 1 kHz, or it might be a few cycles of radiation at a frequency anywhere between 100 Hz and 10 kHz, chirping up or down. The amplitude could be large, in which a good fraction of the energy released by the collapse is radiated in gravitational waves, or it could be negligibly small. It is indeed ironic that, although detecting supernovae was the initial goal of detector development when it started four decades ago, little more is known today about what to expect than scientists knew then.

Radiation from r-modes

Hot neutron stars that rotate faster than about 100–200 Hz appear to be unstable to the emission of gravitational radiation through amplification of their r-modes by the CFS mechanism. In stars colder than about 10^8 K, viscosity may be strong enough to damp out this instability. This instability may explain why only old, recycled, cold pulsars are seen at higher rotation rates. It also suggests that the formation of a rapidly rotating neutron star may be followed by a period of steady gravitational radiation

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

as the star emits angular momentum and spins down to its stability limit. If as few as 10% of all the neutron stars formed since STAR FORMATION began (at a redshift of perhaps 4) went through such a spindown, then they may have produced a detectable random background of gravitational radiation.

Interestingly, the r-modes are disturbances primarily of the fluid velocity; they have little density perturbation. Their name comes from their similarity to the Rossby waves of oceanography. The gravitational radiation they emit is not primarily mass quadrupole (as in equation (12)), but rather mass-current quadrupole, the analog of magnetic quadrupole radiation in electromagnetism. This is the wave counterpart of what is called gravitomagnetism, which is responsible for the Lense–Thirring effect: an extra precession of a spinning gyroscope as it orbits a rotating body such as the Earth caused by the spin–spin gravitational coupling of the gyroscope to the Earth.

Black holes and gravitational waves

Black holes are regions of space–time within which everything is trapped: light cannot escape, nor can anything else that moves slower than light. The boundary of this region is called the event horizon. This boundary is a dynamical surface. If any mass–energy falls into the hole, the area of the horizon increases. In addition, the horizon will generally wobble when this happens. These wobbles settle down quickly, emitting gravitational waves, and leaving a smooth (and slightly larger) horizon afterwards.

Undisturbed black holes are time independent and smooth. In fact, according to general relativity the external gravitational field of such a black hole and the size and shape of its horizon are fully determined by only three numbers: the total mass, electric charge and angular momentum of the black hole. This black hole uniqueness theorem is remarkable, considering how much variety there can be in the material that collapsed to form the black hole and that may have subsequently fallen in.

Observations of the gravitational waves emitted by a wobbling horizon or by a particle in orbit around a black hole have the potential to test the uniqueness theorem and thereby to verify the predictions of general relativity about the strongest possible gravitational fields.

Astronomers now recognize that there is an abundance of black holes in the universe. Observations of various kinds have located black holes in x-ray binary systems in the Galaxy and in the centers of galaxies.

These two classes of black holes have very different masses. Stellar black holes typically have masses of around $10M_\odot$ and are thought to have been formed by the gravitational collapse of the center of a large, evolved RED GIANT STAR, perhaps in a supernova explosion. Massive black holes in galactic centers seem to have masses between $10^6 M_\odot$ and $10^{10} M_\odot$, but their history and method of formation are not yet understood.

Both kinds of black hole can radiate gravitational waves. According to figure 2, stellar black hole radiation will be in the ground-based frequency range, while galactic holes are detectable only from space. The radiation from a black hole typically is strongly damped, lasting only a few cycles about the frequency, which for a spherical black hole is given by equation (22) with $R = 2GM/c^2$:

$$f_{\rm BH} \sim 10 \left(\frac{M}{M_\odot} \right)^{-1} \ {\rm Hz}.$$

Stellar-mass black holes

Radiation from stellar black holes is expected mainly from coalescing binary systems, when one or both of the components are a black hole. Although such systems are thought to be rarer than systems of two neutron stars, the larger mass of the black hole makes the system visible from a greater distance. By measuring the chirp mass (as discussed above) observers will recognize that they have a black hole system. It is very possible that the first observations of binaries by interferometers will be of black holes.

When a two-black-hole binary coalesces, there should be a burst of gravitational radiation that will depend in detail on the masses and spins of the objects. Numerical simulations of such events will be needed to interpret this signal and possibly even to extract it from the instrumental noise of the detector. The research field of numerical relativity is making rapid progress, and it can be expected to produce informative simulations in the first few years of the 21st century, using the largest and fastest computers available at that time.

Massive and supermassive black holes

Gravitational radiation is expected from supermassive black holes in two ways. In one scenario, two massive black holes spiral together in a much more powerful version of the coalescence we have just discussed. The frequency is much lower, but the amplitude is higher. equation (21) implies that the effective signal amplitude is almost linear in the masses of the holes, so that a signal from two $10^6 M_\odot$ black holes will have an amplitude 10^5 times bigger than the signal from two $10M_\odot$ holes at the same distance. Even allowing for differences in technology, space-based detectors will be able to study such events with a very high signal-to-noise ratio no matter where in the universe they occur.

Observations of coalescing massive black hole binaries will therefore provide strong tests of the validity of general relativity in the regime of strong gravitational fields, provided that numerical simulations can match the accuracy of the observations by that time.

The event rate for such coalescences is not easy to predict: it could be zero, but it may be large. It seems that the central core of most galaxies may contain a black hole of at least $10^6 M_\odot$. This is known to be true for our Galaxy and for a number of others nearby. Supermassive black holes (up to a few times $10^9 M_\odot$) are believed to power quasistellar objects and active galaxies (see QUASISTELLAR OBJECTS: OVERVIEW, ACTIVE GALAXIES: OVERVIEW). There is some evidence that the mass of the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

central black hole is proportional to the mass of the core of the host galaxy.

If black holes are formed with their galaxies, in a single spherical gravitational collapse event, and if nothing happens to them after that, then coalescences will never be seen. However, it is believed that GALAXY FORMATION probably occurred through the merger of smaller units, subgalaxies of masses upwards of $10^6 M_\odot$. If these units had their own black holes, then the mergers would have resulted in the coalescence of many of the holes on a timescale shorter than the present age of the universe. This would give an event rate of several per year. If the supermassive black holes were formed from smaller holes in a hierarchical merger scenario, then the event rate could be hundreds or thousands per year. It is likely that only space-based observations of gravitational waves will answer these questions.

A second scenario for the production of radiation by massive black holes is the swallowing of a stellar-mass black hole or a neutron star by the large hole. Massive black holes exist in the middle of dense star clusters. The tidal disruption of main-sequence or giant stars that stray too close to the hole is thought to provide the gas that powers the quasar phenomenon. These clusters will also contain a good number of neutron stars and stellar-mass black holes. They are too compact to be disrupted by the hole even if they fall directly into it.

Such captures therefore emit a gravitational wave signal that may be approximated by studying the motion of a 'point mass' near a black hole. It will again emit a chirp of radiation, but in this case the orbit may be very eccentric. The details of the waveform encode information about the geometry of space–time near the hole. In particular, it may be possible to measure the mass and spin of the hole and thereby to test the uniqueness theorem for black holes. The event rate is not very dependent on the details of galaxy formation, and is probably high enough for many detections per year from a space-based detector.

Gravitational waves from the big bang

Gravitational waves have traveled almost unimpeded through the universe since they were generated at times as early as 10^{-24} s after the big bang. Observing them would provide important constraints on theories of inflation and high-energy physics.

Inflation is an attractive scenario for the early universe because it makes the large-scale homogeneity of the universe easier to understand. It also provides a mechanism for producing initial density perturbations large enough to evolve into galaxies as the universe expands. These perturbations are accompanied by gravitational-field perturbations that travel through the universe, redshifting in the same way that photons do. Today these perturbations should form a random background of gravitational radiation.

The perturbations arise by parametric amplification of quantum fluctuations in the gravitational wave field that existed before inflation began. The huge expansion associated with inflation puts energy into these fluctuations, converting them into real gravitational waves with classical amplitudes.

If inflation did not occur, then the perturbations that led to galaxies must have arisen in some other way, and it is possible that this alternative mechanism also produced gravitational waves. One candidate is cosmic defects, including cosmic strings and cosmic texture. (See TOPOLOGICAL DEFECTS IN COSMOLOGY.) Although observations at present seem to rule cosmic defects out as a candidate for galaxy formation, cosmic strings may nevertheless have produced observable gravitational waves.

If inflation did not occur, there could also be a thermal background of gravitational waves at a temperature similar to that of the cosmological microwave background, but this radiation would have such a high frequency that it would not be detectable by any known or proposed technique.

The random background will be detectable as a noise in the detector that competes with instrumental noise. In a single detector, such as the first space-based detector, this noise must be larger than the instrumental noise to be detected, and one must have great confidence in the detector in order to claim that the observed noise is external. This is how the cosmic microwave background was originally discovered in a radio telescope.

If there are two detectors, then one can multiply the outputs of the two detectors together and sum (integrate). In this way, the random wave field in one detector acts like a matched filtering template, matching the random field in the other detector. This allows the detection of noise that is below the instrumental noise of the individual detectors. For this to work, the two detectors must be close enough together to experience the same random wave field. In practice, the sensitivity of this method falls off rapidly with separation if the detectors are more than a wavelength apart.

Measure of the strength of random gravitational waves

When describing the strength of a random wave field, it is not appropriate to measure the amplitude of any single component. Rather, the rms amplitude of the field is the observable quantity. It is common to use an equivalent measure, the energy density $\rho_{\rm gw}(f)$ in the radiation field as a function of frequency f. For a cosmological field, what is relevant is to normalize this energy density to the critical density $\rho_{\rm c}$ required to close the universe. It is thus conventional to define

$$\Omega_{\rm gw} := \frac{{\rm d}\rho_{\rm gw}/\rho_{\rm c}}{{\rm d}\ln f}. \tag{23}$$

This is roughly the fraction of the closure energy density in random gravitational waves between the frequency f and $2.718f$.

Current and planned detectors may reach a sensitivity of $\Omega_{\rm gw} \sim 10^{-9}$ at 1 mHz and 10^{-10} at 40 Hz, but there is a possibility that backgrounds due to other sources (binary white dwarf systems and r-mode spindown, as discussed

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

above) could obscure a cosmological background at these levels.

Predicted spectrum of cosmological radiation

The simplest models of inflation suggest that the spectrum of the gravitational wave background should be flat, so that Ω_{gw} is independent of frequency over a very large range of frequencies. In this case, the observed fluctuations in the cosmic microwave background radiation set a limit on gravitational radiation at ultra-low frequencies, and this constrains the energy density in the observable range (0.1 mHz–10 kHz) to below about 10^{-13} of closure. This will be too small to be seen by the current and planned detectors on the ground or in space.

However, there is a great deal of room in these models for other spectra. The period before inflation may produce initial conditions for the phase of parametric amplification that give large amounts of radiation in the observable frequency range. One family of models based in superstring theory has a spectrum that rises at high frequencies. If a cosmological background from inflation or from cosmic defects can be observed, it will contain important clues to the nature of the theory that unifies gravitation with the rest of quantum physics.

Conclusions

The first few years of the 21st century should see the first direct detections of gravitational radiation and the opening of the field of gravitational wave astronomy. Beyond that, over a period of a decade or more, one may expect observations to yield important and useful information about binary systems, stellar evolution, neutron stars, black holes, strong gravitational fields and cosmology.

If gravitational wave astronomy follows the example of other fields, such as X-RAY ASTRONOMY and RADIO ASTRONOMY, then at some level of sensitivity it will begin to discover sources that are completely unexpected. Many scientists think the chance of this happening early is very good, since the processes that produce gravitational waves are so different from those that produce the electromagnetic radiation on which most present knowledge of the universe is based, and since more than 90% of the matter in the universe is dark and interacts with visible matter only through gravitation.

Present and planned detectors are known not to be ideal for some kinds of gravitational wave sources. Sensitive measurements of a cosmological background of radiation from the big bang may not be possible with these instruments if the spectrum follows the predictions of 'standard' inflation theory. Most of the normal mode oscillations of neutron stars will be very hard to detect, because the radiation is weak and at a high frequency, but the science there is compelling: neutron star seismology may be the only way to probe the interiors of neutron stars and understand these complex and fascinating objects. Detector technology will continually improve, and these sources provide important long-term goals for this field. There will clearly be much to do after the first observations are successfully made.

Gravitational Radiation Detectors on Earth and in Space

GRAVITATIONAL WAVES, one of the more exotic predictions of Einstein's general theory of relativity, may, after 80 yr of controversy over their existence, be detected within the next decade.

Sources such as interacting black holes, coalescing compact binary systems, stellar collapses and pulsars are all possible candidates for detection; observing signals from them will significantly boost our understanding of the universe. New unexpected sources will almost certainly be found and time will tell what new information such discoveries will bring. A full review of sources of GRAVITATIONAL RADIATION is given by Bernard Schutz.

Gravitational waves are ripples in the curvature of SPACE–TIME and manifest themselves as fluctuating tidal forces on pieces of mass placed a distance apart. The first gravitational wave detectors were based on the effect of these forces on the fundamental resonant mode of aluminum bars at room temperature. Following the lack of confirmed detection of signals, aluminum bar systems operated at and below the temperature of liquid helium were developed and work in this area is still underway. However, the most promising design of gravitational wave detector, offering the possibility of very high sensitivities over a wide range of frequency, uses test masses a long distance apart and freely suspended as pendulums on Earth or in drag-free craft in space; laser interferometry provides a means of sensing the motion of the masses produced as they interact with gravitational waves.

Ground-based detectors will be used to observe sources whose radiation is emitted at frequencies above a few Hz and space-borne detectors will be developed for implementation at lower frequencies. Already gravitational wave detectors of long baseline are being built in a number of places around the world: in the USA (LIGO project led by a Caltech–MIT consortium), in Italy (VIRGO project, a joint Italian–French venture), in Germany (GEO 600 project being built by a team of German and British research groups) and in Japan (TAMA 300 project). A space-borne detector, LISA—proposed by a collaboration of European and US research groups—has been adopted by ESA as a future Cornerstone Mission.

The observation of gravitational waves will not only provide unique information on testing aspects of general relativity but will also open up a new field of astronomy.

Background

Some early relativists were skeptical about the existence of gravitational waves. However, the 1993 Nobel Prize in Physics was awarded to Hulse and Taylor for their experimental observations and subsequent interpretations of the evolution of the orbit of the binary PULSAR, PSR 1913 +16. The decay of the binary orbit is consistent with angular momentum and energy being carried away from this system by gravitational waves.

Gravitational waves are produced when matter is accelerated in an asymmetrical way; however, owing to the nature of the gravitational interaction, significant levels of radiation are produced only when very large masses are accelerated in very strong gravitational fields. Such a situation cannot be found on Earth but is found in a variety of astrophysical systems. Gravitational wave signals are expected over a wide range of frequencies; from $\sim 10^{-17}$ Hz in the case of ripples in the cosmological background to $\sim 10^{3}$ Hz from the formation of neutron stars in supernova explosions. The most predictable sources are BINARY STAR systems. However, there are many sources of much greater astrophysical interest associated with black hole interactions and coalescences, neutron star coalescences, stellar collapses to neutron stars and black holes (supernova explosions), pulsars and the physics of the early universe.

Why is there currently such interest worldwide in the detection of gravitational waves? This is partly because observation of the velocity and polarization states of the signals will allow a direct experimental check of the wave predictions of GENERAL RELATIVITY, but more importantly because the detection of the signals should provide observers with new and unique information about astrophysical processes (see also GENERAL RELATIVITY TESTS: BINARY PULSARS).

Detection of gravitational waves

Gravitational waves are most simply thought of as ripples in the curvature of space–time, their effect being to change the separation of adjacent masses on Earth or in space; this tidal effect is the basis of all present detectors. The problem for the experimental physicist is that the predicted magnitudes of the strains in space caused by gravitational waves are of the order of 10^{-21} or lower. Indeed, current theoretical models suggest that in order to detect a few events per year—from coalescing neutron star binary systems for example—a sensitivity close to 10^{-22} is required. Signal strengths at the Earth for a number of sources are shown in figure 1.

The small signal levels mean that limiting noise sources resulting from the thermal motion of molecules in the detector (thermal noise), from seismic or other mechanical disturbances, and from noise associated with the detector readout, whether electronic or optical, must be reduced to a very low level. For signals above $\sim$10 Hz ground-based experiments are possible, but for lower frequencies where local fluctuating gravitational gradients and seismic noise on Earth become a problem, it is best to consider developing detectors to be used in space.

Initial detectors and their development

The earliest experiments in the field were ground based and were carried out by Joseph Weber of the University of Maryland about 30 yr ago. Having looked for evidence of excitation of the normal modes of the Earth by very low-frequency gravitational waves, Weber then moved on to look for tidal strains in aluminum bars which were at

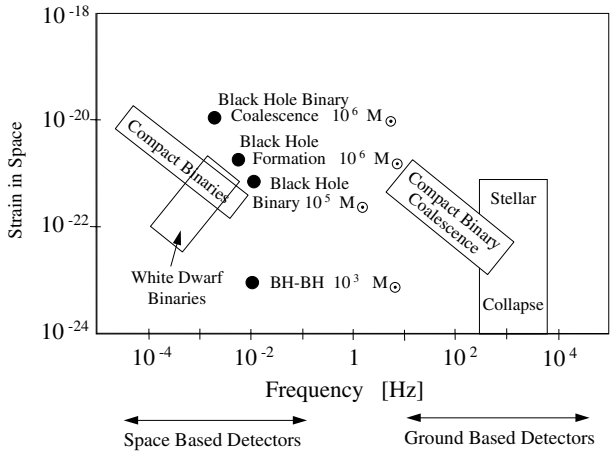

Figure 1. Some possible sources for ground-based and space-borne detectors.

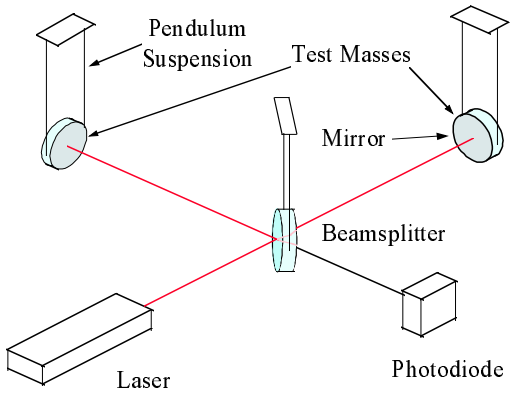

Figure 2. Schematic of gravitational wave detector using laser interferometry.

room temperature and were well isolated from ground vibrations and acoustic noise in the laboratory. The bars were resonant at 1600 Hz, a frequency where the energy spectrum of the signals from collapsing stars was predicted to peak. Despite the fact that Weber observed coincident excitations of his detectors placed up to 1000 km apart, at a rate of approximately one event per day, his results were not substantiated by similar experiments carried out in several other laboratories in the USA, Germany, Britain and Russia. It seems unlikely that Weber was observing gravitational wave signals because, although his detectors were very sensitive, being able to detect strains of around 10^{-15} over millisecond timescales, their sensitivity was far away from what was predicted to be required theoretically.

Development of Weber bar type detectors has continued with the emphasis being on cooling to reduce the noise levels, and currently systems at the Universities of Rome, Padua, Louisiana and Perth (Western Australia) are achieving sensitivity levels better than 10^{-18} for millisecond pulses. Bar detectors have a disadvantage, however, of being sensitive only to signals that have significant spectral energy in a narrow band around their resonant frequency.

Long-baseline detectors on Earth

An alternative design of gravitational wave detector offers the possibility of very high sensitivities over a wide range of frequency. This uses test masses placed a long distance apart and freely suspended as pendulums to isolate against seismic noise and reduce the effects of thermal noise; laser interferometry provides a means of sensing the motion of the masses produced as they interact with a gravitational wave (figure 2).

This technique is based on the Michelson interferometer and is particularly suited to the detection of gravitational waves as they have a quadrupole nature. Waves propagating perpendicular to the plane of the interferometer will result in one arm of the interferometer being increased in length while the other arm is decreased and vice versa. Gravitational wave strengths are characterized by the gravitational wave amplitude h, given by

$$h = 2\Delta L/L \tag{1}$$

where ΔL is the change in the length L of one arm of the detector. Thus h is a measure of the strain in space induced by a gravitational wave.

The induced change in the length of the interferometer arms results in a small change in the interference pattern of the light observed at the interferometer output. A typical design specification to allow a reasonable probability for detecting sources requires a noise floor in strain smaller than 2×10^{-23} Hz$^{-1/2}$ to be achieved. The distance between test masses possible on Earth is limited to a few km by geographical and cost factors. If we assume an arm length of 3 km the above specification sets the requirement that the residual motion of each test mass is smaller than 3×10^{-20} m Hz$^{-1/2}$ over the operating range of the detector, which may be from ~10 Hz to a few kHz. It requires that the optical detection system at the output of the interferometer must be good enough to detect such small motions.

Main noise sources relevant to interferometric gravitational wave detectors

Fundamentally it should be possible to build systems using laser interferometry to monitor strains in space which are limited only by the Heisenberg UNCERTAINTY PRINCIPLE; however, there are other practical issues which must be taken into account. Fluctuating gravitational gradients pose one limitation to the interferometer sensitivity achievable at low frequencies and it is the level of noise from this source that dictates that experiments to look for sub-Hz gravitational wave signals have to be carried out in space.

In general for ground-based detectors the most important limitations to sensitivity result from the effects of seismic and other ground-borne mechanical noise, thermal noise associated with the test masses and their

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

suspensions, and shot noise in the photocurrent from the photodiode which detects the interference pattern.

The significance of each of these sources will be briefly reviewed.

Seismic noise

Seismic noise at a reasonably quiet site on the Earth follows a spectrum in all three dimensions close to $10^{-7}/f^2$ m Hz$^{1/2}$. Thus if the motion of each test mass has to be less than 3×10^{-20} m Hz$^{-1/2}$ at a frequency such as 30 Hz then the level of seismic isolation required at 30 Hz, for example, in the horizontal direction is greater than 10^9. Since there is liable to be some coupling of vertical noise through to horizontal a significant level of isolation has to be provided in the vertical direction also.

Isolation can be achieved in a relatively simple way by realizing that for a simple pendulum system the transfer function to the pendulum mass of the horizontal motion of the suspension point falls off as 1/(frequency)^2 above the pendulum resonance. In a similar way isolation can be achieved in the vertical direction by suspending a mass on a spring. In the case of the VIRGO detector system the design allows operation to below 10 Hz and here a seven-stage horizontal pendulum arrangement is adopted with six of the upper stages being suspended with cantilever springs to provide vertical isolation. Similar systems are being developed in Australia and at Caltech. For the GEO 600 detector, where operation down to 50 Hz is sought, a triple-pendulum system is used with the first two stages being hung from cantilever springs to provide the vertical isolation necessary to achieve the desired performance. This arrangement is then hung from a plate mounted on passive 'rubber' isolation mounts and on an active (electromechanical) anti-vibration system.

In order to cut down motions at the pendulum frequencies, active damping of the pendulum modes has to be incorporated, and to reduce excess motions at low frequencies around the microseismic peak low-frequency isolators have to be incorporated. These low-frequency isolators can take different forms—tall inverted pendulums in the horizontal direction and magnetic antisprings for the vertical direction in the case of the VIRGO system; Scott Russell mechanical linkages in the horizontal and torsion bar arrangements in the vertical for an Australian design; a seismometer–actuator system for GEO 600.

Thermal noise

Thermal noise associated with the mirror masses and the last stage of their suspensions is likely to be the most significant noise source at the lower end of the operating range of long-baseline gravitational wave detectors. The operating range of a detector lies between the resonances of the test masses and their pendulum suspensions, and thus it is the thermal noise in the tails of the resonant modes which is important. For any simple harmonic oscillator, such as a mass hung as a pendulum or the internal resonance of a test mass, the spectral density of thermal motion of the mass at an angular frequency ω can be expressed as

$$\overline{x^2}(\omega) = \frac{4k_{\mathrm{b}}T\omega_0^2\phi(\omega)}{\omega m[(\omega_0^2-\omega^2)^2+\omega_0^4\phi^2(\omega)]} \qquad (2)$$

where k_{b} is Boltmann's constant, T is the temperature, m is the mass and $\phi(\omega)$ is the loss angle or factor of the oscillator of resonant angular frequency ω_0. Inspection of this equation tells us that the thermal noise away from resonance becomes smaller as $\phi(\omega)$ is reduced. For a pendulum, most of the energy is stored in the lossless gravitational field and thus the loss factor is lower than that of the material of the wires or fibers used to suspend the pendulum. Unfortunately this is not the case for the internal resonances of the test masses.

In order to keep the background thermal noise between the pendulum resonances and the internal resonances of the test masses as low as possible, the material loss factors should be as low as possible or the mechanical quality factors of the masses and pendulum resonances should be as high as possible. To achieve the level of sensitivity discussed earlier the loss factors of the test masses (of order 10 kg) must be $\sim 3 \times 10^{-8}$ or lower and the loss factor of the pendulum resonances should be smaller than 10^{-8}. Obtaining these values puts significant constraints on the choice of material for the test masses and the suspending fibers. One viable solution is to use fused silica masses hung by fused silica fibers as the intrinsic loss factor in samples of synthetic fused silica has been measured at around 2×10^{-8}. The use of other materials such as sapphire may be possible. Work in this area is being carried out by a number of universities, predominantly at Moscow and Glasgow (GEO 600 group), and more recently at Perugia, Syracuse and Stanford.

Photoelectron shot noise

For gravitational wave signals to be detected, the output of the interferometer must be held at a particular point on an interference fringe. An obvious point to choose is halfway up an interference fringe since the change in photon number produced by a given differential change in arm length is greatest at this point. The interferometer may be stabilized to this point by sensing any changes in intensity at the interferometer output with a photodiode and feeding the resulting signal back, with suitable phase, to a transducer capable of changing the position of one of the interferometer mirrors. Information about changes in the length of the interferometer arms can then be obtained by monitoring the signal fed back to the transducer.

As mentioned earlier it is very important that the system used for sensing the optical fringe movement on the output of the interferometer can sense strains in space of 2×10^{-23} Hz$^{-1/2}$ or differences in the lengths of the two arms of less than 10^{-19} m Hz$^{-1/2}$, a minute displacement compared with the wavelength of light, $\sim 10^{-6}$ m. A limitation to the sensitivity of the optical readout scheme is set by shot noise in the detected photocurrent, and from

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

consideration of the number of photoelectrons measured in a time τ it can be shown that the detectable strain sensitivity depends on the level of laser power P of wavelength λ used to illuminate the interferometer of arm length L, and on the time τ, such that

$$\text{detectable strain in time } \tau = \frac{1}{L}\left(\frac{\lambda hc}{2\pi^2 P\tau}\right)^{1/2} \quad (3)$$

or

$$\text{detectable strain/Hz}^{1/2} = \frac{1}{L}\left(\frac{\lambda hc}{\pi^2 P}\right)^{1/2} \quad (4)$$

where c is the velocity of light and h is Planck's constant. Thus to achieve the required strain sensitivity level requires a laser, operating at a wavelength of $\sim 10^{-6}$ m, to provide 6×10^6 W power at the input to the interferometer. This is a formidable requirement; however, there are a number of techniques that allow a large reduction in this power requirement and these will be discussed in the next section.

Interferometric techniques for gravitational wave detectors

The situation can be helped greatly if a multipass arrangement is used in the arms of the interferometer as this multiplies up the apparent movement by the number of bounces the light makes in the arms. The multiple beams either can be separate as in an optical delay line or may lie on top of each other as in a Fabry–Perot resonant cavity.

The light should not stay in the arms longer than the characteristic timescale of the signal—otherwise some cancellation of the detected signal may occur. There is thus an optimum number of bounces. If signals of characteristic timescale 1 ms are to be searched for, the number of bounces should not exceed 50 for an arm length of 3 km. With 50 bounces the required laser power is reduced to 2.4×10^3 W, still a formidable requirement.

Power recycling

It can be shown that the optimum signal-to-noise ratio in a Michelson interferometer is obtained when the arm lengths are such that the output light is very close to a minimum. Thus rather than lock the interferometer to the side of a fringe as discussed above, it is usual to make use of a modulation technique to operate the interferometer close to a null in the interference pattern. An electro-optic phase modulator placed in front of the interferometer can be used to phase modulate the input laser light. If the arms of the interferometer are arranged to have a slight mismatch in length, this results in a detected signal which, when demodulated, is zero with the cavity exactly on a null fringe. The detected signal changes sign on different sides of the null, providing a bipolar error signal; this can be fed back to the transducer controlling the interferometer mirror to hold the interferometer locked near to a null fringe.

In this situation, if the mirrors are of very low optical loss, nearly all of the light supplied to the interferometer is reflected back towards the laser. In other words the laser is not properly impedance matched to the interferometer. The impedance matching can be improved by placing another mirror of carefully chosen transmission—a power recycling mirror—between the laser and the interferometer so that a resonant cavity is formed between this mirror and the rest of the interferometer and no light comes back towards the laser. There is then a power build-up inside the interferometer, a build-up which can be high enough to create the required laser power at the beamsplitter from $\sim$10 W or so out of the laser.

Signal recycling

To enhance further the sensitivity of an interferometric detector and to allow some narrowing of the detection bandwidth, which may be valuable in searches for continuous wave (CW) sources of gravitational radiation, another technique known as signal recycling was invented in Glasgow by the late Brian Meers. This relies on the fact that sidebands created on the light by gravitational wave signals interacting with the arms do not interfere destructively and so do appear at the output of the interferometer. If a mirror of suitably chosen reflectivity is put at the output of the system as shown in figure 3, then the sidebands can be recycled back into the interferometer where they resonate and hence the signal size over a given bandwidth (set by the mirror reflectivity) is enhanced.

Application of these techniques

Using appropriate optical configurations the required laser power may thus be reduced to a level ($\sim$10 W) where laser sources are available. It should be noted, however, that trade-offs between the different techniques are possible. For example, the GEO 600 detector uses a four-bounce delay line in each arm with power recycling and signal recycling, whereas the initial designs of the LIGO and VIRGO detectors have Fabry–Perot cavities in the arms and use power recycling but not signal recycling. It is expected that both these experiments will be upgraded to use signal recycling at a later stage of their development.

There are few lasers currently available that can produce CW laser light of enough power and with high enough frequency stability to allow the levels of sensitivity discussed above. Indeed there is only one realistic candidate—the diode-pumped Nd:YAG laser capable of producing several tens of watts of single-frequency light at 1.06 μm wavelength.

Long-baseline detectors under construction on Earth

Prototype detectors using laser interferometry have been constructed by various research groups around the world—at the Max-Planck-Institut für Quantenoptik in Garching, at the University of Glasgow, at California Institute of Technology, at the Massachusetts Institute of

arms making significant angles with each other using laser interferometry.

A particularly exciting experiment is being proposed by an American–European team; it consists of an array of three drag-free spacecraft at the vertices of an equilateral triangle of length of side 5×10^6 km. This cluster is placed in an Earth-like orbit at a distance of 1 AU from the Sun and 20° behind the Earth. Proof masses inside the spacecraft (two in each spacecraft) form the end points of three separate but not independent interferometers. Each single two-arm Michelson-type interferometer is formed from a vertex (actually consisting of the proof masses in a 'central' spacecraft) and the masses in two remote spacecraft as indicated in figure 5.

The three-interferometer configuration provides redundancy against component failure, gives better detection probability and allows the determination of the polarization of the incoming radiation. The spacecraft in which the interferometers are accommodated shields each pair of proof masses from external disturbances (e.g. solar radiation pressure). Drag-free control servos enable the spacecraft to follow the proof masses to a high level of precision, the drag compensation being effected using proportional electric thrusters. Illumination of the interferometers is by highly stabilized laser light from compact Nd:YAG lasers at a wavelength of 1.064 μm. For each interferometer—consisting of a central spacecraft and two distant spacecraft—two lasers in the central spacecraft, each pointing along one of the arms, are phase locked together so they effectively behave as a single laser.

For LISA to achieve its design performance, adjacent arm lengths have to be sensed to an accuracy of better than 30 pm $\mathrm{Hz}^{-1/2}$. Because of the long distances involved and the spatial extent of the laser beams, the low photon fluxes make it impossible to use standard mirrors for reflection; thus active mirrors with phase-locked laser transponders on the spacecraft will be implemented. Telescope mirrors will be used to reduce diffraction losses on transmission of the beams and to increase the collecting area for reception of the beams. Given that the available laser power in each arm is of the order of 1 W, and that sensitivity arguments similar to those already discussed for ground-based detectors can be made, photoelectron shot noise considerations suggest that the diameters of the transmitting and receiving mirrors on the space craft need to be ∼30 cm.

LISA has been adopted by ESA as a Cornerstone Project in their post Horizon 2000 program. However, because of financial uncertainties the timescale of this program is somewhat long and the possibility of an earlier launch as a NASA-led or ESA-led collaborative medium-scale mission is being enthusiastically addressed at present.

Conclusion

A large amount of effort worldwide is now being invested in the development of both ground and spaced based searches for gravitational radiation and we are entering a new era where the signals from neutron star and black hole interactions will widen our understanding of the Universe. Beyond this, however, there is the very exciting prospect that gravitational wave astronomy will, like radio astronomy and x-ray astronomy, allow the discovery of very active sources currently unknown to us.

Bibliography

The existence of gravitational waves was postulated by Albert Einstein:

Einstein A 1916 *Preuss. Akad. Wiss. Berlin, Sitzungsber. Phys.-Math. Klasse* 688

Einstein A 1918 *Preuss. Akad. Wiss. Berlin, Sitzungsber. Phys.-Math. Klasse* 154

First experiments with apparently positive results were carried out by Joseph Weber of the University of Maryland:

Weber J 1969 *Phys. Rev. Lett.* **22** 1320

These results were not confirmed by a number of experimental groups—for a discussion of this see for example

Kafka P and Schnupp L 1978 *Astron. Astrophys.* **70** 97

Tyson J A and Gifford R P 1978 *Ann. Rev. Astron. Astrophys.* **16** 521

A good review of bar detectors and developments towards laser interferometer detectors is well described in

Saulson P R 1994 *Fundamentals of Interferometric Gravitational Wave Detectors* (Singapore: World Scientific)

For a popular account of the development of the gravitational wave field the reader should consult

Thorne K S 1994 *Black Holes and Time Warps* (New York: Norton) ch 10

The challenge of reducing thermal noise in interferometric gravitational wave detectors is highlighted in

Gravitational Waves

Wavelike disturbances in the geometry of space and time. Just as an accelerating or oscillating charged particle will radiate electromagnetic waves, so an accelerating, oscillating or violently disturbed mass, or system of masses, is expected to radiate wave-like gravitational disturbances (i.e. gravitational waves). According to the general theory of relativity, any change in a gravitational field should propagate through space at the speed of light. For example, if the Sun were suddenly to be annihilated, 8.3 min (the light-travel time from the Sun to the Earth) would elapse before the Earth ceased to 'feel' the gravitational influence of the Sun. Likewise, gravitational waves in general should propagate through space at the speed of light.

A gravitational wave vibrates in planes perpendicular to the direction in which it is propagating. The effect of a gravitational wave passing through a solid body (or through a distribution of individual particles) is to stretch the body first along one direction (while compressing it at right angles to this direction) and then, similarly, in the plane perpendicular to this direction. In principle, gravitational waves may be detected by measuring the periodic distortions that they produce in solid bodies or in the separations between freely suspended masses or freely orbiting spacecraft. However, because gravitation is by far the weakest of the fundamental forces, gravitational waves are expected to be exceedingly feeble and difficult to detect (for example, because the gravitational attraction between two electrons is more than 10^{40} times weaker than the electromagnetic interaction, the gravitational waves radiated by a pair of oscillating electrons will also be more than 10^{40} times weaker than the electromagnetic waves that they emit). As yet no man-made device has made a confirmed detection of gravitational radiation from any source.

The most likely sources of potentially detectable gravitational waves are processes involving dramatic changes in strong gravitational fields, for example the collapse of the core of a massive star during a supernova explosion, the formation of a black hole, very close and rapidly rotating binary systems, or collisions and mergers involving neutron stars or black holes. Although no source of gravitational radiation has yet been detected directly, strong confirmation of the existence of gravitational radiation has been provided by the behavior of pulsar PSR 1913+16, which is a member of a binary system consisting of two neutron stars that orbit around each other in 7.75 h. The orbital period of this system is decreasing at a rate that is precisely consistent with what would be expected if the two stars were spiralling in towards each other as a consequence of radiating away rotational energy in the form of gravitational waves.

Graviton

The hypothetical force-carrying particle (gauge boson) for gravitation. Although there is, as yet, no generally accepted quantum theory of gravity, it is widely believed that gravitation, like the other fundamental forces, should be amenable to being formulated in quantum terms and that the gravitational interaction between particles of matter should be conveyed by gravitons. The hypothesized graviton has zero mass, zero charge and a spin value of 2 (expressed in units of the Planck constant divided by 2π).

Gravity Probe B

A relativity gyroscope experiment being developed by NASA and Stanford University to test two unverified predictions of Einstein's general theory of relativity. Due for launch into polar orbit in May 2002. It will very precisely monitor tiny changes in the direction of spin of four gyroscopes on the satellite. Free from disturbance, the gyroscopes will measure how much space and time are warped by the presence of the Earth, and how the Earth's rotation drags space-time around.

Gray, Stephen (1666–1736)

Astronomer and scientist, born in Canterbury, Kent, England. Something of a scientific enigma, Gray at first devoted his energy to astronomy, observing eclipses, sunspots, the satellites of Jupiter, and communicating his results to the first Astronomer Royal, JOHN FLAMSTEED. He was interested in instrumentation and invented a microscope in which a drop of water was the lens. In his later years, he devoted himself to electricity, discovering that electricity could be conducted. He was apparently not allowed to communicate the results of his electrical experiments to the Royal Society by ISAAC NEWTON, while Newton organized its meetings and concentrated on gravity, but was twice awarded its Copley Medal as Newton's influence declined.

Grazing Incidence Optics

When a beam of light is reflected from a mirror or DIFFRACTION GRATING the angle of incidence (θ) is measured from the surface normal (perpendicular to the surface) to the light ray. If this angle is greater than about 80° the reflection is said to be at grazing incidence and the angle between the surface and the ray is called the grazing angle. The grazing angle is therefore $\theta_g = 90^\circ - \theta$. Optical systems in which grazing incidence is employed are called grazing incidence optics.

Optics in which the angles of incidence are near to 90° are called normal incidence optics. Imaging systems use normal incidence, when possible, because ABERRATIONS or image imperfections introduced by the reflection geometry (rather than by diffraction or scattering) become more severe as the incidence angles increase. However, for x-rays there is a compelling reason to tolerate the severe drawbacks of grazing incidence devices.

X-RAYS, electromagnetic radiation with photon energies in the range 0.1–100 keV or with wavelength in the range 124–0.124 Å, will only reflect if the surface is highly polished and at grazing incidence. The higher the photon energy the smaller the grazing angle must be to give a good reflection. At normal incidence all x-rays are absorbed.

The only way to focus x-rays with a broad energy spectrum from a large aperture is to use grazing incidence reflections and so X-RAY TELESCOPES and devices used to focus or concentrate x-rays from laboratory sources such as synchrotron rings are grazing incidence optics.

X-ray reflectivities

The complex refractive index for x-rays in materials is given by $n = (1 - \delta) - i\beta$ where both δ and β are positive and small. The imaginary part describes absorption and is directly related to the mass absorption coefficient $\mu = 4\pi\beta/\lambda\rho$ where ρ is the mass density of the material. The mass absorption is, in turn, directly related to photoelectric absorption.

The real part of n is a little less than unity and therefore the phase velocity of x-rays in materials is slightly higher than the velocity of light in vacuum. Thus when x-rays pass from vacuum into a material the refraction angle (measured from the normal within the material) is slightly larger than the incidence angle. At a critical grazing angle given by $\cos\theta_t = 1 - \delta$ total external reflection occurs, analagous to total internal reflection of visible light at a glass–vacuum boundary. Because of the imaginary part of the refractive index, β, the reflection is not total but for grazing angles smaller than $\theta_t \approx (2\delta)^{1/2}$ the reflection coefficient for x-rays can be high. To obtain good reflectivities the surface must be coated with dense, heavy metals such as nickel, gold, platinum or iridium. Ignoring absorption edges the critical angle in degrees for heavy elements of density ρ (g cm^{-3}) at x-ray wavelength λ measured in Å is given by $\theta_t \approx 0.1\lambda\rho^{1/2}$. For gold the critical angle is approximately $\theta_t = 0.4\lambda$.

The decrements δ and β are functions of wavelength and the specular reflection coefficient for x-rays of a given wavelength can be calculated accurately using Fresnel's equations in the same way as for longer-wavelength electromagnetic radiation. However, since the reflection is only appreciable at grazing angles there is very little difference between the reflection efficiency of the parallel and perpendicular polarizations.

The value of β can be calculated theoretically using numerical electronic wavefunctions or obtained from measurements of photoelectric absorption. The real decrement δ can then be calculated using the Kramers–Kronig relation from dispersion theory. Alternatively δ can be calculated directly using Kramers–Kallmann–Mark anomalous dispersion theory. For x-ray wavelengths sufficiently far from absorption edges ($|\Delta E| > 30$ eV) the refractive index can be predicted accurately. In the vicinity of absorption edges the calculations are limited by the details of the electronic energy structure included in the theory and by extended x-ray absorption fine structure (EXAFS), which is a correction introduced by a second scattering of the out-going primary scattered wave by nearby atoms in the surface. Tabulations of the refractive index decrements for all atomic types over the entire x-ray energy band are available and therefore the Fresnel reflectivity of x-rays from mirror surfaces can be calculated in a straightforward manner.

Figure 1 shows the calculated reflectivity for pure gold. The left-hand panel shows how the critical grazing angle becomes smaller as the photon energy increases. The right-hand panel shows the reduction in reflectivity introduced by absorption edges. There is a series of M-edges in gold starting at 2.1 keV.

Bragg reflections from crystals or multilayers can be used for narrow band imaging and spectroscopy or for enhancing the high-energy response of grazing incidence surfaces but they are inefficient for broad-band use below 15 keV.

Refractive x-ray lenses are not possible because the real part of the refractive index in materials, $1 - \delta$, is too close to unity and the penetration depth is too small because β is relatively large.

Scattering of x-rays at grazing incidence

The wavelength range for x-rays is 0.1–100 Å and therefore roughness and imperfections in the surface chemistry and geometry on the atomic scale are expected to influence specular reflection from the surface. Roughness or chemical contamination introduces small phase and amplitude changes in the reflected x-ray wavefronts and some of the light is scattered (or diffracted) away from the specular direction.

The complete theory of scattering of electromagnetic radiation from surface roughness was originally developed to describe scattering of radar from land and sea but the results apply equally well to the much shorter-wavelength regime of x-rays. Surface roughness is modeled as a two-dimensional aperiodic diffraction grating

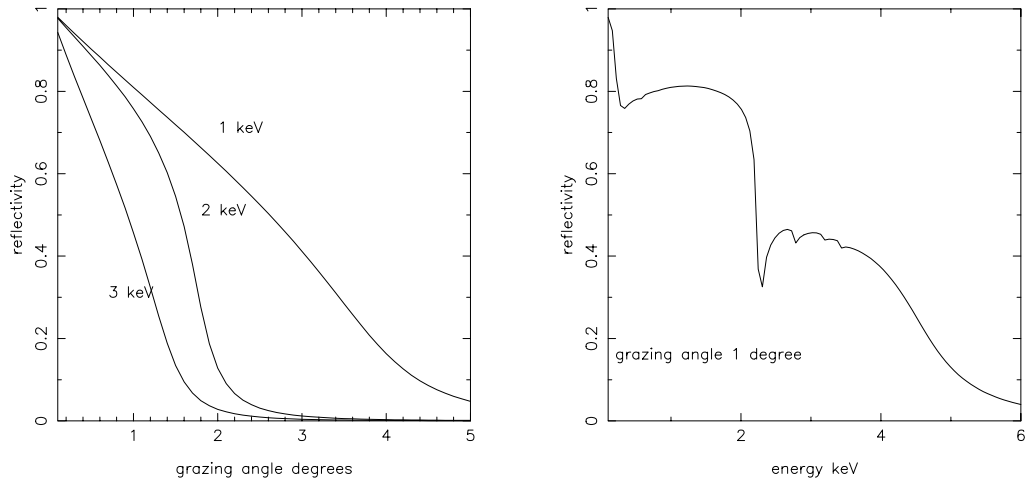

Figure 1. The x-ray reflectivity of gold.

and each Fourier component of the surface height profile, period d, produces diffraction orders m at angles given by the grating equation $\sin\theta_s - \sin\theta = m\lambda/d$ where θ is the angle of incidence and θ_s is the angle of scatter measured with respect to the surface normal. The total integrated scatter (TIS) is the fraction of the incident intensity which is scattered out of the specular beam. If the surface is reasonably smooth and first-order scattering dominates then the TIS $= R_\tau(\theta,\lambda)(4\pi\sigma\cos\theta/\lambda)^2$ where R_τ is the Fresnel reflectivity for polarization τ and σ is the root mean square (rms) of the surface height fluctuations. Typically σ must be $\leq$5 Å rms to keep the TIS at an acceptable level. Surface contamination which is distributed unevenly over the surface can be modeled in a similar way and acts like a phase grating. Any particle or dust contamination will further block or scatter the x-rays.

Surface contamination by hydrocarbons or similar compounds often forms a smooth layer or layers. A Fresnel reflection will result from each interface and the total reflection must be calculated by summing the component wave amplitudes taking into account the phase difference introduced by the thickness of the layers. The contamination acts in the same way as a multilayer coating on a conventional lens. A single monolayer of hydrocarbon contamination can severely compromise or indeed enhance the x-ray reflectivity of a grazing incidence mirror.

Geometries for imaging at grazing incidence

A nearly stigmatic telescope system must have a principal surface that is a sphere centered on the axial focus. If the F-ratio is small enough (small aperture diameter/focal length) then this sphere is well approximated by a plane perpendicular to the optical axis. For an imaging system which uses just one reflection the principal surface of the optic must necessarily be the reflecting surface itself and therefore a grazing incidence system employing one reflection is very astigmatic. A parabolic mirror with high curvature and large enough diameter such that the outer edges are reflecting at grazing incidence will bring rays parallel to the axis into a point focus. However, parallel rays which are slightly off-axis will form a highly comatic image consisting of a circle centered on the axis.

It is possible to produce a nearly stigmatic imaging system using an even number of grazing incidence reflections. The first such system devised was described by P Kirkpatrick and A V Baez in 1948. This comprises two orthogonally mounted cylinders each of which produces a line focus as illustrated in figure 2. The axially symmetric solution to the problem was provided by H Wolter in 1952. The two Wolter geometries which can be used for telescopes are called Wolter type I and type II and are illustrated in figure 3. The solid lines are the physical mirrors, the dashed lines indicate the path of on-axis rays and the dotted lines show the principal surface and surface generators. The first reflecting surface has a parabolic profile while the second is hyperbolic. In fact the surfaces are essentially the same as a CASSEGRAIN TELESCOPE except that grazing incidence rather than normal incidence is used. For the type I design the two physical surfaces meet at a join plane and the distance from this plane to the focus is the focal length. For type II the join plane is in front of the physical surfaces and therefore the focal length is larger than the instrument length. This design is best suited to larger grazing angles and is therefore only useful for longer wavelengths or lower energies in the soft x-ray and extreme ultraviolet bands. Wolter type II telescopes were used on the EXTREME ULTRAVIOLET EXPLORER satellite launched 1992.

Both the Kirkpatrick–Baez (K–B) and Wolter type I geometries can be nested. In the K–B case a large number of reflecting plates can be stacked together such that they have a common line focus. For Wolter I systems a series of surfaces of revolution are placed one inside the other with a common axis. For a Wolter type I aperture of radius R the grazing angle is given by $\theta_g = \tan^{-1}(R/F)/4$ where F

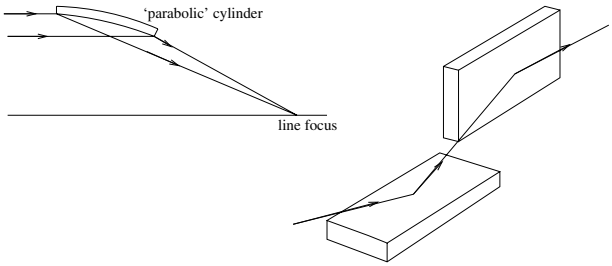

Figure 2. The Kirkpatrick–Baez geometry.

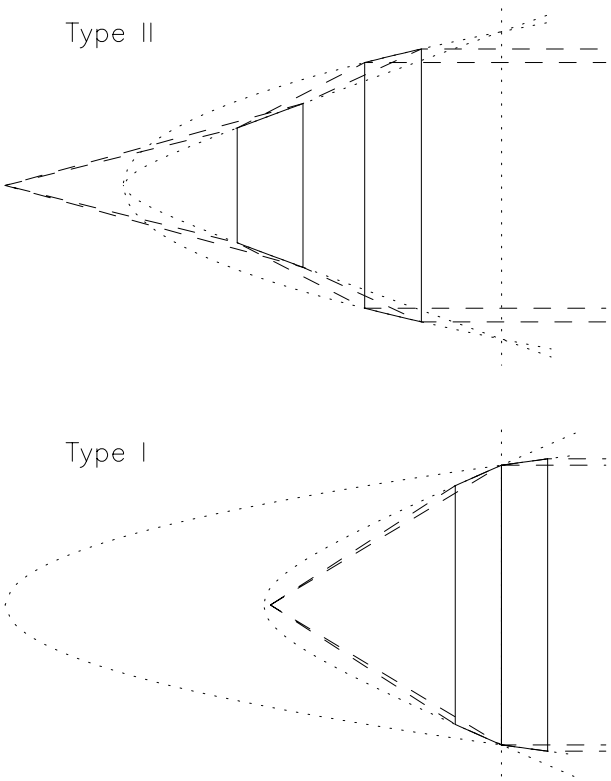

Figure 3. Wolter type I and II geometries.

is the focal length. The F-ratio therefore determines the largest grazing angles in the nest. Efficient nesting can be achieved over radii from R to $R/3$. Further surfaces added at smaller radii will increase the high-energy collecting area but have little effect on the lower-energy collecting area.

Small square pores or channels can be packed together to approximate a K–B or Wolter I geometry. If the channels are packed on a Cartesian grid then the resulting optic works in the same way as the eye of a lobster. The image consists of a true focus produced by an even number of reflections, a cruciform focus produced by a odd number of reflections and a diffuse background produced by no reflections. The Wolter I geometry can be approximated by packing the square pores in a radial pattern and using two successive plates of channels.

Designing grazing incidence telescopes

All the large focusing x-ray telescopes which have been built to date have used grazing incidence reflection in the Wolter type I geometry. The main problem with grazing incidence optics is low surface utilization. The effective area of a K–B or Wolter type I system for wavelength λ is given by $A_{\rm eff} = \frac{1}{2}R^2(\theta_{\rm g}, \lambda)\sin\theta_{\rm g}\, A_{\rm geom}$ where $A_{\rm geom}$ is the geometric area and $R(\theta_{\rm g}, \lambda)$ is the reflectivity from one reflection. The grazing angle must be small so that the square of the reflectivity is high, typically $\theta_{\rm g} \leq 1.5^\circ$, and so the ratio of the polished surface area to the effective area is very large. To give a large collecting area the surfaces must be long in the axial direction and/or they must be nested. The maximum two-reflection reflectivity is usually achieved if the grazing angles on the two surfaces are equal. The surfaces look like cylinders with a slight taper. The individual surface elements are often referred to as shells and it may be advantageous to manufacture a pair of parabolic and hyperbolic surfaces in a single monolithic shell.

The figuring errors must be significantly less than the angular resolution required and the gradient errors must be kept small over the entire axial length of the surfaces. The mirror shells must be thick enough to support the figure but aperture area is inevitably lost at the front ends of each shell. There is therefore a direct trade-off between angular resolution (shell stiffness) and effective area (aperture utilization).

The radius of the field of view is necessarily less than the grazing angle but as the grazing angles increase the upper energy cutoff of the telescope decreases so there is a direct trade-off between the maximum field of view and the broad band response.

Manufacturing grazing incidence telescopes

The traditional way of producing Wolter type I x-ray mirrors is as monolithic shells. Wolter I blanks are drilled out of a block of Zerodur or similar glass ceramic. The blanks are then ground to the correct thickness and figure. Superpolish is achieved by a very fine grinding–polishing process. Provided that the shells are thick enough very high figure tolerances and a superpolish of 3 Å rms can be met giving 0.5 arcsec angular resolution. Using monolithic shells the aperture utilization is limited to $\sim$0.1 by the shell thickness required and the shells are very massive.

Wolter type I surfaces can be approximated by thin conical aluminum foil sectors with a foil thickness $\sim$130 μm. A very large number of nested sections can give a high aperture utilization of up to $\sim$0.6. A high-quality surface finish is produced by laquering or epoxy replication of a smooth mandrel former and high x-ray reflectivity is achieved by coating the surfaces with gold or some other high-Z material. Unfortunately figuring errors limit the angular resolution to $\sim$2 arcmin. The x-ray telescopes on the Japanese satellite ASCA launched in 1993 employed foil mirrors.

Table 1. Large x-ray telescopes.

	Einstein	ROSAT	Chandra	XMM
Focal length (mm)	3440	2400	10 069	7500
Diameter (mm)	580	835	1200	700
Axial length (mm)	1022	1000	1660	600
Number of shells	4	4	4	58
Shell material	Fused quartz	Zerodur	Zerodur	Nickel
Surface coating	chrome–nickel	Gold	Iridium	Gold
HEW (arcsec)	9	5	1	16
FWHM (arcsec)	3	3	0.5	8
Area, 1 keV (cm^2)	400	400	800	1475
Area, 8.0 keV (cm^2)	–	–	100	580

Wolter type I shells can be produced by a replication process. The surfaces are machined on a very stiff, stable mandrel in a similar way to the production of monolithic shells except that the surfaces are external rather than internal to the cylinder. The mandrel is then coated with ∼1500 Å of gold and a thin layer of nickel, ∼1.0 mm thick, is electroformed onto the mandrel surface. Luckily the gold acts as a release agent for the electroforming process and is conveniently transferred from the mandrel onto the electroformed nickel shell. After release the shell has a superpolished gold surface ready for use as an x-ray mirror. Shells can be produced with a thickness as little as 0.3 mm and so the aperture utilization can be ∼0.4. After release residual stress in the electroformed nickel may cause the shells to distort and the shells must be handled very carefully to avoid introducing figure errors. The first replicated Wolter type I mirrors were flown on EXOSAT launched in 1983.

Microchannel plate technology can be used to produce square pores in either the K–B (lobster eye) or the Wolter I approximation (see MICROCHANNEL PLATE DETECTORS). Very small grazing angles arise for the channels near the center of the plates giving a hard x-ray response and the geometry can provide a very wide field of view. The channel walls are thin, the aperture utilization is high and the optics have very low mass. However, it is difficult to align the channels, coat the channel walls and reduce the surface roughness.

Whatever the production process the reflecting surfaces must be kept very clean and free from dust and contamination, during manufacture, through launch to deployment in space.

Large x-ray telescopes

The brightest cosmic x-ray source Sco X-1 (SCORPIUS X-1) gives a flux at the Earth of about 150 photons cm^{-2} s^{-1} in the energy band 0.1–10 keV while typical sources are at least 10 000 times fainter. To detect the weaker sources a collecting area of a few hundred cm^2 is sufficient but to detect distant objects and perform accurate photometry or spectroscopy thousands of cm^2 are required. As the sensitivity increases with larger areas so the angular resolution must improve to avoid confusion and reveal detail in diffuse and extended objects. Successive generations of x-ray telescopes have gradually improved in collecting area and angular resolution.

Figure 4. XMM mirror module number 1.

The first large imaging x-ray telescope was the EINSTEIN Observatory, launched by NASA in 1978. The first x-ray all-sky survey produced with an imaging telescope was taken by ROSAT which was built in Germany and launched in 1990. Both these instruments used a Wolter type I design and monolithic shell technology.

XMM[1] and CHANDRA are the two largest x-ray observatories built to date. Chandra was launched by NASA on 23 July 1999 and XMM was launched by ESA on 10 December 1999. They are complementary in terms of both technology and performance. XMM contains three mirror modules produced using replication technology which provide over 4000 cm^2 of collecting area. Chandra is a single telescope constructed from monolithic shells with an angular resolution of 0.5 arcsec. Both XMM and Chandra are remarkable feats of optical engineering.

Table 1 summarizes the characteristics of these telescopes. Figure 4 shows the complete XMM mirror module number 1.

[1] XMM was renamed XMM–Newton after launch.

Future goals for grazing incidence optics

To achieve a sensitivity in the x-ray energy band comparable with the largest optical, infrared and radio telescopes the collecting area must be $\sim$10 m^2. It is unlikely that monolithic Wolter I shells could ever be produced to fill such an aperture area. However, it is possible to split the aperture into sectors and stack sector plates of Wolter I geometry into mirror modules which could then be integrated into a complete x-ray primary mirror, focusing all the x-ray light into a single focal plane. The XEUS concept under study at ESA is working towards this goal.

The diffraction limit of the angular resolution in x-ray astronomy is potentially very small, $\leq$0.02 arcsec for a modest 10 cm aperture. At present x-ray telescopes are nowhere near this limit. Very high angular resolution is possible if the surfaces can be manufactured and aberrations can be reduced by using multiple reflections. W Cash has suggested this can probably be realized using very-high-quality spherical mirrors in a K–B geometry. Prototype systems with $\sim$0.1 arcsec resolution have already been built. Unfortunately a high level of nesting must be used to give a useful area and the surface elements must be aligned to extremely high precision to reach the diffraction limited performance.

Great Circle

The circle obtained on the surface of a sphere by the intersection with the surface of a plane which passes through the center of the sphere. Any plane which intersects the sphere but does not pass through the center meets the sphere in a small circle. A great circle is, in fact, the largest possible circle that can be drawn on the surface of a sphere. The shortest distance between two points on a sphere is an arc of a great circle passing though those points. Examples of great circles on the Earth are the equator and lines of longitude; on the celestial sphere, the celestial equator, the meridian, ecliptic, etc.

Great Red Spot (GRS)

A huge permanent anticyclone in Jupiter's southern hemisphere, visible as a reddish oval at just over 20 °S. The earliest unequivocal observation was by Heinrich Schwabe in 1831 (the often-quoted sighting by Robert Hooke in 1664 now seems to have been of a similar but different spot). The GRS became a striking feature around 1880, when it developed a deep red coloration. It was also prominent in the early 1970s, but on other occasions the color has been less pronounced, fading on occasion to a pale buff or salmon pink and sometimes disappearing completely, to leave what is known as the *Red Spot hollow*. Its size has varied too: from about 10 000 to 14 000 km (north–south) by 24 000 to 40 000 km (east–west). The GRS drifts back and forth in longitude, and over the course of the twentieth century it completed about three circuits back and forth around the planet. There is also a 90-day oscillation in latitude that takes it nearly 2000 km either side of its mean position. In addition, it rotates counter-clockwise with a period of about 7 days. That the GRS is anticyclonic in nature is well accepted. What is not clear is what continues to drive it; one theory is that it is powered by the energy released as latent heat from the condensation of gases below. Its color variations may be caused by variations in the concentartion of phosphine (PH_3), or even of organic compounds.

Great Wall

A vast sheet-like aggregation of galaxies that is about 800 million light-years long, 280 million light-years 'high', but only about 15–20 million light-years 'thick'. One of the largest known structures in the universe, it lies at a distance of about 300 million light-years. The coma cluster, one of the nearest great clusters of galaxies, forms part of the 'wall'.

As with other remote structures in the universe, the distance and dimensions of the Great Wall depend on the value of the Hubble constant, H_0, the above figures being based on a value of 70 km s^{-1} Mpc^{-1}. In general terms, the size of the Great Wall, expressed in megaparsecs, is about $60/h$ by $170/h$, and its distance about $65/h$, where $h = H_0/100$. For example, if $H_0 = 70$ km s^{-1} Mpc^{-1}, then $h = 70/100 = 0.7$, and the length of the 'Wall' is $170/0.7 \approx 250$ Mpc ≈ 800 million light-years.

Green Bank (National Radio Astronomical Observatory)

Located in Green Bank, Pocahontas County, West Virginia. The site of the world's largest fully steerable radio telescope, which was under construction during 1999 and 2000. The National Radio Astronomy Observatory (NRAO) is a facility of the US National Science Foundation, and is operated under a cooperative agreement by Associated Universities, Inc. (AUI).

Funding for the new 100 m (330 ft) telescope was provided by the NSF's Division of Math and Physical Sciences. The telescope has actual surface dimensions of 100 by 110 m. Its structure allows the telescope to view the entire sky above 5° elevation. Operations are expected to begin during 2000.

Of the other instruments at Green Bank, the 42 m telescope closed on 19 July 1999, while the 91 m telescope collapsed on 15 November 1988. The collapse was due to the sudden failure of a key structural element in the box girder assembly that formed the main support for the antenna. The loss of the 91 m telescope resulted in the Green Bank Telescope Project.

The Green Bank Interferometer (GBI) is also operated by the NRAO. It includes three radio telescopes of 26 m (85 ft) diameter, designated 85-1, 85-3 and 85-2 (85-1 is also known as the Tatel Telescope). 85-1 and 85-2 form a one-baseline interferometer, funded by NASA, which is engaged in monitoring variable radio sources. This GBI–NASA monitoring program observes x-ray binary stars and active galactic nuclei.

The VLBI tracking station in Green Bank is one of four such NASA facilities dedicated to the support of very long baseline interferometry satellites.

Greenhouse Effect

The greenhouse effect is the radiative influence exerted by the atmosphere of a planet which causes the temperature at the surface to rise above the value it would normally reach if it were in direct equilibrium with sunlight (taking into account the planetary ALBEDO). This effect stems from the fact that certain atmospheric gases have the ability to transmit most of the solar radiation and to absorb the infrared emission from the surface. The thermal (i.e. infrared) radiation intercepted by the atmosphere is then partially re-emitted towards the surface, thus contributing additional heating of the surface.

Although the analogy is not entirely satisfactory in terms of the physical processes involved, it is easy to see the parallels between the greenhouse effect in the atmosphere–surface system of a planet and a horticultural greenhouse: the PLANETARY ATMOSPHERE plays the role of the glass cover that lets sunshine through to heat the soil while partly retaining the heat that escapes from the ground. The analogy goes even further, since an atmosphere may present opacity 'windows' allowing infrared radiation from the surface to escape, the equivalent of actual windows that help regulate the temperature inside a domestic greenhouse.

Physical description

A more physical description is given by the simple two-stream approximation for the solution of radiative equilibrium in a planetary atmosphere. In the simplest case of a gray atmosphere (the opacity to thermal radiation is independent of wavelength) and in the absence of absorption of the solar radiation, the thermal emission from the surface has the following expression:

$$B(\tau_g) = \frac{\sigma\theta_g^4}{\pi} = \frac{W_S}{\pi}\left(1 + \frac{3}{4}\tau_g\right) \tag{1}$$

where B is the integral of the Planck function over all wavelengths, σ is Stefan's constant, θ_g is the surface temperature, W_S is the constant downward solar energy flux and τ_g is the infrared optical depth at the surface. From this expression, one notes that the surface temperature is greater than it would be if the atmosphere were totally transparent to thermal radiation (i.e. when $\tau_g = 0$). This reference value, defined as the equilibrium effective temperature, is given by

$$\theta_{eq} = \left(\frac{W_S}{\sigma}\right)^{1/4} \tag{2}$$

and the surface temperature may then be expressed as

$$\theta_g = \theta_{eq}\left(1 + \frac{3\tau_g}{4}\right)^{1/4}. \tag{3}$$

The atmosphere being in radiative equilibrium, the fact that the surface temperature is larger than the equilibrium temperature implies that, at higher levels, the temperature must decrease below that value. Since the atmospheric temperature, expressed as a function of the optical depth τ, is

$$\theta(\tau) = \theta_{eq}\left(\frac{1}{2} + \frac{3\tau}{4}\right)^{1/4} \tag{4}$$

one notes that, for values of τ smaller than $\frac{2}{3}$, temperatures are indeed below θ_{eq}.

A comparison between equations (3) and (4) reveals a temperature discontinuity near the surface, the surface being somewhat warmer than the layer just above it. This corresponds to a difference $\delta B = W_S/2\pi$ in the radiative budgets of the two systems: the surface is assumed to only radiate upwards within 2π, whereas an atmospheric layer radiates both upwards and downwards. Formally, the amplitude of that discontinuity decreases as τ_g increases (if $\tau_g = 1$ and 100, then $\delta\theta/\theta_{eq} = 3.1\%$ and 0.5%, respectively). Physically, however, this temperature discontinuity is hydrostatically unstable and convection will tend to counter it. In this simple approximation, the radiative lapse rate is

$$-\frac{\partial\theta}{\partial z} = \frac{3}{8}\frac{(\theta/H)\tau}{1 + \frac{3}{2}\tau} \tag{5}$$

where H is a scale height characteristic of the vertical distribution of the infrared absorbing gas(es). The temperature lapse rate varies from zero (i.e. isothermal) at the top of the atmosphere to a maximum value at the surface. At some point, it may become superior to the adiabatic lapse rate, in which case convection sets in.

The case of a semi-infinite gray atmosphere opaque to both solar and thermal radiation can also be solved in the two-stream approximation and leads to the following reduced source function $B^*(\tau) = \pi B(\tau)/W_S(0)$:

$$2B^*(\tau) = \left(1 + \frac{\alpha}{2\mu_0}\right) + \left(\frac{3\mu_0}{2\alpha} - \frac{\alpha}{2\mu_0}\right)(1 - e^{-\alpha\tau/\mu_0}) \tag{6}$$

where $W_S(0)$ is the SOLAR CONSTANT at the top of the atmosphere, α is the ratio (assumed to be constant with altitude) of the extinction coefficient for solar radiation to that for thermal radiation, μ_0 is the cosine of the zenith solar angle and τ is the optical depth for thermal radiation. The boundary conditions are

$$2B^*(0) = 1 + \frac{\alpha}{2\mu_0} \tag{7}$$

$$2B^*(\infty) = 1 + \frac{3\mu_0}{2\alpha} \tag{8}$$

and their ratio is

$$\frac{B^*(\infty)}{B^*(0)} = 4\frac{x+1}{(x+2)(x-2)} \tag{9}$$

with $x = 2(1 + \alpha/\mu_0)$ varying from 2 to ∞. For values of $\alpha/\mu_0 \leq \frac{3}{2}$ (weak to moderate solar extinction versus thermal) the solution corresponds to a greenhouse

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

atmosphere in which the temperature increases with increasing optical depth, reaching values larger than the equilibrium effective temperature at some depth. For larger values, the solution is the reverse, i.e. the temperature decreases with optical depth because solar radiation is deposited in the upper atmospheric layers instead. In all cases, the temperature varies monotonically with altitude.

In real non-gray atmospheres, the extinction (of either solar or thermal radiation) varies both with altitude and with wavelength within each spectral domain. Then, an important additional feature may be the existence of a high-altitude temperature inversion if absorption of solar photons occurs preferentially in the upper atmospheric layers. The temperature in the stratosphere increases with altitude above a temperature minimum overlying a tropospheric greenhouse, provided that solar radiation is not completely blocked above these levels. In terms of the parameter α, these conditions are met if $\alpha \gg 1$ over a reasonably large fraction of the solar spectrum, and, at the same time, $\alpha \ll 1$ over most of the rest of the spectrum.

One may quantify the amplitude of an atmospheric greenhouse in at least two ways. The simplest estimator is just the relative increase in surface temperature compared with the equilibrium effective temperature $\Delta\theta/\theta = (\theta_g - \theta_{eq})/\theta_{eq}$. A more elaborate estimator is the effective value of α that can be evaluated from the radiative properties of the atmosphere. This represents a global value of α characterizing the whole atmosphere over the whole spectrum. From equation (6), one derives the following equation:

$$\frac{\pi[B(0) - B(\tau_g)]}{W_S(0) - W_S(\tau_g)} = \frac{\mu_0}{4\alpha}\left(3 - \frac{\alpha^2}{\mu_0^2}\right) \tag{10}$$

which may be solved for α:

$$\frac{\alpha}{\mu_0} = (\delta^2 + 3)^{1/2} - \delta \tag{11}$$

where

$$\delta = \beta - \frac{\chi}{2}[(\beta^2 + 3)^{1/2} - \beta + 2] \tag{12}$$

$$\beta = \frac{2\pi B(\tau_g)}{W_S(0) - W_S(\tau_g)} \tag{13}$$

and

$$\chi = \frac{W_S(0) - W_S(\tau_g)}{W_S(0)}. \tag{14}$$

These quantities are listed in table 1 for the terrestrial planets and TITAN. By all accounts, VENUS is the champion of the greenhouse effect, with the EARTH and Titan coming in second and third. MARS definitely shows the weakest case. The following section provides an attempt to explain these striking differences in terms of the climatic evolution of each planet.

Actually, as inferred from equations (6)–(9), it is not necessary that there be a surface boundary for a greenhouse effect to take place. For instance, the tropospheric thermal structure of the giant gaseous planets (Jupiter, Saturn, Uranus, and Neptune) is partly due to a greenhouse effect exerted by molecular hydrogen, which is a fairly efficient infrared absorber. Because there is no solid surface, however, this effect is spread out over a large altitude range. Furthermore, with the possible exception of Uranus, these planets possess an internal source of heat that strongly modifies the lower boundary condition and tends to overwhelm the greenhouse effect.

As noted above, the conditions that lead to the establishment of a greenhouse effect can also be reversed, thus leading to an anti-greenhouse effect. For instance, this occurs when a high-altitude haze absorbs or scatters visible sunlight and lets infrared radiation escape. On Earth, it has been predicted that extended fires resulting from a global nuclear conflict would inject large amounts of soot particles in the stratosphere that would act in such a way and provoke a dramatic surface cooling (so-called 'nuclear winter').

The above description focused on the atmospheric greenhouse effect. It is also possible for a greenhouse to occur in solid phase, for instance in the upper layers of ice deposits. The same conditions apply, that is the icy material needs to be somewhat transparent to sunlight and opaque to infrared radiation. It has been suggested that this mechanism is currently active at the surface of icy satellites.

Greenhouses in the solar system

From measurements collected in the solar system over the last 40 yr, it appears that all planets with a substantial atmosphere exhibit a greenhouse effect. The amplitude of this effect varies greatly from one planet to another, depending on the relative strength of the physical parameters involved (heliocentric distance, surface pressure, composition, feedback mechanisms, etc). In itself, this variety provides very useful clues for a better understanding of the impact of the various parameters. There are four cases of atmospheric greenhouse for bodies with a solid surface: Venus, Earth, Mars and Titan. Recent studies suggest that the greenhouse effect has played a major role in the climatic evolution of these planets. In addition, there are two cases of a suspected solid-state greenhouse, on IO and TRITON.

Atmospheric greenhouses

(*a*) *Venus*. Venus represents the archetype of the atmospheric greenhouse. Observationally, the first piece of evidence came in the late 1950s when measurements of the Venusian emission at centimetric wavelengths revealed a surface temperature on the order of 730 K. This value is about 500 K larger than the equilibrium effective temperature and could not readily be explained by the existing models of the Cytherean atmosphere. In 1960, Carl Sagan was the first to recognize that two of the main atmospheric constituents—CO_2 and H_2O—were probably responsible for a strong greenhouse effect. The Pioneer Venus mission later confirmed his hypothesis by providing a detailed account of the contribution of

Table 1. Physical quantities characterizing the greenhouses on the terrestrial planets and Titan.

Descriptor	Quantity	Venus	Earth	Mars	Titan
Surface temperature	θ_g (K)	731	288	218	94
Equilibrium temperature	θ_{eq} (K)	231	255	212	82
Relative increase of surface temperature	$\Delta\theta/\theta = (\theta_g - \theta_{eq})/\theta_{eq}$	2.16	0.13	0.03	0.15
Surface emission	$\pi B(\tau_g)$ (W m^{-2})	16 170	326	50	4.12
Solar flux at the top of the atmosphere	$W_S(0)$ (W m^{-2})	937	882	512	10.3
Solar flux reaching the surface	$W_S(\tau_g)$ (W m^{-2})	20	162	102	0.35
Relative extinction of atmosphere for light and IR	α ($\mu_0 = \frac{1}{2}$)	0.02	0.71	1.62	1.29

the various greenhouse agents: in decreasing order of importance, they are CO_2, H_2O, H_2SO_4 clouds, SO_2, CO and HCl (see VENUS: ATMOSPHERE).

One of the enigmas regarding the present-day Venus is the very low abundance of water. If Venus once possessed as much water as the Earth, what process made it disappear almost completely? In answer to this question, it was suggested that Venus has experienced a 'runaway greenhouse' in its early stage. In the original models (1960–84), it was considered that all of the water outgassed by the crust accumulated in the atmosphere as steam because initial conditions were already too warm for water to condense at the surface. Then, a runaway developed from the positive feedback between the accumulation of steam in the atmosphere and the greenhouse effect induced by that steam. This mechanism led to a high abundance of water vapor in the stratosphere, where it was photodissociated by solar UV photons. Hydrogen atoms hydrodynamically escaped from the atmosphere, thus sealing the fate of water on Venus. These early models, however, did not produce a complete loss of water because of a stratospheric cold trap that set in when the partial pressure of water vapor was still about 20 bar. Subsequent modeling (1988), taking into account moist convection as well as the 30% reduced luminosity of the fainter young Sun, suggested instead that an ocean may have existed at the surface, where temperatures reached the boiling point of water. Through the same feedback and loss mechanisms, this 'moist greenhouse' scenario leads to a complete dry-out of the atmosphere since the stratospheric cold trap does not set in before nearly all of the water has been lost.

(*b*) *Earth*. Earth's greenhouse is very mild in comparison with that of Venus. The surface temperature is only 33 K warmer than the equilibrium temperature. Yet, it has a profound significance for the existence and the development of life on our planet. As on Venus, the main greenhouse gases in EARTH'S ATMOSPHERE are CO_2 and H_2O. Besides a larger heliocentric distance, the case of the Earth reflects three fundamental differences with respect to Venus: (a) a smaller surface pressure (1/90th that of Venus) which limits the total infrared optical depth; (b) the existence of an atmospheric opacity window between 8 and 12 μm, an interval which contains a significant portion of the thermal emission from the surface; (c) a regulation mechanism for the natural abundance of atmospheric CO_2. Under the influence of weathering alone, the amount of CO_2 in the atmosphere tends to decrease owing to its dissolution in pluvial and surface waters and the formation of calcium carbonate in ocean waters. (In present-day oceans, the precipitation of calcium carbonate on the seafloor is performed by shelled organisms, mainly calcareous plankton. In the early stages, it may have been performed by bacterial mats.) On the other hand, tectonic and volcanic activity releases some of the CO_2 sequestered in seafloor carbonates. The two processes counterbalance each other and result in a stable equilibrium state for the Earth climate. This balancing mechanism has in fact been invoked as a way of resolving the 'faint young Sun' paradox: given the lower luminosity of the early Sun, the Earth should have experienced a global ice age during its first 2–3 billion years. The fossil record shows that this was not the case. Indeed, with a surface entirely covered by glaciers, the CO_2 sink due to the weathering cycle would have been much reduced and the amount of atmospheric CO_2 would have increased rapidly. This would have led to a reinforced greenhouse effect that would have raised the surface temperature above the melting point of water ice.

Since the beginning of the industrial era, human activity has resulted in a steady increase of the amount of atmospheric CO_2 and the climatic implications of that have now become a subject of concern. Present modeling suggests that a doubling of the CO_2 abundance would result in a global warming of about 2.5 K (other minor species such as CH_4 and CFCs may also have a significant impact by closing the 8–12 μm window). This estimate takes into account the feedback effect due to water vapor but assumes that the influence of clouds remains constant. The influence of an enhanced cloud cover is two-fold: it increases the albedo, therefore reducing the greenhouse effect, but it also increases the infrared opacity of the atmosphere, thereby increasing the greenhouse effect. It is generally thought that a moderating influence would prevail, although there are also 'worst-case' scenarios in which an enhanced cloud cover leads to a mean surface temperature increase of 4–5 K. In any case, because of the increased melting of the polar ice sheets and the subsequent rise of the mean sea level, a significant warming would have dramatic consequences for the habitability of the coastal areas in many countries.

(*c*) *Mars*. Mars presents a weak greenhouse effect, with a surface temperature only 6 K warmer than the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

equilibrium value. This may be explained by two key factors: (a) the surface pressure is 7/1000th that of the Earth and (b) the atmosphere is too cold to contain a significant amount of water vapor. Even though CO_2 constitutes 95% of the Martian atmosphere—which incidently contains more CO_2 than that of the Earth—the low surface pressure severely limits the infrared optical thickness. This effect is compounded by the lack of water vapor. Furthermore, the Martian greenhouse is regularly perturbed by quasi-periodic global dust storms which are triggered in the southern hemisphere. In the case of storms encircling the planet and lasting one season, calculations show that the mean seasonal daily insolation is dramatically reduced (by factors of tens to thousands depending on the latitude and the season). This may explain, for instance, the observed 5 K decrease of the mean diurnal surface temperature at the Viking 1 landing site after the 1976–7 global dust storm. However, the influence of dust loading in the atmosphere is not a one-way street. Evidence from Viking and Mars Global Surveyor also indicates atmospheric heating near the surface, even for large amounts of dust (see MARS: ATMOSPHERE).

The Red Planet has not always been so cold and dry. Surface morphological features observed by various orbiting spacecraft can only be explained by the presence of liquid water at some remote stage of the Martian evolution. It is currently assumed that a greenhouse effect generated by a thick CO_2 atmosphere (1000–5000 hPa) created a much warmer and wetter climate on the early Mars. This stage—during which life may have developed—probably lasted a few million years, until most of the CO_2 was converted into carbonates by the weathering cycle. The lack of tectonic activity on Mars prevented any recycling of these carbonates into carbon dioxide, thus quenching the atmospheric greenhouse. In principle, it would be possible to transform Mars into a habitable planet (terraforming) provided that most of the carbonates are converted back into atmospheric CO_2. Other necessary conditions for life would be production of O_2 by plants, protection from CO_2 toxicity by a buffer gas such as N_2 and shielding from solar UV radiation by CFCs.

(*d*) *Titan*. Titan, the largest satellite of Saturn and the only satellite in the solar system with a substantial atmosphere (1500 hPa surface pressure), represents an interesting case of greenhouse effect which is intermediate between those of Venus and the Earth. Despite the large distance from the Sun, the amplitude of the atmospheric greenhouse effect is relatively large. The main greenhouse gases are N_2 (constituting more than 94% of the atmosphere), CH_4 (less than 6%) and H_2 (0.1%). The abundance of the last of these constituents is critical since its absorption affects the transparency of the unique opacity window located between 16 and 25 μm. It is worth noting that the warming of the surface would be about 10 K greater were it not for the anti-greenhouse effect caused by a thick stratospheric haze.

Solid-state greenhouses

Io and Triton are very different in terms of surface composition and internal structure. One feature they may have in common, however, is the presence of a solid-state greenhouse at their surface. Io's surface is almost entirely covered with a SO_2 porous frost. From the positions of the near-infrared absorption bands due to this frost, it has been argued that a reverse temperature gradient exists at the subsolar point, i.e. the subsurface at 10–20 cm depth would be some 40 K warmer than the surface (at 85 K). However, other sulfur bands (SO_2 and S_8) measured by Voyager in the mid-infrared would argue against that conclusion. On Triton, the evidence is more indirect. Voyager images showing plumes of dark material extending several kilometers into the tenuous atmosphere suggest that local solid-state greenhouse warming of the subsurface CH_4–N_2 ice leads to rapid sublimation, resulting in a geyser-like phenomenon.

Gregorian Telescope

A type of reflecting telescope originally designed in 1663 by the Scottish mathematician, James Gregory. It utilizes a concave paraboloidal primary mirror and a concave ellipsoidal secondary mirror that is located outside the focus of the primary. Light reflected from the secondary travels back down the telescope tube, through a central hole in the primary, to the eyepiece. Because the secondary mirror causes light rays to converge at a smaller angle than the rays reflected directly from the primary, it increases the effective focal length of the instrument, so enabling a telescope of long effective focal length to be contained within a relatively short tube. The Gregorian optical system produces an upright image but suffers from having a very small field of view. Gregorian instruments, constructed by instrument-makers such as James Short (1710–68), became popular during the eighteenth century largely because their concave secondaries were easier to make than were the convex secondaries of the broadly similar Cassegrain instruments. Several modern solar telescopes are based on the Gregorian design, since it produces a real image of the Sun which can be occulted by a disk (to reduce scattered light or extract heat).

Gregory [Gregorie], James (1638–75)

Scottish mathematician and optician, born in Aberdeen. Gregory described in *Optica Promota* a design (which he never realized) for the first practical reflecting telescope in which a perforated primary concave parabolic mirror converges the light to the focus of a concave ellipsoidal secondary mirror. The light is reflected back to the ellipsoid's second focus behind the main mirror. A real image is formed at the common focus of the two mirrors (by contrast to the virtual image in a Cassegrain telescope). The *Gregorian telescope* (as the design came to be called) is used in solar instruments where the light and heat of the Sun can be drawn out of the instrument by a blockage placed at this position. (For the first Gregorian telescope made, *see* JOHN HADLEY, ROBERT HOOKE.) After a time in Padua, Gregory returned to Scotland (St Andrews, Edinburgh) and worked on pure mathematics. He invented a brilliant method to determine the scale of the stellar universe, by comparing Sirius (as an assumed typical star) with the Sun (assumed the same). Waiting until a planet became the same brightness as Sirius, he calculated the fraction of light that, at that time, the planet intercepted and reflected from the Sun. He was able to estimate Sirius's distance in units of the Sun's distance, arriving at a number of 83 190 AU, which he realized was a lower limit because of limitations in the scale of the solar system then known (1668). When in 1685 NEWTON repeated Gregory's calculation he concluded that Sirius was at 1 million AU.

Groombridge 1830

This star (abbr. Gr 1830), despite its being at the limit of naked-eye visibility (apparent magnitude 6.42), is very well known due to its large proper motion. It is identified by its number in the *Catalogue of Circumpolar Stars*, compiled by the wealthy amateur astronomer Stephen Groombridge (1755–1832) from observations made at his private observatory in Blackheath, approximately one kilometer from the Royal Observatory at Greenwich. Groombridge used a fine transit circle of 3.5 inches aperture with circles 4 feet in diameter, made for him in 1806 by Edward Troughton (1753–1835). This excellent instrument was the first successful transit circle used in Britain, and was one of the inspirations of G B Airy (1801–92), the seventh Astronomer Royal, to design his own great transit circle which came into use in 1851. Groombridge suffered a stroke in 1827 and was unable to complete the reductions of his observations. These were completed under Airy's supervision and the catalog, containing the positions of 4243 stars in the declination band 38–90°, was published in 1838. 'Groombridge' remained the standard reference for circumpolar stars for over 150 years; a revised edition was published in 1905.

Groombridge 1830 is a yellow main sequence star, spectral type G8Vp, apparent magnitude 6.42, situated about 16° south of γ Ursae Majoris in the Plough. It lies at a distance of 30 light-years, and has a parallax of 0.109″. Its absolute magnitude is 6.6. The significance of Groombridge 1830 was first recognized in 1842 by F W A Argelander (1799–1875), Director of the Bonn Observatory, who analyzed observations of its position made by various observers since 1794 and demonstrated that it had the then largest-known proper motion of any star. Even today its proper motion of 7.058″ per annum is the third largest known, surpassed only by Barnard's Star and Kapteyn's Star.

Groups of Galaxies

Gravity creates a huge variety of cosmic structure, but most galaxies are found in groups of no more than a few dozen members. Groups range from the satellite systems of giant galaxies to loose associations a few times denser than their surroundings to compact cores of rich galaxy clusters. The common thread linking these examples is that the galaxies making up a group interact more with each other than they do with the rest of the universe; thus a group is a dynamical unit.

Groups are important for the evolution of galaxies and of large-scale structures. GALAXY FORMATION appears to be a drawn-out process, involving the collapse of primordial perturbations, accretion of gas and dark matter, outright merging of distinct objects and outflows of gas enriched by supernovae. Most galaxies conduct these transactions in group environments. However, group environments are unstable; while the galaxies in a group are forming, the group itself may be separating out from the cosmic expansion, collapsing under the influence of gravity, accreting new members and finally merging with other groups to build clusters and superclusters.

We can study the present outcome of these ongoing processes in our immediate vicinity and glimpse some earlier stages at high REDSHIFT. However, reconstructing the evolution of groups is a difficult problem. Two powerful tools which complement optical studies are computer simulations and multiwavelength observations. Simulations model the key dynamical ingredients of groups, including the DARK MATTER IN GALAXIES which is otherwise inaccessible. Observations at radio and x-ray wavelengths show how intergalactic gas responds as groups evolve.

Evolutionary stages

Figures 1 through 4 show four groups, ordered by stage of development. Group evolution begins when a bound configuration of several galaxies collapses out of the Hubble flow; the LOCAL GROUP (LG) is now at this stage, with the Milky Way (MW) and M31 approaching each other for the first time (figure 1). One of our nearest neighbors, the M81 group (figure 2), illustrates a more advanced stage; as the HI image shows, three galaxies are linked by a complex structure indicating that they have already undergone at least one passage. STEPHAN'S QUINTET (figure 3), a compact group, contains an extended, possibly tidal feature in neutral hydrogen and a central cloud of hot gas visible in x-rays; this gas may have been heated by a fast, interpenetrating encounter between two galaxies. Finally, V Zw 311 (figure 4) is actually the core of cluster Abell 407; it is likely that several of these galaxies will merge over the next $\sim$1 Gyr.

These four examples represent not only different evolutionary stages but also different evolutionary *tracks*. For example, the LG will become more compact as the MW and M31 draw closer, possibly evolving into a system like the M81 group, but probably not attaining the dramatic status of Stephan's Quintet, let alone V Zw 311.

Collapse

The LG (figure 1) is probably the best place to study a collapsing group. Most of its luminosity is associated with the MW and M31, which are currently separated by $\sim$0.73 Mpc and approaching each other at 120 km s^{-1}. A simple model treats the main galaxies as point masses moving along a linear orbit—an ellipse of zero width. In this approximation, the two galaxies coincided at the big bang $t_0 \simeq 13$ Gyr ago, separated smoothly with the Hubble flow, reached a maximum separation of $\sim$1 Mpc some 5 Gyr ago and are now falling together. To account for this history, the LG's total mass must be about $4 \times 10^{12} M_\odot$ and its mass-to-light ratio $M/L_V \simeq 100$. This is several times most estimates of the MW's M/L ratio, a sign that unseen dark matter is important in extragalactic dynamics.

Thus it seems that much of the LG's mass resides in structures larger than individual galaxies. Cosmological N-body simulations show that gravity deforms a smooth distribution of dark matter with a plausible spectrum of density fluctuations into a complex web of 'pancakes' and filaments; this web constantly evolves as ever-larger scales break away from the Hubble expansion. Halos of dark matter form at the intersections of filaments and grow as mass flows along the filaments. In this picture, the MW and M31 are presumably linked by a major filament and are 'sucked together' as this filament collapses.

Spins and swings

In gravitational clustering, galaxies acquire their spins from tidal torques. At early times, the material which eventually forms a galaxy has an irregular shape, and as density fluctuations grow this material feels a torque due to the tides of other proto-galaxies. Groups seem natural places to apply this scenario; for example, it has been argued that the MW and M31 are mutually more or less edge-on because each provided the tidal torque which spun up the other. The further assumption that the total spin and orbital angular momentum of the LG is zero then yields a definite prediction for the M31's transverse motion with respect to the MW.

This simple calculation is less plausible on closer inspection. First, in a tally of angular momentum, spins are less important than satellite orbits; for example, the LARGE MAGELLANIC CLOUD's orbit about the MW has several times the angular momentum of the MW's spin, and the same may be true for M31 and M33. Second, the external torque on the MW–M31 binary due to the nearby galaxies shown in figure 1 is sufficient to give the pair a transverse velocity of at least $\sim$40 km s^{-1}. This orbital swing completely dominates the total angular momentum of the LG; clearly the LG's dynamical isolation is very imperfect. It is possible that MW and M31 set each other spinning, but the reflex torque on their relative orbit is tiny compared with the torques due to surrounding galaxies. Tests of the tidal torque hypothesis based on auditing the angular momentum of the LG seem doomed to founder on this complication.

Least-action models

To investigate the effects of surrounding galaxies in greater detail requires more than two free-falling bodies. An elegant approach minimizes the action of a system of point-like galaxies subject to mixed boundary conditions: peculiar velocities vanish as $t \to 0$, and all galaxies reach their observed positions at the present. This approach assumes that each galaxy's trajectory and gravitational field are adequately reproduced by a single particle. However, it also admits a rather strong test; given the present masses and redshift-independent distances of galaxies, it predicts their redshifts.

When applied to the LG this method yields impressive agreement between predicted and observed redshifts. Plausible solutions, in which the MW and M31 approach each other for the first time, assign the LG a total mass consistent with the simple two-galaxy estimate above. However, the transverse velocity of M31 depends sensitively on the volume simulated, growing to several hundred km s^{-1} when the other galaxies in figure 1 are included; indeed, it is possible that yet more distant galaxies may further modify the solutions. These results, if correct, completely rewrite the past and future of the LG; the MW and M31 are no longer partners in a dance lasting aeons but 'ships passing in the night' at several times their escape velocity. PROPER MOTIONS for M31 and other LG galaxies would settle the issue.

Virial equilibrium

Simple models assume that bound groups reach a quasi-equilibrium state in which galaxies have isotropic orbits with random phases. This state of randomized grace results from scattering of galaxies by each other and by masses outside the group. However, when do these scatterings occur? If a group is isolated and remains fairly spherical then its constituent galaxies are not deflected from their radial trajectories until the group has collapsed to a small fraction of its maximum radius. In this case the collapse is fairly violent, and the new-born group first reaches equilibrium at ∼200 times the mean cosmic density. At the opposite extreme in which a nascent group is strongly influenced by surrounding objects the collapse is gentle and the group attains equilibrium at only ∼30 times the mean density. This is basically the same set of alternatives considered in the discussion of the LG.

Once a group is in equilibrium, a time-averaged version of the *virial theorem* applies: $2\langle T\rangle + \langle U\rangle = 0$, where angle brackets denote time averages and T and U are the kinetic and potential energy of the group, respectively. Of course, these time-averaged quantities cannot be determined observationally; instead, we observe an ensemble of groups and use orbital randomness to justify taking ensemble averages. Observable quantities include the mean harmonic radius of the group, $r_{\rm h}$, and the line-of-sight velocity dispersion, σ. These parameters may be used to check that group has actually had time to reach virial equilibrium. The collapse time for an isolated, spherical group is approximately the Keplerian period of a particle at the edge of the group, or $\sim 2.9 t_{\rm c}$, where

$$t_{\rm c} = \frac{2 r_{\rm h}}{\sqrt{3}\sigma} \qquad (1)$$

is the *crossing time*. Starting from the big bang, it takes a group about one collapse time to reach equilibrium, so a

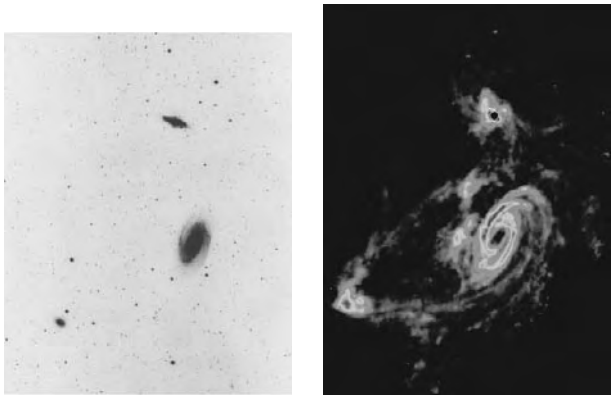

Figure 2. The M81 group in (left) visible light and (right) neutral hydrogen. (Courtesy M Yun.)

reasonable criterion might be $3t_c < t_0$. This limit is stricter than necessary for groups which are strongly influenced by neighboring masses, since such groups attain equilibrium with little or no collapse.

In view of the evidence for dark matter in the LG and in rich galaxy clusters, much effort has been devoted to measuring the masses of bound groups. For groups in equilibrium, the virial theorem provides an estimate of the dynamical mass,

$$M_{\rm d} = \frac{6\sigma^2 r_{\rm h}}{G}. \qquad (2)$$

Group mass-to-light ratios obtained using this approach generally show a wide scatter about a median value of several hundred. Some of this scatter represents fluctuations around virial equilibrium. However, a far larger and more systematic uncertainty arises in assigning galaxies to groups; if $M_{\rm d}$ is to provide meaningful group masses, the procedures used to identify groups must be carefully calibrated.

Catalogs and parameters

In the days before redshift surveys, groups were identified by noting galaxies with similar positions, apparent distances, and other signs of association. This subjective process produced accurate membership lists for nearby groups (e.g. figure 2), but contamination by foreground and background galaxies became much more serious at larger distances. As more redshifts became available it became clear that some 'traditional' groups extend along the line of sight for many Mpc; in such cases, a virial analysis is useless since σ reflects Hubble expansion instead of internal dynamics.

Redshift surveys down to a fixed limiting magnitude are probably the best available starting point in constructing group catalogs. However, redshifts reflect peculiar motions as well as Hubble expansion, and this distorts the galaxy distribution deduced from redshift surveys. Consequently, algorithms for group finding cannot treat radial and transverse directions on the same footing. Most group-finders use a 'friends of friends' algorithm which links two galaxies if their projected separation and line-of-sight velocity difference are less than some cutoff values; each set of galaxies linked either directly or via intermediaries defines a group.

The velocity cutoff strongly influences the resulting catalogs; if it is too high then unrelated galaxies along the line of sight may be linked together, while if it is too low then *bona fide* groups may be broken up. The same velocity information is used to define groups and to calculate their velocity dispersions, so it is no surprise that dispersions are also sensitive to the velocity cutoff. Tests run on simulated redshift surveys derived from cosmological N-body experiments offer some guidance in selecting distance and velocity cutoffs that produce reasonable group catalogs.

A typical catalog generated in this manner links about half of all galaxies into groups. Most groups have three or four members, while a small fraction are much richer. The median density of such groups is about 100 times the background density, and about half the groups have crossing times short enough to be virialized. The mass-to-light ratios derived for these groups are roughly consistent with the value obtained for the LG.

Dynamical evolution

It has been convenient so far to treat groups as systems of point-like galaxies. However, in reality galaxies are not points, and groups may have a good deal of dark matter not associated with individual galaxies. This can have dramatic consequences. For example, virial equilibrium is at best a temporary condition; in the long run, an isolated group cannot attain true equilibrium until all its galaxies coalesce to form a single group remnant.

Galactic encounters

Thanks to their finite sizes, galaxies are subject to tides. Galaxies in close proximity are simultaneously stretched and squeezed by tidal forces. DISK GALAXIES respond by forming dramatic bridges and tails of stars and gas which reflect the effects of tides on rotationally supported disks; ELLIPTICAL GALAXIES, supported by random motions, may exhibit distended envelopes and off-center isophotes. The explanation of such features as relics of tidal interactions was a key step in understanding the peculiar morphologies of colliding galaxies.

Groups of galaxies are likely sites for tidal interactions. Simple estimates and detailed simulations indicate that in a typical group there is roughly one close encounter per crossing time. A curious feature of tidal interactions is that slower encounters do more damage; groups have relatively low velocity dispersions, so most encounters in groups are slow enough to produce rather spectacular effects.

One example of tidal interactions is shown in figure 2. Even before the HI observations there were signs that the two brightest galaxies in this group were interacting; evidence included the 'grand design' spiral of M81 and an

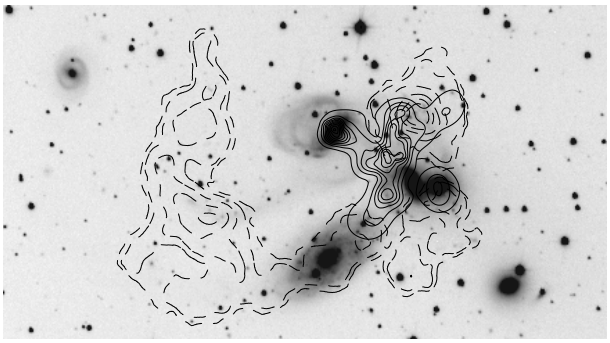

Figure 3. Stephan's Quintet, a compact group of galaxies. Plotted on top of the optical image (courtesy M Moles) are thin contours of HI emission (courtesy B Williams) and thick contours of x-ray emission (courtesy H Ebeling). The large spiral galaxy at the bottom is a foreground object.

'explosion', now recognized as a burst of star formation, in M82. The HI maps reveal complex filaments linking these galaxies as well as the third most luminous member, NGC 3077. These structures appear to be bridges and tails extracted from the extended gas disks of the individual galaxies by tidal forces during a fairly recent triple encounter; this encounter may represent the initial collapse of the M81 group.

Tidal interactions are common in COMPACT GROUPS OF GALAXIES where three or more galaxies are seen in near proximity. Besides tidal signatures similar to those already described, many disk galaxies in such groups have asymmetric rotation curves or other unusual kinematic features. Such kinematic peculiarities are among the first signs of a tidal interaction; bridges and tails develop later as perturbed stars drift away from their parent disks.

A compact group with a rather complicated history is shown in figure 3. This is Stephan's Quintet, discovered in 1877. As often happens, not all the galaxies are the same distance; in this case, the largest spiral is a foreground object, while the other five galaxies, including the small spiral on the left, are associated. Of these five, two exhibit tidal tails and other signs of interactions. However, tides are not the only forces at work here—velocity fields of both neutral and ionized hydrogen reveal *two* components separated by at least 700 km s^{-1}, while x-rays show a cloud of hot gas at the center of the group. The data suggest that gas is heated by a high-velocity shock between two distinct streams of tidal material, with further energy input from localized formation of massive stars. If so, at least two tidal encounters are required, since the debris of a single passage generally separate at roughly the encounter velocity. Moreover, the large shock velocity implies a deep potential well associated with one or more massive dark halos. Finally, the hot gas responsible for the x-ray emission points to a long-term change, since such gas, once heated, is slow to cool off.

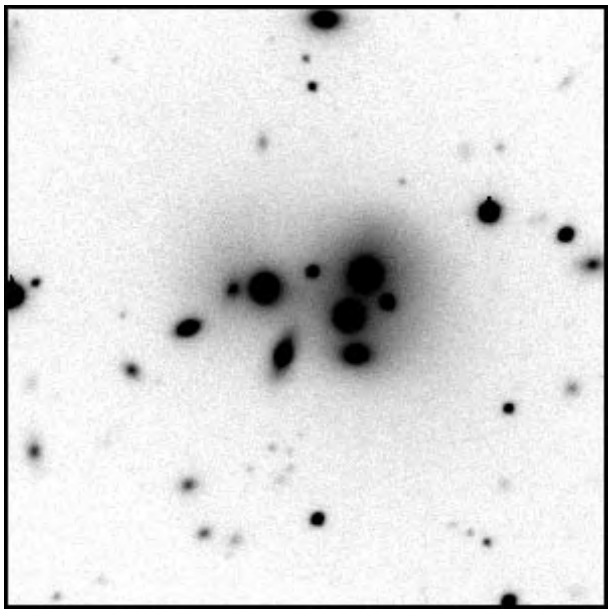

Figure 4. 'The once and future cD', V Zw 311, is a complex of galaxies at the center of a poor cluster (courtesy D Schneider).

Orbital decay

Another consequence of extended mass distributions in groups is the decay of galactic orbits. Tidal encounters between galaxies cause significant orbital decay—roughly speaking, the work required to raise tidal features of visible stars and of dark matter comes from the relative motion of the participants. Two equally matched galaxies whose halos interpenetrate after falling from a great distance will never return to anything like their maximum separation, but will pass even closer the next time around, and merge after a few orbits. This decay is slower in unequally matched encounters, but no less inexorable; it represents a one-way process, a randomization of the ordered relative motions of two galaxies. A similar process occurs when a galaxy orbits within the common halo of a larger group. In the limit where the group halo is much more massive than the galaxy this process can be described by several analytic approximations, none perfect yet all predicting that the galaxy will spiral inward after some M/m orbits, where M is the mass of the group and m is the mass of the galaxy.

Orbital decay can have dramatic consequences in extremely compact groups like the one in the center of V Zw 311 (figure 4). Here we see nearly a dozen early-type galaxies embedded in a common envelope of comparable total luminosity. The velocity dispersion of this group is $\sigma \simeq 600$ km s^{-1}, while the brighter group members have velocities within $\sim$200 km s^{-1} of the mean. Assuming this system is bound, its virial mass is about 10 times the total mass of the visible galaxies, and the unseen material is probably more extended than the luminous envelope. If the brighter galaxies are now on roughly circular orbits,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

they will spiral toward the center and presumably merge in ∼1 Gyr.

While objects as extreme as V Zw 311 are fairly rare, orbital decay occurs in both loose and compact groups. Numerical simulations in which galaxies and dark matter are represented using many thousands of particles are the most reliable way to follow the decay of galactic orbits. Such simulations show that galaxies spiral inward about as fast as predicted by the analytic models. The orbital decay timescale depends on the initial set up, being shorter if most of dark mass is associated with individual galaxy halos and longer if most of the dark mass is invested in a common group halo. However, unless the initial conditions are somehow fine-tuned, the orbits of massive galaxies shrink quite noticeably with each revolution.

In view of this relentless evolution, one might wonder whether it is correct to estimate group masses using the virial theorem. Numerical studies show that the systematic non-equilibrium effects are fairly modest; on the average, galaxies move about as fast as they would if their orbits were not decaying, and the virial theorem yields consistent mass estimates. However, as galaxies spiral in they explore less and less of the group's potential well, and any mass which lies beyond the region they sample will not be detected by a virial analysis.

Mergers

When galaxies spiral toward the center of a group it also becomes more and more likely that they will capture each other and merge. Merging can be described as a combination of orbital decay and tidal disruption. As two or more galaxies undergo successively closer passages, they are tidally stripped from the 'outside in'; most of the stripped material remains bound to the merging system and forms the body of the resulting merger remnant.

The outcome of a merger depends on the participants. Much attention has focused on the hypothesis that elliptical galaxies form by mergers of spiral galaxies. This suggestion is supported by observations of 'twin-tailed' merger remnants which have luminosity profiles and kinematic properties resembling bright elliptical galaxies and by numerical experiments which detail the mechanics of such catastrophic transformations. Together with the companion hypothesis that violent encounters can trigger bursts of star formation, merging succeeds in linking normal and peculiar galaxies into a coherent evolutionary scheme (see GALAXIES: INTERACTIONS AND MERGERS). Yet it is unlikely that all ellipticals resulted from mergers of equal-mass spirals. Some elliptical galaxies may have had multiple bursts of star formation, while others seem more thoroughly 'scrambled' than typical spiral–spiral mergers. If these objects originated in multiple mergers, they probably did so in group environments.

There are many groups with recent or ongoing mergers. One example is the loose, spiral-rich group containing Cen A, a peculiar elliptical galaxy with an active nucleus (see NGC 5128/CENTAURUS A). The dark bisecting dust lane, subtle 'shells' superimposed on the luminosity

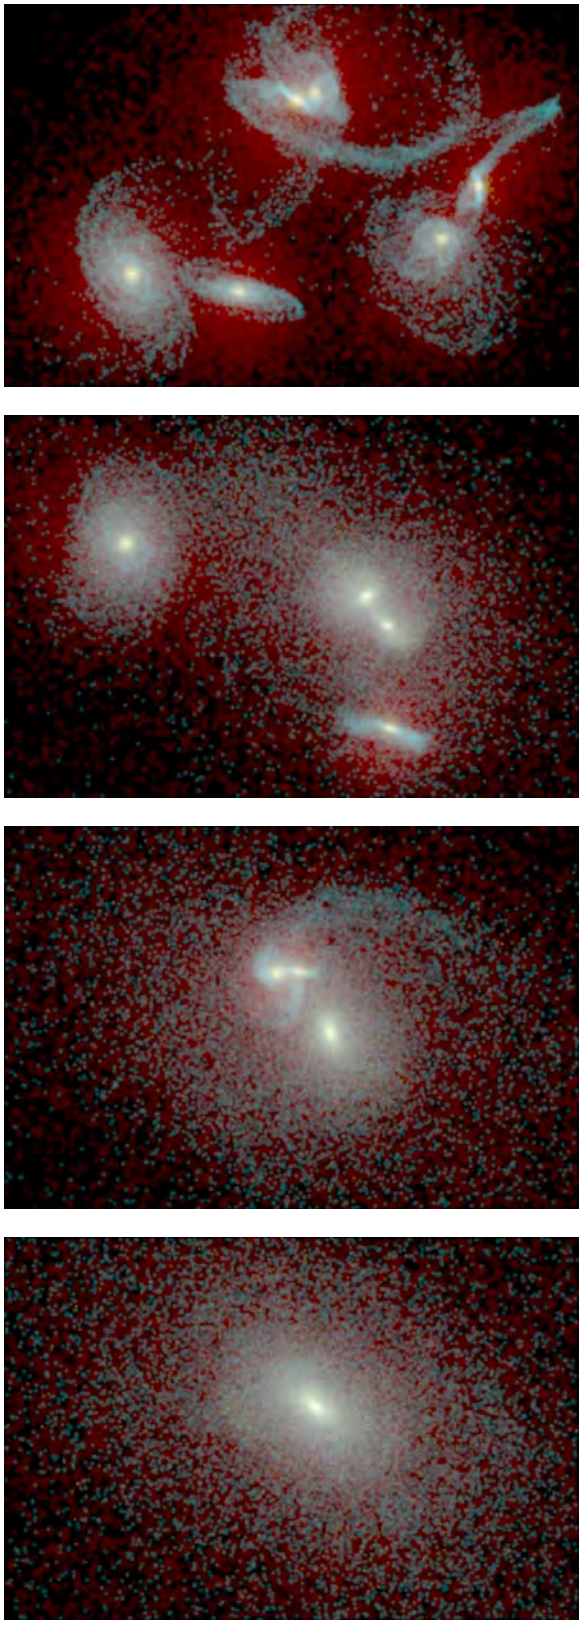

Figure 5. Numerical simulation of a compact group. These frames span an interval of ∼3 Gyr.

profile, unusual kinematics revealed by planetary nebulae and irregular structure of its extended envelope all suggest that Cen A swallowed a good-sized gas-rich companion ∼1 Gyr ago. Another example is the small group of four galaxies including NGC 3921, a classic twin-tailed remnant of a recent merger between two disk galaxies of comparable mass. A third example is Hickson Compact Group 95, in which two smaller spirals appear to be simultaneously merging with a larger elliptical galaxy.

In the case of V Zw 311 (figure 4), the extended envelope surrounding the galaxies probably represents material stripped in the early stages of the merging process. Further stripping as the galaxies sink toward the center of the group will liberate more material, building the merger remnant from the outside in. Once the larger galaxies finish merging, V Zw 311 will contain a very luminous central galaxy with an extended envelope; the expected parameters of this object suggest that we are witnessing the formation of a 'cD' galaxy similar to those which dominate the central regions of many galaxy clusters.

A numerical simulation illustrating the later stages of orbit decay and merging is presented in figure 5. This experiment started with a compact near-equilibrium configuration of six disk galaxies, each surrounded by a modest dark halo. The first frame shows the system shortly before two pairs merge; note the twin-tailed morphology of the pair at the top. Later frames show a further merger of the two remnants, a violent interaction between the composite remnant and the two remaining disk galaxies, and the final remnant, which resembles an elliptical galaxy. Scaling the initial disk galaxies to the MW, the group starts with a diameter of ∼120 kpc and takes about 3 Gyr to completely merge.

In absolute terms, the merger rate in a loose group is a good deal lower than in a compact group. However, this difference is largely due to the long crossing times of loose groups; within broad limits, there is about one merger per crossing time in loose and compact groups alike. Since loose groups are a good deal more common than compact ones, they probably dominate the net merger rate. Demographic estimates show that while galaxies in compact groups are ∼20 times more likely to undergo violent interactions and mergers, only one merger in four occurs in a compact group. The timescale for a typical loose group to merge is several times the age of the universe; nonetheless, a modest fraction of galaxies in loose groups have probably undergone multiple mergers.

Where are the relics of group mergers to be found? Some compact groups seem to be truly isolated, and the remnants of such groups should appear as bright, isolated elliptical galaxies. A small number of possible fossils have now been identified; these galaxies typically have extended halos of hot, x-ray-emitting gas similar to those seen in compact groups and poor clusters. However, while ongoing merging in groups has been building up the population of merger remnants, gravitational clustering has been incorporating these remnants into new groups and larger structures. Even today we find groups 'caught in the act' as they fall together and coalesce to form clusters. Once incorporated into clusters, galaxies are less likely to merge since their encounter velocities are now too high for tidal capture; if cluster ellipticals formed by merging, they can only have done so before the clusters themselves had collapsed. Elliptical galaxies in clusters may have formed in dense groups at redshifts $z \sim 2$; if so, compact groups are the low-redshift analogs of the birthplaces of cluster ellipticals.

Grubb, Thomas (1800–78) and Grubb, Howard (1844–1931)

Irish telescope makers, based in Dublin, then in St Albans, England. Thomas was born in Waterford and set up a machinery business. After making a 9 in telescope for himself, he made many giant reflecting telescopes commercially. One of his first contracts was for a Cassegrain reflector for ROMNEY ROBINSON of Armagh Observatory, which introduced mechanical design features of significance for the future, including the viewing position of the user (through a hole in the center of the main mirror, not from the top of the telescope), the mirror support system and its clock-driven equatorial mounting. With this successful start, the firm made telescopes that were exported all over the world, to Madras, Madrid, Mecca, Melbourne and Mississippi, to list just one letter of the alphabet. Howard, born in Dublin, joined the business and diversified to a range of optics. In 1925 the firm was taken over by CHARLES PARSONS, becoming the firm of Grubb-Parsons, and moving to Newcastle.

Grus

(the Crane; abbrev. Gru, gen. Gruis; area 366 sq. deg.) A southern constellation which lies between Piscis Austrinus and Tucana, and culminates at midnight in late August. It was first shown on Petrus Plancius' celestial globe of *c*. 1598, though it is usually attributed to the Dutch navigators Pieter Dirkszoon Keyser (also known as Petrus Theodorus) and Frederick de Houtman, who charted that part of the southern sky in 1595–7. On later globes Plancius gave it the now obsolete name of Phoenicopterus (the Flamingo).

A small but not inconspicuous constellation, the brightest stars in Grus are α Gruis (Al Na'ir), magnitude 1.7, β Gruis, magnitude 2.1, and γ Gruis, magnitude 3.0. There are four other stars brighter than fourth magnitude. Interesting objects include the naked-eye optical double stars δ Gruis, which has yellow (G6–8) and red (M4.5) components, magnitudes 4.0 and 4.1, separation about 13′, each of which is a binary, with components of magnitude 12.8 and 8.8, separation 5.6″ and 60.6″, respectively, and μ Gruis, which has yellow (G8) components, magnitudes 4.8 and 5.1, separation about 17′, the former of which is a close binary with a component of magnitude 6.7, separation 0.15″.

There are no bright star clusters, nebulae or galaxies in Grus.

Guide Telescope

A second telescope, attached to, and aligned parallel to, the main telescope, which is used to monitor the position of the object of interest in the field of view while the main telescope is being used to obtain a long-exposure image of the object. Because of imperfections in the telescope mounting, flexure of the telescope or its mounting and imperfections in the drive mechanism, the object that is being observed will tend, to some extent, to wander around the field of view during a long exposure. To compensate for this, the telescope must be guided (i.e. it must be adjusted, continually or at regular intervals, to ensure that the object remains in the center of its field of view). Traditionally, this is done by the observer adjusting the telescope controls to keep the object at the center of the field of view of the guide telescope—a tedious and time-consuming process. A widely used alternative is the autoguider, an electronic device that senses when the object drifts from its correct position and generates a signal that causes the slow-motion drives to restore the main telescope to the correct position. The autoguider may be attached directly to the guide telescope or be used to monitor a region of the field of view of the main telescope close to the object of interest. If the object of interest is too faint to be seen in the guide telescope, the guide telescope may be adjusted to focus on a nearby brighter object (guide star) while the main telescope remains pointed at the object being imaged. This process is called off-axis guiding.

In smaller sizes of telescope the role of guide telescope may have to be fulfilled by the finder.

Gum Nebula

A very large, near-circular emission nebula, approximately 36° in diameter, in the constellations Puppis and Vela. The largest known nebula in the sky, it was discovered by the Australian astronomer C S Gum (1924–60), and is believed to be an ancient supernova remnant, with an age exceeding a million years. It is a convoluted mass of nebular wisps and loops, many of them very faint, but there are also numerous brighter parts. Its distance has been estimated at 1300 light-years, indicating that the nebulosity is approximately 840 light-years across. Within one of its brightest regions both the brightest-known O-type star ζ Puppis (spectral type O5f) and the brightest Wolf–Rayet star γ^2 Velorum (type WC8), are found.

The much more recent Vela pulsar and supernova remnant also lie within the Gum Nebula, which for many years has rivalled the Crab Nebula in interest for astrophysicists.

H I Region

A cloud of interstellar matter consisting predominantly of neutral hydrogen atoms. 'Neutral' means not ionized—each hydrogen atom consists of a proton and its lone electron; this is what is implied by 'H I' (pronounced 'H one'). In H II ('H two') regions, the hydrogen is ionized, each atom having lost its electron. In mass and volume, neutral hydrogen accounts for about half of all interstellar matter. A typical H I region is 15–20 light-years across, and contains 50 solar masses of hydrogen at a temperature of around 100 K. H I regions emit no visible light, but are detectable by their radio emission at a wavelength of 21 cm (frequency about 1420 GHz). This so-called 21 cm radiation is what first allowed the form of our Galaxy to be mapped in the mid-twentieth century: neutral hydrogen is present in the disk of the Galaxy, concentrated in the spiral arms, and 21 cm radiation is little affected by intervening interstellar matter. H I regions have also been detected in other spiral galaxies, and in irregular galaxies, though they are largely absent from elliptical galaxies.

Compare: H II regions.

H II Regions

The birth of stars occurs in the densest parts of molecular cloud complexes. The radiation fields and stellar winds of newly formed stars excite and stir the surrounding gas. Low-mass stars ($M \leq 5M_{\odot}$) affect only relatively small volumes of the cloud. The stronger radiation fields and winds of more massive stars ($M \geq 10M_{\odot}$) can excite, ionize and excavate holes in the parent molecular cloud. A few massive stars can clear out the dense gas from the star-forming regions, exposing the recently formed group of stars. The ultraviolet stellar photon flux ionizes the surrounding gas, creating the beautiful and complex NEBULAE known as H II regions (or regions of ionized hydrogen).

The stars that create them are among the brightest, most massive and shortest-lived stars in galaxies. They have surface temperatures above 3×10^4 K and are brighter than 10^4 Suns, although their masses are only 20–100 times as great. They end their lives by exploding as SUPERNOVAE less than about 10 million years after birth, a time short compared with the age (about 4 500 million years) of our solar system. These massive stars are generically designated as OB stars and are excellent tracers of regions undergoing active STAR FORMATION both in our Galaxy and in external galaxies.

Physical properties

The spectra of H II regions at optical wavelengths are easy to recognize and contain strong emission lines of H, C, N, O and S. These lines provide us with information about the chemical abundances, densities and temperatures of the photoionized plasma. Additionally, the shapes and widths of these emission lines provide information about the spatial distributions and velocities of the emitting ions. This plasma has elemental abundances similar to those found in the solar system, and by terrestrial standards is very hot and dilute. The gas temperature is about (8–10) $\times$ 10^3 K and the average number densities are in the range 10^2–10^4 particles cm^{-3}, far below the densities in the best vacuum ever achieved on Earth. However, H II regions by terrestrial standards are huge and can contain far more material than in the Sun (cf table 1).

Not all H II regions are visible to optical telescopes. A fraction of these objects is buried deep in the parent molecular clouds and can be detected only at long wavelengths using RADIO TELESCOPES or infrared detectors. They are called ultracompact H II regions (UCHIIRs). The fraction of H II regions which these represent is generally believed to be about 20% of the total number of H II regions. They were discovered as recently as the 1960s and more than 200 are at present known. Thanks to the fast growth in radio and IR techniques, our knowledge of these objects has increased enormously in recent years. This is also true for optically observed regions, particularly after the launch of the Hubble Space Telescope and the advent of the new generation of large optical telescopes. Advances in optical, IR and radio studies together have provided us with a wealth of unprecedented detail about these fascinating objects.

Classification

H II regions in the Milky Way are classified into three main categories by their average sizes. In order of increasing size they are (i) UCHIIRs, (ii) compact H II regions and (iii) extended or 'classical' H II regions. There is a recently defined class, hypercompact (or superultracompact) H II (SUCHII) regions. They are detected at radio wavelengths and only a handful of them are at present known. Their observed properties indicate that they are denser and more compact than UCHIIRs and may be the youngest H II regions yet found.

The larger H II regions can be found in external galaxies. These include giant and supergiant H II regions. Table 1 lists these six categories along with their characteristic physical parameters including N_*, which is a (very) rough guide to the number of massive stars which excite them. This has been estimated by assuming that each star produces 10^{48} ionizing photons s^{-1}, a number we will use subsequently.

In external galaxies, the population of H II regions delineates the distribution of star-forming regions. Giant and supergiant H II regions are not single objects but a conglomerate of many individual H II regions occupying a large fraction of the volume of their parental giant molecular clouds. These objects trace the locations where vigorous star-formation activity, or a 'starburst', is taking place in gaseous (spiral and irregular) galaxies. Giant H II regions can be used as distance indicators for their host galaxies.

In SPIRAL GALAXIES, H II regions are located preferentially either along the spiral arms or in ring-like distributions at/or surrounding the dynamical centres of the host galaxies (these are called nuclear and circumnuclear starbursts). A beautiful example of a spiral arm distribution is found in the grand-design spiral galaxy M51. In the case of the nuclear and circumnuclear starbursts, the gas that is fuelling the star-forming activity was probably driven towards the dynamical center by a series of different perturbations in the disk, including interactions with other galaxies and stellar bars. Similar flows may also fuel the intense power generated in ACTIVE GALACTIC NUCLEI (AGN). This possible connection suggests that the starburst and AGN phenomena can coexist in the central regions of many galaxies. An intriguing example of an active galaxy with circumnuclear regions is the face-on SEYFERT 2 GALAXY, NGC7742.

In the case of IRREGULAR GALAXIES, which are smaller and more gas-rich, the population of H II regions is randomly distributed and does not follow a regular pattern. For instance, the brightest H II region complex in the Large Magellanic Cloud is called the 'TARANTULA' NEBULA and represents a violent starburst. It does not seem to be coincident with any particularly significant point of this galaxy. The most dramatic examples of small galaxies undergoing starburst phenomena are the so-called 'H II

Table 1. Types of H II regions.

Type of region	Size (pc)	Number density (cm^{-3})	Ionized mass ($M_\odot$)	Number of ionizing stars N_*
SUCHII	≈0.003	$\geq 10^6$	$\approx 10^{-3}$	1
UCHII	≤0.1	$\geq 10^4$	$\approx 10^{-2}$	1
Compact	≤0.5	$\geq 5 \times 10^3$	≈1	1
Classical	≈10	≈100	$\approx 10^5$	Few
Giant	≈100	≈30	10^3–10^6	$\approx 10^5$
Supergiant	>100	≈10	10^6–10^8	$\approx 10^5$

galaxies'. These are very small and dim galaxies that are difficult to detect other than in the emission lines of their H II regions.

Physical processes in H II regions

Stellar photons with energies greater than the ionization potential of hydrogen ($I_H = 13.6$ eV) ionize hydrogen and other elements. The excess energy goes into kinetic energy of the ejected electron, and this is shared with other particles by collisions, heating the gas. Photoionization takes place from the ground level of hydrogen (photoionization from higher levels is rarely important). This is balanced by proton and electron recombination into any level. The resulting cascade downwards gives the hydrogen recombination line spectrum. Lines are produced over a wide range of wavelengths from the UV to the radio region.

The degree to which the hydrogen is ionized depends on the balance between the rates of photoionization and recombination. If the characteristic time for a photon and an electron to recombine is much greater than the characteristic ionization time of an atom, the hydrogen will be essentially fully ionized. This indeed is the case in the interiors of H II regions and far less than 1% of the hydrogen is in the neutral form.

The gas temperature in H II regions is remarkably constant because of a thermostatting mechanism. The heating rate per unit volume is proportional to the number density of neutral hydrogen, which decreases with increasing gas temperature. The cooling of the plasma is largely due to the radiative decay of electron-impact-excited levels of ions such as O^{2+}. The lines produced are called 'forbidden' lines because of their low transition probabilities. The rate of emission of radiation in these lines is proportional to the populations of the excited levels from which they originate which are essentially proportional to a Boltzmann factor which increases as the temperature increases. Thus, an increased gas temperature results in decreased heating and increased cooling while the converse is true for a lowered temperature. This thermostat regulates the gas temperature to the value quoted.

The forbidden lines carry information about the physical structure of H II regions. The gas temperature and density determine the ratios of line intensities. The ratio of the intensity of the 436.3 nm line of O^{2+} to the sum of the intensities of the 500.7 nm and 495.9 nm lines is a good probe of temperature, whereas the ratio of the intensities of the 372.6 nm and 372.9 nm lines of O^+ probes the density. Many other lines can be used. Care is needed in the interpretation of such data. The ionization state of any particular element depends on the energy distribution of the photons to which the parent element is exposed. This energy distribution is strongly influenced by photoabsorption by helium. Hard photons are absorbed nearest the star and so ions with the highest parent ion ionization potential are found there (e.g. O^{2+}, N^{2+}). The radiation field is softer further out and lower parent ionization ions (e.g. O^+, N^+) predominate. The phenomenon is called 'ionization stratification'. Consequently, measurements of temperature from O^{2+} lines do not probe the same regions as the density measurements from O^+ lines. The lines can be used to obtain elemental abundances relative to hydrogen. In fact, the use of H II regions as probes of abundance variations in distant galaxies has proved to be one of the most reliable methods of obtaining this information.

Emission lines enable astronomers to probe the dynamics of H II regions. The DOPPLER EFFECT, to which there are two contributions, determines the wavelength (or frequency) width of a spectral line. Lines are broadened by thermal velocities as well as by internal bulk nebular velocities. These two velocities are about equal for hydrogen and a hydrogen line has two comparable contributions to its width. The thermal velocity of a heavy ion (e.g. O^+) is much smaller than that of the hydrogen so forbidden lines are broadened by bulk motions. Comparison of forbidden line and hydrogen line widths enables these two contributions to be distinguished. In addition to their effects on the line widths, bulk motions also affect the wavelength of the line maximum intensity. Thus line widths and peak wavelengths map velocity fields.

Important information on nebular structures can also be obtained at radio wavelengths from e.g. hydrogen radiofrequency recombination lines. Nebulae also have a strong radio continuum spectrum produced by bremsstrahlung. This gives information on the total recombination rate in the ionized gas and is one means of estimating the number of stars which excite the nebula.

Because photons are continuously absorbed in balancing recombination, the stars do not ionize an indefinitely large region. When a star 'switches on', the gas is initially fully ionized out to the 'Strömgren radius' $R_S = (3S_*/4\pi n_0^2\beta)^{1/3}$ where n_0 is the hydrogen number density of the surrounding gas, S_* is the number of ionizing photons produced per second by the ionizing star(s) and $\beta(\approx 2.6 \times 10^{-13}$ cm^3 s$^{-1})$ is the hydrogen recombination coefficient. We find $R_S \approx 31/n_0^{2/3}$ pc. (This is an overestimate since dust in nebulae also absorbs photons.)

The transition zone between neutral and ionized gas is termed an 'ionization front' (IF) and has a thickness about equal to the mean-free-path of an ionizing photon in the neutral gas. This distance is approximately $0.05/n_0$ pc, far smaller than R_s. Consequently, nebulae bounded by ionized–neutral zones—'ionization bounded' H II regions—are sharp edged. If the nebula has insufficient hydrogen to absorb all the stellar UV there is no transition zone, all the gas is ionized and the region is called 'density bounded'.

H II region dynamics

The ionizing photons propagate outwards from the star to set up the Strömgren sphere. Conditions across the IF are related by equations analogous to the well-known Rankine–Hugoniot (R–H) jump conditions, which hold across shock fronts. However, the principle that the specific entropy increases across a shock usually allows only one solution to the R–H conditions, namely a compressive shock. The situation across IFs is more complicated since radiative heating and cooling of the gas means that this entropy condition is no longer relevant. There are in fact four allowed transitions whose nomenclature was first introduced in a classic paper by F D Kahn in 1954.

Across 'R-type' IFs, the density increases. They move supersonically into the neutral gas and divide into weak-R types and strong-R types according to whether the ionized gas moves supersonically or subsonically respectively away from the IF. Strong R-type fronts demand special circumstances for their existence and are of no astrophysical significance. Across 'D-type' fronts the density decreases. These fronts move subsonically into the neutral gas and again divide into weak D-type fronts and strong D-type fronts according to whether the ionized gas moves subsonically or supersonically with regard to the IF, the reverse of the R-type nomenclature. There is a 'forbidden' gap in IF velocity, roughly between $2c_I$ and $c_N^2/2c_I$, where $c_I(\approx 10$ km s$^{-1})$ and $c_N(\approx 1$ km s$^{-1})$ are respectively the sound speeds in ionized and the neutral gas. The internal structures and propagation of IFs were examined in classic papers by W I Axford and F A Goldsworthy in 1961. These studies (and that of Kahn) show that if an initially fast IF has a velocity which tries to decrease into the forbidden gap, a shock wave moves ahead of the IF into the neutral gas. The increased gas density behind the shock makes the IF velocity drop to a value below that of the lower limit of the gap.

If a star is suddenly switched on in a uniform region of neutral hydrogen (see H I REGION), a weak R-type front sweeps across the neutral gas, ionizing it but leaving its density (and velocity) essentially unchanged. The speed of the ionization front V_F is given by $V_F = J/n_0$, where J is the ionizing photon flux at the IF and n_0 is the neutral gas number density. As the IF moves outwards from the star, the flux is reduced by geometrical dilution (since the IF is a spherical surface centered on the star) and absorption by hydrogen atoms to maintain ionization balance. Clearly V_F decreases as the IF moves away from the star. The ionized gas has a pressure that is a factor $2T_i/T_0$ greater than that in the neutral gas (the factor of 2 arises because each hydrogen atom produces two particles when ionized). The ionized gas temperature typically is $T_i \approx 8000$ K and the neutral gas temperature is $T_0 \approx 100$ K. The ionized gas is overpressured with respect to the neutral gas by a factor of over 100 and will expand at a speed of approximately c_I. As long as $V_F \gg c_I$, this is of no significance. However, when the IF velocity drops to about $2c_I$, a shock is driven ahead of the IF and it switches from weak R-type to weak D-type. The H II region acts as a spherical piston pushing a shock front into the neutral gas. This occurs after a time approximately equal to $(n_0\beta)^{-1}$, which is roughly the recombination time in the ionized gas. The radius of the IF when this occurs is about equal to R_S.

The expansion of the H II region continues with the IF remaining weak D-type and the shock gradually weakening with time. In principle, the expansion continues until the H II region is in pressure equilibrium with its surroundings when its radius would be $(2T_i/T_0)^{2/3}R_s(\approx 30R_S)$ and the mass of ionized gas would be a factor $2T_i/T_0(\approx 160)$ greater than that in the initial Strömgren sphere. The density in the final equilibrium state is $n_f \approx (T_n/2T_i)n_0(\approx 0.006n_0)$, far lower than the original neutral density. A lower bound to the time taken to reach this final pressure equilibrium is $t_f \approx 8.8 \times 10^8/n_0^{2/3}$ yr.

It is instructive to ask whether a final pressure equilibrium state is likely. Let us first take average conditions in the general interstellar medium. The interstellar gas pressure at the solar circle (the distance of the Sun from the center of our Galaxy) is $P_{ISM} \cong 10^{-12}$ dyn cm^{-2}. The H II region reaches pressure equilibrium at a radius of about 30 pc and a density of about 0.4 cm^{-3}. However, the time to reach this equilibrium state is very long ($\cong 10^7$ yr) and most massive stars would have evolved significantly off the main sequence before equilibrium could be achieved. On the other hand, the H II region set up by a star buried deep in a high-density molecular core where the pressure is much greater ($\sim 10^{-7}$ dyn cm^{-2}) could reach equilibrium in a time $\sim 10^4$ yr with a radius of about 0.1 pc and a density $\sim 4 \times 10^4$ cm^{-3}. Such values are similar to these determined observationally for UCHIIRs. We will discuss these similarities later.

During the expansion process, both the ionized gas and the shocked neutral gas acquire kinetic energy. Once the shock has been established, that in the neutral gas dominates. The velocity in the ionized gas rapidly falls below the sound speed and its energy is largely thermal. This comes from the heating of the gas by the stellar radiation field. The kinetic energy of the neutral gas arises from the expansion work done on it by the hot gas. Comparison of the kinetic energy in the neutral gas at any time with the total radiant energy absorbed up to that time shows that the former is much less than 1% of the latter. Nearly all the radiant energy absorbed in the ionized gas is radiated away in the forbidden lines.

Observations of regions of star formation show that the gas around young stars is far from homogenous. If an IF encounters a strong negative density gradient and overruns it, the gas expansion is accelerated. For stars located near the boundary of the dense molecular core in which they formed, the ionized gas accelerates out of this core and creates an extended flow. The evolution in a decreasing-density environment displays a rich variety of hydrodynamic phenomena including shocks in the ionized gas, receding ionization fronts, rapid evaporation of the dense core and the creation of new clumps in the expanding shocked gas.

Two factors influence the dynamical evolution of flows set up in a dense core. The first is the position of the star in the core. If the pressure equilibrium Strömgren sphere is contained within the densest part of the core for a star located there, a long-lived pressure equilibrium region can be formed. By contrast, if the star is located towards the core boundary, the IF can move rapidly outside the core region into the envelope and a transient high-pressure region is set up. The second factor is the density variation in the envelope that surrounds the core.

As an illustration, detailed investigations of the evolution of an H II region produced in an envelope with a power law density distribution with distance r, $n \propto r^{-\omega}$, show the following. If $\omega < 3/2$, the interface between the IF and the leading shock accumulates neutral gas (exactly as in the uniform-density case described above). If $\omega = 3/2$, the IF and the shock move together without a neutral interface. If $\omega > 3/2$, the IF overtakes the shock and moves out of the cloud: in this case, steep enough density distributions can lead to velocities as high as 100 km s^{-1}. Such velocities are not produced in uniform-density media when the expansion velocity never exceeds the sound speed in the ionized gas.

Another important dynamical process needs to be included. Massive stars lose material from their surfaces in a continuous stream, a 'stellar wind'. This wind is driven by radiation pressure and the typical speed ($\approx$2000 km s^{-1}) is about three times the escape velocity of the star. The mass-loss rate for a supergiant star is about $10^{-6} M_\odot$ yr^{-1}, and that for a main sequence star about $10^{-7} M_\odot$ yr^{-1}. The wind kinetic energy output rate (known as the 'mechanical luminosity') ranges from about 10^{36} to 10^{34} erg s^{-1}, far less the rate at which the star pumps radiant energy into the ionized gas. When the wind impacts on the nebular gas, it acts as a piston and pushes a shock wave into the gas, sweeping it up into a shell. The wind itself is slowed down by another shock wave. The wind gas is shocked to a high temperature ($\approx 10^7$–10^8 K) and the pressure of this hot gas drives the shell. Remarkably, the fraction of the mechanical energy of the wind transformed into kinetic energy of swept-up gas is constant (about one-fifth), far higher than the radiation conversion efficiency, and consequently, stellar winds play an important role in the dynamics of H II regions.

The evolution and dynamics of H II regions where wind activity is important are different from those where the winds are weak. The most immediately obvious difference is that a hole is blown around the star. A spectacular example of this is in the ROSETTE NEBULA where the hole is blown by the combined winds of several stars. Additionally, the velocities of the ionized shells can be several times the sound speed, much higher than in uniformly expanding H II regions. The compression of the nebular gas by the shock increases the recombination rate considerably and the IF, which initially outruns the shell, may become trapped inside the shell.

A simple evolutionary scheme

A simple expansion scheme may connect the different classes of H II region. SUCHII regions and UCHIIRs are buried inside the inner, high-pressure, parts of the parent molecular clouds and are invisible to optical telescopes. Compact H II regions are bright and visible and are located next to the opaque regions. They therefore seem to be more evolved objects. Extended optically visible H II regions represent the more mature expanded state of these objects.

Even this simple scheme meets with difficulties. The fraction of objects in each class should be roughly the time that it takes the region to expand from one class into another, divided by the typical lifetime of the star. The number of UCHIIRs known is larger than expected if they really do expand to become compact regions. This has been termed the 'lifetime problem'. There is no clear answer to this problem at present although recent surveys have found faint extended emission in several samples of UCHIIRs. This implies that some of these objects are larger, partially mitigating the problem. The simplest way around the lifetime problem is to assume pressure confinement.

Structures in H II regions

H II regions show complex structure on large and small scales. The 'Pillars of Creation' in M16, the EAGLE NEBULA, are a spectacular example. Many H II regions display such dark clouds of neutral material silhouetted against the nebula. An important question is whether the structure is primordial (i.e. reflects conditions in the neutral gas prior to ionization) or is produced by dynamical processes. Opinion at present favors the former because observational data on the structure of star-forming regions show that the neutral gas is fragmented on all

Dirac House, Temple Back, Bristol, BS1 6BE, UK

scales. However, it is far from clear that the latter do not contribute. There are a variety of ways in which this could happen. For example, a wind-driven shell can fragment by a combination of Rayleigh–Taylor and thin-shell dynamical instabilities if the shell accelerates because of, for example, a steep drop in density ahead of the shell. On the other hand, primordial clumps may actually be destroyed by photoionization or by the passage of the shock ahead of the IF.

If the neutral material in the star-forming cloud is clumpy, considerable revision has to be made to our description of H II region dynamics. If a neutral clump survives inside the H II region, it acts a mass injection source. Mass injection occurs either by photoionization of the clump or by hydrodynamic ablation as the H II region gas moves around it. Which process is dominant depends on factors including the location of the clump with respect to the star and the strength of any stellar wind. The injected gas may move subsonically or supersonically with respect to the flow in the H II region (in the latter case, localized shocks are set up in the H II region around the clumps, generating localized supersonic velocities). The injection of mass can lead to a situation where matter has to flow out of the H II region and become neutral. In this case, the H II region is bounded by a recombination front through which ionized gas flows, recombines and becomes neutral (the opposite of an IF). Such a region can be in pressure equilibrium and models of this nature have been proposed for UCHIIRs.

Stellar nurseries revealed

The ORION NEBULA is just one of several star-forming regions in the Orion molecular cloud complex. In this complex, both low- and high-mass star formation is taking place. It has been known for about three decades that in the Orion nebula there exist compact knots that have similar spectra to H II regions. These knots are extremely small, characteristically about 500 AU in size, and are therefore not stars. An early suggestion was that the radiation came from the ionized surfaces of neutral clumps embedded in the H II region. A second suggestion was that the clumps contained stars and that the bright knots were externally ionized envelopes around these very young stars. It was, however, the first Hubble Space Telescope images of the objects obtained in 1993 which revealed their true natures. They are actually externally ionized disks of material around young low-mass stars and are known as PROPLYDs (PROTOPLANETARY DISKS). They are seen silhouetted against the nebular backgrounds and, in several, the stars are clearly visible. Thus massive star and consequent H II region formation has provided a new window for the study of low-mass stars. They also have provided new laboratories for the study of the interaction of stellar UV radiation and fast stellar winds with neutral material. Many of these objects have a 'teardrop' shape with tails pointing away from θ^1 Ori C, the brightest star in the TRAPEZIUM cluster which is responsible for the excitation of the Orion nebula. Although there are some difficulties yet to be resolved, it is likely that the morphology can be accounted for by models where an ionized flow of gas off the disk interacts with the fast stellar wind from θ^1 Ori C.

Some important problems

Most theoretical studies of H II region evolution assume that the stellar winds and radiation fields turn on suddenly with full main-sequence mechanical and radiative luminosities. The actual way this happens is unclear and has consequences for the subsequent ionization and dynamics. Moreover, massive stars commence nuclear burning when they are still in the process of accreting matter and are therefore surrounded by dense dusty cocoons when this turn-on occurs. It is therefore likely that there is an initial phase of combined inflow and outflow. There has been little work so far on the propagation of IFs into clumpy dusty media, in particular any studies of the possible transition from an H II region headed by an IF to one headed by a recombination front.

Gas in regions where active star formation is continuously taking place can be compressed by wind- and supernova-driven shock waves. Any magnetic field in the unshocked gas can be greatly magnified provided that the shocked gas cools well. Under such circumstances, IFs may move into gas where the magnetic pressure dominates the gas pressure. Magnetohydrodynamic IFs behave in a much more complex fashion than do the 'classical' hydrodynamic IFs described above; in particular there are many more jump possibilities.

The morphologies of H II regions have been the subject of many theoretical studies. For example, UCHIIRs have a whole range of morphologies ranging from simple spherical, through core–halo, irregular and cometary. It is likely that many of the differences in appearance are the result of viewing aspect. In particular, cometary UCHIIRs have been widely studied. The cause of this particular morphology has been variously ascribed to the generation of umbrella-shaped stellar-wind-supported envelopes around moving stars, flows produced at the edges of dense clouds ('champagne' flows) and flows produced when a stellar wind from a stationary star blows into a spatially varying distribution of mass-injecting clumps. Ultimately, the confrontation of theory with very detailed observational data will resolve these uncertainties.

Bibliography

There are several good books describing the physics of H II regions.

Dyson J E and Williams D A 1997 *The Physics of the Interstellar Medium* 2nd edn (Bristol: Institute of Physics Publishing)

Osterbrock D E 1989 *Astrophysics of Gaseous Nebulae and Active Galactic Nuclei* (Mill Valley: University Science Books)

Högbom, Jan (twentieth century)

Swedish astronomer, pioneer in radioastronomy and interferometry, invented the *Högbom CLEAN algorithm* for deconvolving an interferometric image from the effects of incomplete sampling. In general the raw map produced by an interferometer is too dirty for scientific analysis. CLEAN uses the sampling function of the radio telescope interferometer (the 'dirty beam') to match the brightest peaks on the observed brightness distribution ('dirty map') of a radio source. It subtracts (deconvolves) the effect of the bright radio sources seen by the dirty beam from the map and looks in the residual map for less bright peaks. The position of each source is saved in a 'CLEAN component' table in the CLEAN map file, and the algorithm stops when the residual brightness distribution consists mainly of noise. A CLEAN radio map is then reconstructed from the CLEAN components. There are many variants on Högbom's basic CLEAN algorithm (associated with the names of Clark, Cornwell, Cotton–Schwab, Gerchberg–Saxton, Steer, Steer–Dewdney–Ito, and van Cittert).

Hadrons

Subatomic particles that are composed of quarks and which are acted on by the strong nuclear force. Hadrons may be subdivided into mesons and baryons, a meson consisting of a quark–antiquark pair and a baryon of three quarks. Most hadrons, with the exception of protons and neutrons (which are baryons), have very short lifetimes.

See also: baryons, fundamental forces, mesons, neutron, proton, quark, subatomic particles.

HALCA (Highly Advanced Laboratory for Communications and Astronomy/Muses-B)

Japanese–US radio astronomy observatory, the first very long baseline interferometry satellite. Launched in February 1997 into a highly elliptical ($1000 \times 10\,000$ km) Earth orbit. Equipped with an 8 m antenna operating at frequencies near 1.6, 4.8 and 22 GHz. Returned high resolution images of quasars and distant active galaxies. An alternative name is Haruka, the Japanese pronunciation of the HALCA acronym. Haruka is Japanese for 'far away'.

Hale, George Ellery (1868–1938)

American astrophysicist, born in Chicago, IL, as an undergraduate at MIT invented the spectroheliograph, which made it possible to photograph the Sun's prominences in daylight. At the University of Chicago he used a 40 in lens as the basis for the telescope of the Yerkes Observatory, completed 1897. Founded Mount Wilson Observatory, where he discovered the magnetic fields in sunspots. Planned and completed the 60, 100 and 200 in reflectors, the last, on Mount Palomar, named for him after his death. He was the first astronomer to be officially called an astrophysicist and started the *Astrophysical Journal*.

Hall, Asaph (1829–1907)

Carpenter, computer and astronomer; born in Goshen, CT. While at the US Naval Observatory in Washington, DC, he discovered the two satellites of Mars, naming them Deimos and Phobos.

Halley, Edmond (1656–1742)

Astronomer and scientist, born in Hagerston, Shoreditch (near London), became professor at Oxford and second Astronomer Royal at the Royal Observatory, Greenwich. From the island of St Helena, he cataloged the positions of about 350 southern hemisphere stars (*Catalogus Stellarum Australium*), including his own discovery of the globular cluster Omega Centauri; he also discovered the globular cluster M13. He dedicated a planisphere of the southern hemisphere stars to King Charles II. The planisphere flatteringly included a now disused constellation (in Carina) which Halley named 'Robur Carolinum', the oak tree in which Charles hid after his defeat by Cromwell after the battle of Worcester. He observed a transit of Mercury and invented the idea to use transits of Mercury and Venus to determine the distance of the Sun. Using PTOLEMY's catalog, he deduced that the stars had moved relative to each other and detected this 'proper motion' in three. Apart from his own scientific contributions Halley was a friend of NEWTON. He supported NEWTON in his controversy with Leibniz over who invented the calculus, persuading him to distribute his work in the *Principia*, whose publication Halley paid for, and helping him access FLAMSTEED's observations of the Moon before they were completed to Flamsteed's satisfaction. This last was thought by the two friends to be necessary for Newton to be able to test his theory of gravitation, but it was Halley who provided the more successful and dramatic proof. Using Newton's theory of cometary orbits, Halley calculated that the comet of 1682 was periodic, and predicted (*A Synopsis of the Astronomy of Comets*) that it would return in 76 years. It did (after Halley's death), and it is now called Halley's Comet. Halley is considered the founder of geophysics, especially for his work on trade winds, the tides and the magnetism of the Earth, and with the *Breslau Table of Mortality*, he laid the actuarial foundations for life insurance and annuities.

Halo, Galactic

A spherical or spheroidal distribution of globular star clusters and old stars that surrounds a spiral galaxy. The diameter of a galactic halo is comparable to, or larger than, the overall diameter of the disk within which the spiral arms are located (about 100 000 light-years in the case of the Milky Way Galaxy, the galaxy of which the Sun is a member).

The globular clusters are composed of 'Population II' stars—old, metal-poor stars that formed at an early stage in the evolution of galaxies from clouds of hydrogen and helium that contained very little in the way of heavier elements. The halo of our own galaxy also contains individual Population II stars that circulate around the galactic center in orbits that are tilted at random angles to the galactic plane. Because these stars do not share in the orderly motion of stars in the galactic disk (all of which are proceeding in the same direction around the galactic center, in the same plane), their velocities relative to the Sun are much higher than those of stars in the disk population. Consequently, they are known as 'high velocity' stars.

Studies of motions of distant globular clusters and of the rates at which stars and gas clouds in the galactic disk revolve around the galactic center show that the total mass of the Milky Way Galaxy is about 10^{12} solar masses, about ten times greater than the combined mass of all the stars, gas and dust that can be detected directly, and that most of this mass is contained in the halo. Similar results have also been obtained for other spiral galaxies. These observations imply that up to 90% of the mass of a typical spiral galaxy is made up of dark matter. While part of this total may be provided by objects with extremely low luminosities, such as brown dwarfs (stars with masses too low to enable nuclear energy generation to occur in their cores) or black holes, much of it may exist in the form of exotic elementary particles.

Hamilton, James Archibald (1748–1815)

Irish astronomer, born in Athlone, on the recommendation of NEVIL MASKELYNE became first director of Armagh Observatory, where he supervised the erection of the equatorial telescope by EDWARD TROUGHTON. The benefits of his efforts were reaped in science not by himself but by the third director of Armagh Observatory ROMNEY ROBINSON.

Haro, Guillermo (1913–88)

Mexican astronomer, director of the Mexican Institute of Astronomy, and the Tonantzintla Observatory. Independently of George Herbig, he identified small emission-line nebulae in the Orion nebula, associated with but differing from T Tauri stars. These objects, now known as *Herbig–Haro objects*, are thought to be shock-excited impact regions with their energy derived from outflowing jets from young stars.

Harriot, Thomas (*c*. 1560–1621)

Teacher, probably born in Oxfordshire, Harriot travelled with Sir Walter Raleigh to Virginia as cartographer and navigator, writing on his return *A Briefe and True Report of the New Found Land of Virginia*. He was Ralegh's tutor and mathematics teacher and introduced simplified notation for algebra, inventing the symbols $<$ for 'less than' and $>$ for 'greater than', as well as . for multiplication. When he died he left a large number of manuscripts, and his scientific genius emerged. He had corresponded with JOHANNES KEPLER on optics and had discovered what is now known as Snell's law of refraction before Snell. He observed Halley's Comet in 1607 (Kepler had discovered the comet six days earlier) and a second comet in 1618. From 1609 to 1613 he made numerous telescopic astronomical observations. He observed the moons of Jupiter, unaware of GALILEO's discovery. His drawing of the Moon, the first recorded, preceding Galileo by several months, he was also first to record sunspots. These were not isolated events—he made 199 observations of the Sun over three years and deduced the Sun's rotation period. In contrast to Galileo, who published his book on his telescopic discoveries within weeks of making them, Harriot published none of his discoveries and therefore had no influence on the development of optics or astronomy (publish, or the ideas perish), although his influence as a teacher on the development of mathematics in England was profound.

Harrison, John (1693–1776)

Clockmaker, born in Foulby, West Yorkshire, England. In 1713 the British Government offered a valuable prize for the invention of a method to determine longitude accurately. Harrison developed a series of clocks through wooden models, and in 1726 invented the bimetallic pendulum that compensated for thermal expansion due to the variations of climate expected on long sea voyages, as well as several other mechanical devices to minimize friction. He made three spring-pendulum chronometers (H1, H2, H3) which worked regularly even during the rolling of a ship. They were finally surpassed in accuracy by a watch-like marine chronometer (H4), which, in a voyage to Jamaica (1761–2) determined longitude with an accuracy of two geographical miles. He was shamefully treated by the Board of Longitude, which made up conditions to delay awarding him the prize, and was finally awarded it in his old age by the intervention of King George III. Harrison's restored chronometers are displayed in the Royal Observatory, Greenwich.

Hartebeesthoek Radio Astronomy Observatory

The Hartebeesthoek Radio Astronomy Observatory (HartRAO) is located in the Gauteng Province of South Africa, 60 km NW of Johannesburg. It is one of four national research facilities operated by the National Research Foundation. The Observatory was established in 1975 at the former NASA Deep Space Station 51, which was founded in 1961 to support unmanned US space probes to the Moon and planets, a function it fulfilled from 1961–74.

HartRAO operates a 26 m radio telescope which is equipped with cryogenic receivers for 1.6, 2.3, 5.0, 6–6.7 and 8.5 GHz. It has instrumentation for continuum, spectroscopic and pulsar observations. It also participates in a variety of networks using the technique of very long baseline interferometry (VLBI) for high-resolution imaging of compact radio sources and for geodesy. As the only operational radio telescope in Africa, it plays a cardinal role providing both NS extensions to northern networks and EW extensions to southern networks. It is a key element in the ground network of VLBI stations that support the Japanese space VLBI satellite, Halca.

HartRAO operates a number of global positioning system (GPS) receivers in Southern Africa as part of the International GPS Service (IGS) and serves as a regional IGS data center. From early 2000 HartRAO will also operate a satellite laser ranging system, making the Observatory a fiducial geodesy station for the African continent. The ITRF94 position of the 26 m radio telescope provides the datum for the South African WGS94 National Survey Network.

Hartmann, Johannes Franz (1865–1936)

Born in Erfurt, Germany, became professor in Potsdam where he developed astrophysics. During this time an 80 cm refracting telescope was installed in the observatory for photographic use. Its performance was disappointing, and Hartmann developed the method of testing optics today named after him. The *Hartmann test* consists of partly obscuring the lens with a *Hartmann shutter*, and revealing differences of optical focus in the various zones of the lens. Hartmann refigured the telescope's lens and was able to use it for spectroscopy. After a spell at Göttingen as director of the observatory, he went to La Plata, Argentina, where he developed a theory on novae and discovered from its light curve that the minor planet Eros is a rotating non-spherical body.

Harvard–Smithsonian Center for Astrophysics

The Harvard–Smithsonian Center for Astrophysics (CfA) is a joint facility of the Smithsonian Institution and Harvard University that combines the staff and resources of the Smithsonian Astrophysical Observatory and the Harvard College Observatory under a single director to pursue research in nearly every branch of modern astrophysics—from laboratory measurements of the structure of atoms and molecules to observations of the large-scale structure of the universe. Investigations are organized broadly in seven divisions: atomic and molecular physics, high-energy astrophysics, optical and infrared astronomy, planetary sciences, radio and geoastronomy, solar and stellar physics and theoretical astrophysics.

Observational facilities include the multipurpose Fred Lawrence Whipple Observatory (FLWO) on Mount Hopkins in Arizona and the Oak Ridge Observatory in Massachusetts, as well as a 1.2 m radio telescope at the CfA headquarters in Cambridge, MA. The major instrument on Mount Hopkins, the Multiple Mirror Telescope (MMT), is operated jointly with the University of Arizona. Also located at FLWO is a 10 m diameter reflector to detect gamma rays; a 1.2 m imaging optical/infrared telescope; a 1.5 m spectroscopic telescope; an optical and infrared interferometer operated in collaboration with the University of Massachusetts, the Paris Observatory at Meudon, NASA Ames and MIT's Lincoln Laboratory; and, a 1.3 m infrared telescope operated by a consortium for a 2 micron all-sky survey.

Major support facilities in Cambridge offer a host of computers connected by a local-area network. Special laboratories are maintained for petrologic and mineralogic studies of meteorites and lunar samples, for spectroscopy of atoms and molecules, and for development of instrumentation (e.g. advanced optical and x-ray detectors). Major projects include development of a submillimeter telescope array in Hawaii, conversion of the MMT to a single-mirror telescope 6.5 m in diameter, and participation in the Magellan Project to build two 6.5 m diameter telescopes at Las Campanas, Chile.

CfA instrumentation operating in space includes a high-resolution camera on the Chandra X-ray Observatory, ultraviolet coronagraph spectrometers on the Spartan and Solar and Heliospheric Observatory (SOHO) spacecraft, special mirrors on the Transition Region and Coronal Explorer (TRACE), and detectors on the Submillimeter Wave Astronomy Satellite (SWAS). Development of new instrumentation for the Space Infrared Telescope Facility (SIRTF) continues.

Numerous facilities serving the general astronomical community are located at the CfA: the Institute for Theoretical Atomic and Molecular Physics; the International Astronomical Union's Central Bureau for Astronomical Telegrams and the Minor Planet Center; the US gateway for SIMBAD, an international astronomical computer database; and Harvard's extensive collection of astronomical photographic plates. In addition, the Astrophysics Data System (ADS), operated on behalf of the National Aeronautics and Space Administration (NASA), Control Center is also based here.

Hat Creek Radio Observatory

Located 400 km north of Berkeley, California. It is the site of the BIMA Millimeter Array, a 10-antenna aperture synthesis telescope which operates at wavelengths of 3 mm (70–116 GHz) and 1 mm (210–270 GHz).

The array is operated by the BIMA consortium, consisting of the Radio Astronomy Laboratory of the University of California at Berkeley, the Laboratory for Astronomical Imaging of the University of Illinois, and the Laboratory for Millimeter Astronomy of the University of Maryland, with support from the National Science Foundation.

The BIMA telescopes are 6.1 m in diameter. The antennas may be located at various stations along an approximately T-shaped track to allow antenna separations ranging from 7 m to 2 km. Normally, the antennas are deployed in one of four standard configurations which provide angular resolutions of roughly 0.4, 2, 6 or 14″ at 100 GHz.

Hawking, Stephen W (1942–)

Cosmologist and theoretical astrophysicist, born in Oxford, England, where he studied physics at University College. Moved to Cambridge to take up research in general relativity and cosmology, became Lucasian professor (an appointment earlier held by ISAAC NEWTON, with whom Hawking has been compared). Hawking worked to develop a valid mathematical treatment of the 'singularities' in the theory of general relativity, that is the central regions in black holes, where conventional mathematics breaks down. Uniting quantum theory and general relativity, he showed that black holes can emit energy, now known as *Hawking radiation*. He investigated the conditions in the energy released in the Big Bang at the creation of the universe, and predicted that many mini-black holes would be created, perhaps as heavy as 10 tons but only the size of a proton. Hawking found that the smaller mass black holes would lose energy by Hawking radiation, and would have evaporated in the lifetime of the universe. They therefore have had an effect on the formation of structure early in the universe's history but have now disappeared. Another remarkable proposal by Hawking is his 'no-boundary proposal' explained by him as meaning '... that both time and space are finite in extent, but they don't have any boundary or edge .... There would be no singularities, and the laws of science would hold everywhere, including at the beginning of the universe.' Hawking suffers from motor neurone disease and, confined to a wheelchair, he speaks through a voice-synthesizer. Nevertheless, he has taken up an arduous and highly successful career as a popularizer of science through lectures, TV and other public appearances, and a best-selling popular book on cosmology *A Brief History of Time*.

Hawkins, Gerald

British-born astronomer, professor at Boston University, claimed to have 'decoded' Stonehenge. He found a pattern of alignments with 12 major lunar and solar events, finding a way to predict eclipses of the Moon, the summer and winter solstice, by use of the 56 Aubrey holes, the Heel Stone, and the four Station Stones. His work was supported by astronomer FRED HOYLE and savagely criticised by archaeologists, (e.g. 'Moonshine on Stonehenge' by R J C Atkinson). Undeterred, he turned to a similar problem in Peru, the possible astronomical alignments and associations found in the mysterious lines and gigantic geometric figures at Nazca, mapped by MARIA REICHE.

Haystack Observatory

The Haystack Observatory is a multidisciplinary research center of the Massachusetts Institute of Technology, and its primary mission in astronomy is the advancement of scientific research and technical developments in radio interferometry. Current emphasis is on Very Long Baseline Interferometry (VLBI) observations at 3 mm wavelength aimed at high-resolution imaging of quasars, and on the application of VLBI geodetic techniques to measurements of the Earth's orientation parameters. The facilities of the Observatory include 37 m and 18 m diameter radio telescopes, and a multi-station VLBI correlator. The Observatory's mission includes training students in instrumentation technology and providing opportunities for students to link their education to research through radio astronomy using the Observatory's telescopes. The radio astronomy program at Haystack Observatory is guided by the Northeast Radio Observatory Corporation, a consortium of twelve educational institutions.

Heavy Elements

Chemical elements of relatively high atomic weight. Because less than 2% of the mass of a solar-type star is made up of elements heavier than helium, the term 'heavy element', in an astrophysical situation, is applied to all elements that have mass numbers greater than that of helium (4).

See also: atom, cosmic abundance of elements, element (chemical), nucleosynthesis.

Heckmann, Otto Hermann Leopold (1901–83)

Astrometrist and cosmologist, became director of the Hamburg Observatory, and of the European Southern Observatory in Chile. By determining the motions of the stars in the direction of several star clusters (including the Praesepe, or Beehive cluster), he was able to see which stars were moving together in the cluster, and which, although in the same direction, were moving differently. Eliminating the latter from consideration, he was able to identify the true members of each cluster and clarify their H–R diagrams. He organized the international effort to produce the third *Astronomische Gesellschaft* to show the proper motions of 180 000 stars. As a cosmologist, he rigorously used general relativity to find open and flat solutions to the EINSTEIN field equations for a homogeneous, isotropic, possibly rotating universe.

HEGRA Experiment

The La Palma cosmic-ray observatory HEGRA (High-Energy Gamma-Ray Astronomy) is an air shower experiment, located at the OBSERVATORIO DEL ROQUE DE LOS MUCHACHOS (2200 m above sea level, 28.75°N, 17.89°W) on the Canary island of La Palma, and is operated by institutes from Germany, Spain and Yerevan.

The main scientific goal is gamma-ray astronomy in the energy range from 500 GeV to 100 TeV using the technique of ground-based imaging atmospheric Cerenkov telescopes. A unique feature of the HEGRA experiment is the use of five Cerenkov telescopes to simultaneously measure the same air shower (stereoscopic observation). This technique yielded an energy spectrum with unprecedented precision of up to 24 TeV for the Blazar Markarian 501 during flaring states in 1997.

From 20 TeV up to 10 PeV air showers are also detected with the showerfront sampling technique using arrays of 243 scintillator counters, 99 wide-angle Cerenkov counters and 17 Geiger towers spread over an area of 200 m $\times$ 200 m.

Hektor

A Trojan asteroid discovered by August Kopff in 1907, designated (624) Hektor. It belongs to the largest group of Trojans, orbiting ahead of Jupiter around the L_4 Lagrangian point. Hektor orbits the Sun at a mean distance of 5.17 AU (774 million km) in a period of 11.76 years; the inclination is 18° and the eccentricity 0.02. Its rotation period, as determined from its light curve, is 6.92 h. Hektor is the largest and brightest of the Trojans. Variations in its light curve suggest that it is elongated, measuring about 300 × 150 km; alternatively it could be shaped like a dumbbell, or a contact or close binary asteroid. Like the majority of Trojans, Hektor is D-type, with a reddish reflectance spectrum indicating a carbon-rich surface.

Helioseismic Observations

This article describes how wave motions of the Sun are observed and utilized to learn about the properties of the solar interior.

Most of what we know about the Sun, and the rest of the universe, is based on observations of electromagnetic (e.g. light) waves. We cannot see more than about 100 km below the visible surface of the Sun because the material rapidly becomes opaque to electromagnetic waves. To 'see' deeper we observe, at the surface, wave motions of the solar material itself that easily travel large distances through the solar interior. HELIOSEISMOLOGY is the science of using these motions to study the Sun's internal structure and dynamics.

Figure 1. Line-of-sight component of the velocity of the solar photosphere shown as light (dark) shades for away (toward) motions. Solar rotation causes the large variation from left to right, while the oscillations are the fine-grained texture seen most clearly at disk center. (Courtesy of SOHO/SOI consortium. SOHO is a project of international cooperation between ESA and NASA.)

Wave motions

When most physical bodies are disturbed from an equilibrium state they tend to vibrate as they return to equilibrium. The Sun is no exception. In the case of the Sun, the disturbances that make it vibrate are believed to be violent convective motions (SOLAR INTERIOR: CONVECTION ZONE) beneath and within a few hundred km of the visible surface, and to a much lesser extent, rare, powerful explosions (solar flares) above the surface (SOLAR FLARE OBSERVATIONS). The convective disturbances occur continually, so the surface of the Sun is always oscillating. The goal of helioseismic observations is to detect and measure as many of the oscillations as accurately as possible.

Once produced, several types of wave motion can propagate inside the Sun (HELIOSEISMOLOGY: THEORY). Just as with light waves, these waves can be refracted, reflected, attenuated, scattered, dispersed, and absorbed, depending on the characteristics of the medium through which they travel. It is these phenomena that enable detailed probing of the interior. The waves are more than 10^{12} times larger than visible light, so using them to study the Sun is akin to using light waves to study a 1 mm diameter marble. One simple type of wave motion occurs when material is displaced from its equilibrium position and then moves back toward its original position under the combined forces of gravity and pressure from the immediate surroundings, producing what is usually called buoyancy. It oscillates about this position because of inertia until the wave energy is dissipated. Such buoyancy-driven motions are called gravity waves. Another wave motion is driven by pressure gradients and consists of alternating regions of changing pressure. These are the well-known acoustic or sound waves. Other types of wave motion are possible within the Sun, but they have not yet become significant in helioseismology.

Waves moving within the Sun may be confined to natural cavities by reflection and refraction. If the wave motions last long enough, standing wave patterns may form. The resonant frequencies of the standing wave oscillations are determined by propagation conditions (e.g. sound speed) within the entire cavity. Cavities that trap acoustic waves produce resonant pressure (p) modes. Cavities that trap gravity waves produce gravity (g) modes. The strong density gradient at the surface of the Sun supports surface gravity waves called fundamental (f) modes. High-frequency waves are not trapped at the solar surface. These waves may travel from their point of origin once through the solar interior and then leak outward in the solar atmosphere. Both trapped and untrapped waves are important for helioseismology. The former are used to learn about average properties within the trapping cavities, and the latter are used for diagnosing local, and possibly short-lived, conditions in the solar interior.

Basic observations

There is scant evidence or expectation that the type of waves that propagate within the Sun reach the Earth directly. Therefore we detect them indirectly, observing their effect at the surface of the Sun using traditional astronomical techniques.

Solar oscillations were first detected by R Leighton in 1960 by measuring the line-of-sight component of the motion of the solar photosphere using the Doppler effect. This remains the most powerful observational method. Figure 1 is a picture of the Sun's line-of-sight motions at a single instant of time. Images like this are the major (but not the only) source of helioseismic data.

If we isolate a few arcsec of the solar surface and measure its Doppler velocity or brightness as a function

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of time, we find characteristic oscillations with periods of 5 ± 2 min superimposed on other, non-periodic variations. The Doppler velocity oscillation is strongest at the center of the solar disk with an amplitude of about 300 m s^{-1}, and decreases roughly proportional to the cosine of the angle away from disk center. This shows that the motions are nearly radial to the solar surface. If we make measurements higher in the solar atmosphere, we find a greater amplitude and a tendency for the average period to shift to shorter values. The oscillations have been detected above the chromosphere (SOLAR CHROMOSPHERIC OSCILLATIONS) but have not been used much for helioseismology. Intensity oscillations mimic the velocity oscillations in most respects except that they are superimposed on a noisier background and they are phaseshifted relative to the velocity oscillation by roughly one-quarter of a period. The sense of the phaseshift is that brightest emission occurs when the atmosphere is most compressed downward, consistent with a nearly adiabatic compression. The amplitude of intensity oscillations is about 1% (depending on spectral wavelength), and does not decrease strongly away from the disk center.

If we enlarge the measured area of the Sun, the oscillation signal decreases with the square root of the area. This demonstrates that the signals are in phase and coherent over only a small spatial distance. This finding led early observers to conclude that the oscillations were a local, atmospheric phenomenon. The picture changed as simultaneous observations at many spatial locations became possible, and as theoretical work progressed. The birth of helioseismology occurred when it was realized that the oscillations seen at a single point on the Sun are the incoherent addition of millions of larger-scale oscillations. Shortly afterward it was also recognized that some of these oscillations are global in scale and sample the average properties over large portions of the solar interior.

Helioseismic observations are made using a wide range of solar instruments. Conceptually the simplest is just a stable detector exposed to sunlight. Since the amplitude of the 5 min intensity oscillation averaged over the entire solar disk is about 10^{-6}, as long as this instrumental set-up can accurately detect tinier intensity fluctuations in less than a minute, it can be used for helioseismology. The Earth's atmosphere is generally too noisy to permit this to succeed from the ground, but it has been done from space and from high-altitude balloons. Adding optical filters to restrict which wavelengths reach the detector enables more useful observations. These types of observation have also been done in space. Next in complexity are intensity measurements made with small telescopes that form images of the Sun's disk on detector arrays (segmented diodes or charge coupled device arrays). The primary requirement for using such instruments is that the noise from all sources at a single detector element be less than the amplitude of the solar oscillations, and preferably less than the non-oscillatory solar noise sources as well. This enforces stringent requirements on guiding stability, but such observations are relatively easy to do from the ground and have been made since the mid-1980s.

The next jump in instrumental complexity is to observe the Doppler shift of a single solar spectral line. Here the simplest instrument consists of a detector preceded by a spectrometer that isolates the red and blue wings of a spectral line so that the relative intensities of unimaged sunlight can be interpreted as a Doppler shift. Since the two isolated wavelengths are so close together, many noise sources affect both intensities almost identically. This enables high-quality, ground-based observations. However, since the amplitude of the 5 min oscillation averaged over the solar disk is only about 0.7 m s^{-1}, the spectrometer must be sensitive and stable. The spectrometer of choice is a cell filled with heated sodium or potassium vapor in a magnetic field. Such cells can be arranged to scatter or transmit light preferentially at discrete wavelengths in the wings of a resonance line of the element. These instruments have been in use since the mid-1970s. Vapor cells are also used in imaging instruments, but by sacrificing some stability (the required noise level at an element of an imaging instrument is about 10 m s^{-1}), more spectral lines can be observed with other spectrometers. The current instrument of choice is a temperature-stabilized, narrow-band birefringent filter, often combined with a rapidly tunable Michelson interferometer. These instruments allow simultaneous measurements of Doppler shift to be made over a well-resolved image of the Sun. Filter systems have been in use since the mid-1980s. The number of elements that can simultaneously be observed across the solar disk has increased by about an order of magnitude per decade as detector technology has improved. Current observations use up to 10^6 individual elements.

Trapped oscillations and global helioseismology

For a nearly perfect sphere such as the Sun it is appropriate to use spherical harmonic functions to represent the trapped modes. A single mode can be represented as a single spherical harmonic using a set of three integers l, m, n. The degree, l, is the number of nodal lines on the solar surface, and for p modes ranges from zero to thousands; it is a measure of the spatial wavenumber of the mode—from the scale of the entire Sun to the scale of granulation. The azimuthal order, m, is a measure of the number of nodal lines that cross the equator, and ranges from zero to plus and minus the degree number; it represents the concentration of a mode toward the equator. Roughly speaking, the radial order, n, is the number of nodal surfaces (in the vertical component of the velocity) encountered in the radial direction, and is seen in observations to range from zero to nearly 50. Theory predicts, and observations confirm, that the Sun is oscillating in millions of different p modes simultaneously. Of these, about 3×10^5 are long lived enough to remain coherent around a solar circumference and are the foundation of global helioseismology. The remaining modes, of higher degrees, are not globally

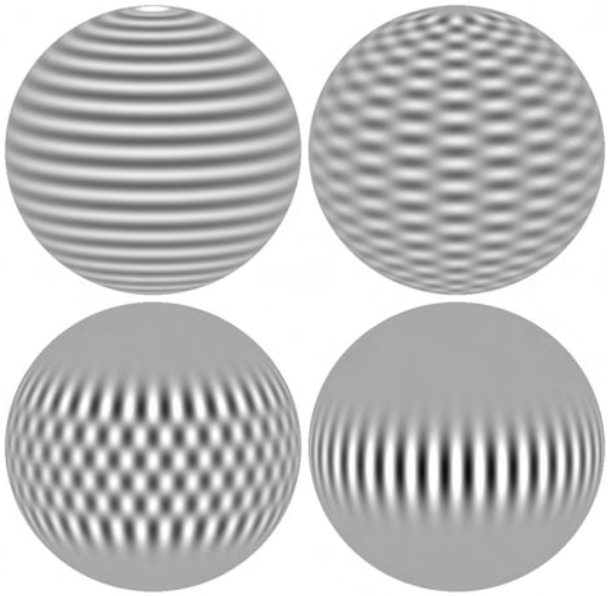

Figure 2. Spherical harmonic representations of p-mode oscillations of degree 40. The azimuthal orders in sequence are 0, 10, 35 and 40. The line-of-sight component of material motion is represented as light and dark shades of gray. Seen from a latitude of 10 degrees.

coherent and are used mainly for local helioseismology (SOLAR INTERIOR: LOCAL HELIOSEISMOLOGY).

Different modes sample different volumes of the solar interior. That is, they are confined within resonant cavities that extend over different ranges in depth and latitude. Figure 2 represents four different global p modes showing their extent in latitude. Since p-mode frequencies are controlled by the sound speed within the sampled volumes, it is possible to deduce the radial variation of sound speed by measuring the frequencies of many different p modes. P-mode frequencies are also affected by the average rotation within the sampled volume, and the frequency variations allow the rotation profile with depth and latitude to be unraveled (SOLAR INTERIOR: ROTATION). Thus, the essence of global helioseismology is to measure the frequencies of p-mode (and f-mode) oscillations as accurately as possible to deduce interior conditions (SOLAR INTERIOR: INVERSIONS OF HELIOSEISMIC DATA).

The major task for global observational helioseismology is to produce an accurate spectrum of solar oscillations in terms of spherical harmonic integers and cyclic frequency, ν. In such a spectrum, the global p modes appear as peaks of power at specific values of l and m at specific frequencies that depend on n. Displaying a three-dimensional spectrum is difficult, and it is common to make two-dimensional projections. A frequent projection is to select an l value and show the spectrum as a function of m and ν (figure 3). This projection reveals that the frequencies of p modes vary with m value, and this provides the basis for determining the internal rotation of the Sun

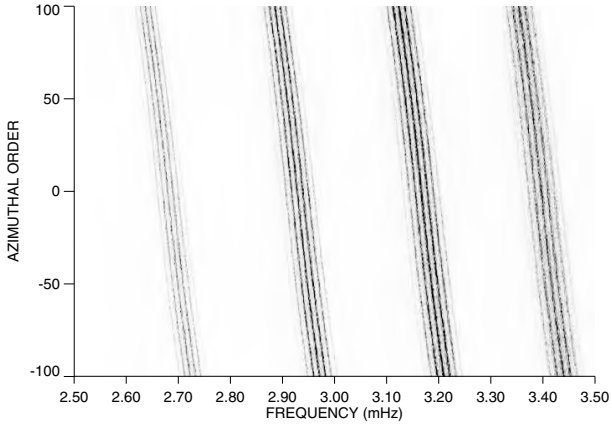

Figure 3. A section of the observed spectrum of p-mode oscillations for spherical harmonic degree 100 and four values of radial order. Dark indicates more power. The frequency variations are caused by solar rotation. Spatial leakage produces the finely spaced patterns. (Data from the GONG project, managed for the National Science Foundation by the National Solar Observatory.)

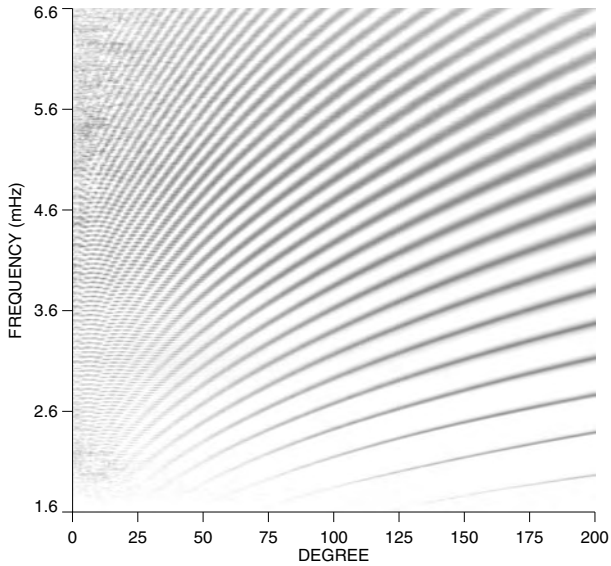

Figure 4. A portion of the observed spectrum of solar oscillations averaged over m after a correction for solar rotation. Dark indicates more power. The spectrum has been processed to reduce the dynamic range so that oscillations over most of the span can be seen. Note individually resolved modes to the left. (From observations at the geographical South Pole by an NSF-supported Bartol/NASA/NSO team.)

as well as departures from spherical symmetry. An even more popular projection removes the effects of solar rotation and then averages the result over m. The resulting spectrum, displayed as a function of l and ν, represents the spectrum that the Sun would produce if it were not rotating. An example of this kind of spectrum is figure 4.

To help define the observational requirements needed

to obtain the best possible spectrum of solar oscillations, we note that a time series of images and the l, m, ν spectrum are transform pairs of each other. Thus, if we want excellent frequency (ν) resolution, we need to acquire images for a long period of time. Similarly, to get the best possible resolution in l and m, the entire surface of the Sun should be observed. At present this is technically impossible and sets limits to the accuracy of a spectrum of solar oscillations. Seeking guidance from theory, we expect that p-mode oscillations should range in l, m from zero (the entire surface of the Sun oscillating in unison) to about 4000 (a horizontal scale of about $1/4000$ of the solar circumference or 1.1 Mm). The highest frequency p-mode oscillations that are expected to be reflected by the strong gradients in the solar atmosphere are about 5.6 mHz (180 seconds period). This means that we should sample the oscillations at least as frequently as every 90 seconds. One of the surprises of helioseismology was that mode-like oscillations are observed at higher frequencies. Some of these high-frequency oscillations may be caused by reflections high in the solar atmosphere (TRANSITION REGION MODELS), but most are thought to result from interference of outward traveling waves from a source with waves from the source that travel once through the solar interior. These waves have been clearly seen to frequencies of 11 mHz and there is evidence that they exist to a much higher frequency. Their amplitude weakens rapidly with increasing frequency and, as a practical matter, most helioseismic observations are made once per minute with little problem from inadequately sampled, weak, high-frequency waves.

A few low-frequency, low-degree p modes are expected to last without significant change for several years. This means that observations should continue for that long in order to measure the frequencies of long-lived modes accurately. Data gaps generate noise and other spectral artefacts, and observers strive to make their data as continuous as possible to produce the cleanest spectra.

Since we cannot at present observe oscillations simultaneously over the entire solar surface, there is a spread in the range of l, m values that are close matches to an oscillation pattern observed only over the visible hemisphere of the solar surface. This ambiguity causes smearing and artefacts in the spectrum. The best that can be done is to observe the full solar disk and try to use knowledge of the leakage to estimate the spectrum as if there had been no leakage.

Several steps are needed to convert a time series of Doppler velocity or intensity measurements to a helioseismic spectrum. For unimaged measurements, gaps in the time series are filled (generally using autoregressive interpolation), and a Fourier transform of the time series is computed. The result is a spectrum of the low-degree oscillations ($l = 0$ to 3). Imaged observations undergo the same steps, but each image is first decomposed into a set of spherical harmonic coefficients. It is the time series of these coefficients that are Fourier transformed to produce the oscillation spectrum. There are numerous variants of these basic steps.

Once a spectrum is produced, the frequencies of the modes must be determined. This is not trivial because the spectra are noisy, there is a varying background beneath the peaks, the shape of the peaks is intrinsically asymmetric, and there is leakage of spectral features from nearby values of l, m and ν.

Local helioseismology and short-lived oscillations

Several techniques have been developed to study the local structure and dynamics of the solar interior. The various methods use observations that are essentially the same as those used for global helioseismology. The primary difference is in how they are analysed. The simplest method consists of isolating a region of the solar disk and producing a Fourier transform spectrum of the oscillations of the region in terms of spatial wavenumber and temporal frequency. Such a spectrum is very similar to that shown in figure 4, but is usually projected into a k_x, k_y plane at a given frequency. It has the appearance of rings of power. The rings are distorted if the region is moving, or if it has a structural asymmetry. Analysis usually involves finding the flow and temperature distributions that best fit the observed distortions.

Another method is based on a Hankel spatial transform and Fourier temporal transform of p-mode oscillation patterns. This produces a spectrum in which inward and outward pattern propagation directions are separated with respect to a single point on the solar surface. If the central point is a sunspot or strong magnetic region, it is found that far more power moves inward than outward. Thus, sunspots are acoustic sinks (SUNSPOT OSCILLATIONS AND SEISMOLOGY). A spatial map of this difference can be built up by successively moving the center of the analysis to different positions.

A completely different method is closely related to terrestrial earthquake seismology. The time is measured for a particular oscillation to travel from one point on the solar surface, through the interior, to another point. Time differences can be related to variations of the properties of the material through which the wave motion passed. Figure 5 shows a so-called time–distance plot averaged over a large part of the solar disk. Plots like this are constructed by correlating the oscillation signal at a point with the signal at varying distances away as a function of time lag. Usually, the distant signal is averaged over a complete or partial annulus centered on the target point. The analysis can also be done backward to measure travel time differences for waves moving in the opposite direction. The time–distance technique is sensitive to geometrical image distortion and timing errors, so these potential observational problems require close attention. It is also necessary to carefully isolate just those waves that penetrate to a desired depth and have a particular frequency range since travel time is a strong function of frequency owing to surface effects. There are also tricky

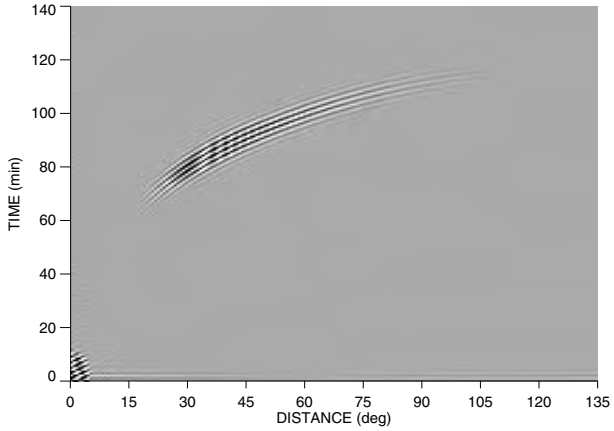

Figure 5. Observed correlation between high-frequency untrapped oscillations at a point and oscillations at different times and distances. The curved lines are prominent at the times and distances that correspond to one passage of the waves from near the surface, through the interior, to the surface again. Only oscillations with frequencies of 8.7±1 mHz and that reached a depth of about 150 Mm were used to compute this diagram. (Observations obtained at the South Pole by an NSF-supported Bartol/NASA/NSO team.)

problems of interpretation when the length of the wave is comparable to the scale of variation of the solar interior.

The newest technique for local helioseismology uses observations of the wave field at the solar surface and mathematically propagates them through the equivalent of a lens. The 'lens' can be focused at various depths to make images of features that perturb the normal progress of the wave motions. This method is called helioseismic holography because of its similarity to laser holography

The state of the art

In the 1970s, helioseismic observations were made using instruments designed for other purposes and located at single ground-based observatories. By the mid-1980s, the capabilities of such observations were fully exploited. Time resolution and continuity were improved by deploying simple, inexpensive instruments around the world in networks, and by mounting expeditions to the geographical South Pole to take advantage of continuous sunlight during the austral summer. Observations were also made from space serendipitously using an instrument designed to study solar irradiance. As solid state detector arrays became available, instruments were built to exploit them for helioseismic observations.

By the early 1990s, instrumental designs had matured, and funding agencies were convinced of the scientific merit of helioseismology, so that today, helioseismic observations have been done by a variety of space and ground-based projects. This complementarity is vital since it is the only way to detect systematic errors that can seriously affect helioseismic measurements. Space provides the great advantage of continuous sunlight unaffected by the vagaries of weather and atmospheric distortions. On the other hand, ground-based facilities can be repaired and upgraded, and are not limited by weight, power and data bandwidth constraints. Both types of observation are needed.

The major helioseismic space instruments commenced observations early in 1996 on board SOHO, the Solar and Heliospheric Observatory, a joint project of ESA and NASA. There are three helioseismic instruments on SOHO: GOLF, VIRGO and SOI/MDI. GOLF (Global Oscillations at Low Frequencies) is a non-imaging instrument that uses a sodium vapor resonance spectrometer to detect low-degree Doppler velocity oscillations. VIRGO (Variability of solar IRradiance and Gravity Oscillations) measures solar intensity oscillations with non-imaging detectors operating at three wavelengths, and also provides 12-element resolution of the solar disk intensity. SOI-MDI (Solar Oscillations Investigation—Michelson Doppler Imager) resolves the solar disk using a 1024^2 element CCD camera and a narrow-band tunable filter that provides Doppler velocity, continuum and spectral line intensity, and longitudinal magnetic field. Because of data bandwidth restrictions, only subsets of the data can be provided continuously. One such product is a reduced resolution Doppler image.

Future space helioseismic missions may seek higher angular resolution and higher time cadence (both important for local helioseismology), and helioseismology from a direction away from the Earth (important for studies of the solar poles and for deep probing of the solar core). A space mission may also be warranted if a promising way to detect g modes can be devised.

Current ground-based helioseismic observations are primarily produced by international networks established to obtain high observational duty cycles. Duty cycles of up to 90% can be obtained using six sites well distributed in longitude. The longest operating network is BiSON (Birmingham Solar Oscillation Network) organized by the University of Birmingham and operating continuously since 1981. It consists of six non-imaging potassium vapor resonance spectrometers. A similar set of instruments, except using sodium vapor, is organized in the IRIS (International Research on the Interior of the Sun) project. This project was started by the Université de Nice and has been taking continuous data since 1989. It has recently joined efforts with other projects to enhance the quality of non-imaged helioseismic data.

Ground-based imaging networks date back to 1994 when the TON (Taiwan Oscillation Network, managed by Tsing Hua University) started taking data continuously at three sites. The data are intensity images of the Sun filtered by a 1 nm filter centered on the Ca II K line. These intensity images have a diameter of about 1000 pixels and are obtained once per minute. In 1995, the GONG (Global Oscillation Network Group) started continuous Doppler velocity observations at six sites. This project is managed by the National Solar Observatory for the National Science Foundation. The GONG instruments use a Michelson interferometer to produce rapid modulation

of 220 pixel diameter images from which the Doppler shift can be determined. The data also include intensity and line strength images once per minute and line-of-sight component magnetograms less frequently. It is planned to continue the operation of GONG through a complete solar cycle and to increase the resolution to an 800 pixel diameter image size.

Several smaller networks are operational. The HdHN (High Degree Helioseismology Network) is a cooperation between the University of Southern California and the Crimean Astrophysical Observatory. The two sites operate resonance vapor spectrometers arranged to provide Doppler velocity images with diameters between 500 and 1000 pixels. The RODOMA (Roma Doppler and Magnetic) network intends to provide Doppler velocity and line-of-sight magnetograms from sites in California, Austria and Uzbekistan. These instruments will use potassium resonance spectrometers in an imaging mode with an image diameter of about 400 pixels. The ECHO (Experiment for Coordinated Helioseismic Observations) network is a cooperation between the High Altitude Observatory and the Instituto Astrofisica de Canarias, and will have sites in Hawaii and the Canary Islands to provide roughly 200 pixel diameter Doppler images, also using potassium resonance spectrometers.

Although non-imaged helioseismic measurements have been available more or less continuously since the early 1980s, imaged data were very sporadic until the mid-1990s. Notable exceptions were observations made at Big Bear Solar Observatory, at the South Pole, and a collaboration between the High Altitude Observatory and National Solar Observatory. Many of the basic discoveries of helioseismology were made using these observations. A revolution has occurred in the last few years with the availability of nearly continuous, high-quality imaged and non-imaged observations from space and ground-based networks.

The quality of helioseismic observations is currently very good. Signal-to-noise ratios are limited mainly by the Sun itself. The major lack is continuous intensity and Doppler velocity measurements at a resolution of the order of 1000 pixels per diameter. It would also be beneficial to have simultaneous observations at several heights in both intensity and Doppler velocity. A more rapid cadence of observation would reduce small effects of aliasing of high-frequency oscillations into low frequencies. Almost all imaged observations suffer from aliasing of spatial information. The only cure is to ensure that no spatial frequencies are present above the Nyquist sampling frequency.

Spectral leakage of modes is a serious problem for global helioseismology. This corrupts the oscillation spectrum so that when many modes overlap it is difficult to assign a unique frequency to each one. The situation is even worse when the individual modes cannot be resolved. An additional complication is an asymmetry in the spectral line profiles which varies with frequency, degree, and whether intensity or velocity is observed. Several explanations for this phenomenon have been suggested, but a consensus has not yet been achieved.

The most outstanding observational problem is to detect g modes. Many detections have been claimed in the past, but none has survived careful scrutiny. The problem is that noise from non-oscillatory processes is strong in the frequency range where g modes are expected, and, evidently, the g modes are weak. It seems likely that some new observational approach is required to cancel the effects of background noise while preserving the coherent g-mode signals.

The major growth area in observational helioseismology is to detect time variability of previously inaccessible regions of the Sun. Global helioseismology techniques have recently revealed zonal velocity flows near the base of the convection zone that vary with a 1.3 year period. Helioseismic holography has recently been used to make images showing the eruption and evolution of solar active regions on the far side of the Sun, many days before they rotate onto the side facing Earth. These results are initial contributions of helioseismology to a better understanding of the mystery of the solar activity cycle (SOLAR CYCLE). The new ability to make images of the far side of the Sun should become a powerful tool for the study and prediction of space weather.

Since the birth of helioseismology, the confrontation of solar models with observations has stimulated improvements in the models so that current agreement is at the one per cent level. In other words, the theoretical solar model is basically correct. Thus, a solar physics explanation for the deficit of neutrinos observed from the Sun was ruled out several years ago on the basis of helioseismology (SOLAR INTERIOR: NEUTRINOS). However, the disagreement between observed and predicted frequencies is far larger than the errors of measurement. Until recently, using improved physics in the models produced better agreement. Currently we have the odd situation that improving the physics in the models causes larger discrepancies. Evidently there is a significant missing element in the solar models. Tracking that down should yield another in the long series of surprises produced by helioseismology.

Starting in 1975, helioseismic observations have given us a continually improving picture of the nature of the solar interior. There have been many surprises. Perhaps the most sobering one is that many of our preconceptions about the nature of the solar internal structure and dynamics were found to be incorrect—sometimes spectacularly so. While much has been learned, much remains to be done.

Helioseismology

The study of the internal structure and dynamics of the Sun through the analysis of solar oscillations. The Sun vibrates like a gong with periods ranging from minutes to hours, but principally in the range 3 to 20 min. These oscillations can be detected as small periodic Doppler shifts in the wavelengths of spectral lines emitted by localized regions of the solar surface as they rise toward, and fall away from, the observer. The oscillations are produced by sound waves (pressure waves) that propagate through the solar globe. The speed of sound depends on various factors, including temperature and density, both of which increase with increasing depth below the solar surface. Consequently, a wave moving downward from a point on the surface is refracted and eventually curves back to meet the surface at another point. The sharp change in density at the surface then reflects the wave back down into the solar interior, enabling it to bounce repeatedly around the Sun and thereby produce standing waves that cause different parts of the solar surface to vibrate up and down in a systematic fashion. The deeper the wave penetrates, the fewer the points at which it meets the surface. By analyzing the millions of different modes of oscillation, and separating out those that penetrate to different depths, solar physicists can study the structure of the solar interior in the same sort of way as geophysicists use seismic waves to study the interior of the Earth. Furthermore, by comparing the speeds at which waves travel in the same direction as, and in the opposite direction to, the rotation of the Sun itself, it is possible to determine how the rotation rate of the solar interior varies with depth and latitude.

Helioseismology provides information on the variation with depth of temperature, density, pressure, chemical composition and rotational velocity. Observations made by ground-based projects such as the Global Oscillation Network Group (GONG) and instruments carried on spacecraft such as SOHO, have shown, for example, that the boundary between the radiative and convective zones occurs 71.3% of the way from the center to the surface and that the differential rotation that is observed in the photosphere extends down to the base of the convective zone.

Helioseismology: Theory

Observations have shown that the solar surface is in a state of continual oscillation, involving a very large number of different modes (see HELIOSEISMIC OBSERVATIONS). The observed frequencies depend in a relatively simple manner on the structure and rotation of the solar interior. To use this information to probe the Sun we need to understand how the properties of the oscillations reflect conditions in the solar interior.

The Seismic Sun

The observed solar oscillations share many similarities with the waves used in geoseismology to probe the interior of the Earth. However, while geoseismology is mostly based on travel times of waves travelling, e.g. from an Earthquake to a seismograph, global helioseismology uses frequencies of standing waves in the Sun (recently, analyses more akin to geoseismology have also been developed: see SOLAR INTERIOR: LOCAL HELIOSEISMOLOGY). Even so, the observations can be discussed conveniently in terms of propagation of waves through the Sun. The waves relevant in the observed frequency range are acoustic waves, whose properties depend primarily on the sound speed, which is roughly proportional to the square root of temperature. Thus, as one moves to greater depth within the Sun, the sound speed increases. The acoustic waves are believed to be generated immediately below the solar surface, by the intense turbulence in the uppermost part of the convection zone (see SOLAR INTERIOR: CONVECTION THEORY). With the exception of those travelling radially, the waves are refracted by the increasing sound speed (cf figure 1), as they propagate towards the solar interior; they undergo total internal refraction at the so-called lower turning point, at a distance r_t from the solar center. When the wave reaches the surface again, it is reflected by the rapidly shrinking scale of variation of the density (at least for frequencies below about 5 mHz). Thus the wave travels in a series of 'bounces' between the surface and the turning point.

Interference between such bouncing acoustic waves gives rise to the observed modes; since the dominant restoring force for acoustic waves is pressure, the modes are known as p modes. Conditions of regularity for waves propagating in a sphere enforce a specific pattern to these standing waves: as a function of position on spherical surfaces they behave as spherical harmonics (see also HELIOSEISMIC OBSERVATIONS, figure 2). This defines two of the three wavenumbers characterizing a given mode: the degree l and the azimuthal order m. The degree measures the total number of nodal lines on the solar surface; very roughly, the 'average horizontal wavelength' on the surface is given by $\lambda_h \simeq 2\pi R/l$ where R is the solar surface radius. For modes with $l = 0$ (the so-called *radial modes*) the Sun preserves its spherical shape while pulsating. The azimuthal order m is between $-l$ and l; it provides a measure of the number of nodal lines crossing the equator. For each (l, m) the Sun has a set of modes distinguished by the third wave number, viz. the radial order n which essentially measures the number of nodal surfaces in the radial direction.

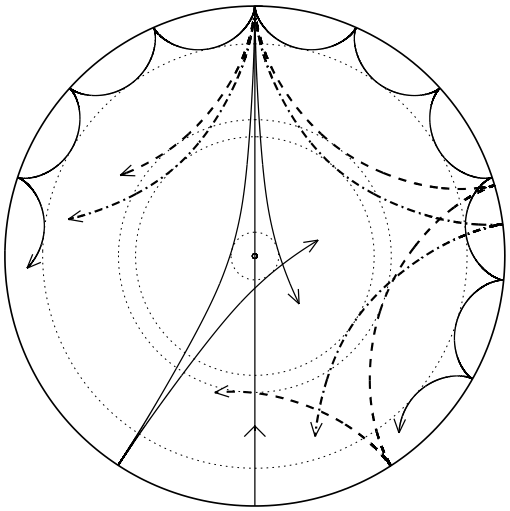

Figure 1. Propagation of rays of sound in a cross-section of the solar interior. The ray paths are bend by the increase in sound speed with depth until they reach *the inner turning point* (indicated by the dotted circles) where they undergo total internal refraction. At the surface the waves are reflected by the rapid decrease in density.

As is clear from figure 1 there is a relation between the initial direction of propagation of the waves, the depth of the turning point and the separation between successive bounces at the surface: modes propagating more nearly vertically reach a greater depth and returns to the surface further from the start. More precisely, the location of the turning point is determined by the relation $c(r_t)/r_t = 2\pi\nu/(l + 1/2)$, where c is the speed of sound and ν is the (cyclic) oscillation frequency, $\nu = 1/\Pi$ where Π is the pulsation period. The observed modes cover a range in degree from zero to more than one thousand. Correspondingly, the turning points range from very near the center to a few thousand kilometres below the solar surface. This is what allows inverse analyses (see SOLAR INTERIOR: INVERSIONS OF HELIOSEISMIC DATA) to infer local properties, in particular the sound speed, within the Sun. The frequency of a given mode depends essentially only on the structure outside the turning point. Hence, by combining frequencies of two modes with slightly differing turning points (see the dashed and dash-dotted rays in figure 1), information is obtained about conditions between the turning points. Needless to say, the actual analysis is substantially more complex and involves a large number of modes; but the principle, corresponding essentially to peeling off layer after layer of solar structure as the layers of an onion, still holds. In particular, the solar internal sound speed has been determined with high precision and resolution; comparison with the sound speed in solar models shows both generally good

Dirac House, Temple Back, Bristol, BS1 6BE, UK

agreement and some very intriguing differences (see SOLAR INTERIOR: STANDARD MODELS).

The oscillation frequencies also depend on the dynamics of the solar interior. Particularly important is the effect of rotation. The spherical-harmonic pattern is advected by rotation, increasing the observed frequency of modes travelling in the same direction of rotation and decreasing it for modes travelling in the opposite direction. The resulting so-called *rotational splitting* essentially reflects an average of the solar angular velocity over that part of the Sun which is occupied by the given mode. In addition to the variation in radial extent, there is a variation of the extent in latitude with the azimuthal order, modes with $|m| = l$ being concentrated near the equator, while modes with low m extending over the entire range in latitude. Thus, similarly to the case of structure, discussed above, it is possible carry out inversions to infer the angular velocity as a function of both latitude and depth. The results reveal a complex pattern of rotation which is so far not understood (see SOLAR INTERIOR: ROTATION).

It should finally be noticed that, in addition to the acoustic modes discussed so far, other types of modes are possible in the Sun. At relatively high degree one observes the so-called f modes, which are essentially surface gravity waves. Furthermore, solar models show the possible existence of internal gravity (or g) modes, with amplitudes strongly concentrated near the core of the model. Such modes would therefore provide excellent diagnostics of the structure and rotation of the solar core; unfortunately, however, they have so far not been definitely observed.

Properties of solar oscillations

The goal of the theoretical treatment of helioseismology is to relate the observable properties of the oscillations, in particular the frequencies, to the properties of the solar interior. In principle, the oscillations should be described by the complete set of magnetohydrodynamical equations governing the behavior of the solar interior. The description should then also include the convective motions in the outer approximately 28% of the solar radius, as well as the coupling to the radiation field in the solar atmosphere.

In practice, many simplifications are possible, making the problem tractable. The amplitudes of the observed modes are so small that the oscillations can be regarded as small perturbations around a state of equilibrium. Also, the effects on the oscillations of rotation and magnetic fields can be regarded as small perturbations, relative to oscillations of a spherically symmetric equilibrium model; the latter corresponds to a normal model of the solar interior. Finally, the characteristic thermal time scale in the most of the Sun is far longer than the pulsation period, and as a result the modes can to a good approximation be regarded as adiabatic, occurring without heat loss or gain; also, microscopic viscosity can certainly be neglected. Although some of these simplifications become questionable near the solar surface, they indicate that the basic problem of helioseismic theory is that of small-amplitude adiabatic oscillations around a spherically symmetric equilibrium structure. This is sufficiently simple that the frequencies of a given solar model can be computed with high precision; consequently, the observed frequencies provide a clean measure of solar structure which is relatively simple to interpret.

We now turn to the properties of such adiabatic oscillations.

Equations of linear oscillations

We assume that the amplitudes are so small that quantities of higher order than one in the perturbations can be neglected. It is convenient to work in terms of the displacement $\boldsymbol{\delta r}$ induced by the oscillation, related to the oscillation velocity $\boldsymbol{v}$ by

$$\boldsymbol{v} = \frac{\partial \boldsymbol{\delta r}}{\partial t} \, .$$

Two descriptions of the perturbations are used: the Eulerian perturbations, indicated by a prime, are at a given location, while the Lagrangian perturbations, indicated by δ, correspond to following the motion. The two are closely related: for example, the Eulerian and Lagrangian pressure perturbations p' and δp satisfy

$$\delta p = p' + \boldsymbol{\delta r} \cdot \nabla p_0 \, , \tag{1}$$

where p_0 is the pressure in the equilibrium model.

It is now straightforward to write down the linearized equations of hydrodynamics:
Equation of continuity:

$$\rho' + \mathrm{div}(\rho_0 \boldsymbol{\delta r}) = 0 \, ; \tag{2}$$

equations of motion:

$$\rho_0 \frac{\partial^2 \boldsymbol{\delta r}}{\partial t^2} = -\nabla p' + \rho_0 \nabla \Phi' + \rho' \nabla \Phi_0 \, ; \tag{3}$$

and Poisson's equation:

$$\nabla^2 \Phi' = -4\pi G \rho' \, . \tag{4}$$

Here ρ is density, Φ is the gravitational potential, and G is the gravitational constant. In addition, the perturbations in pressure and density are related by the adiabatic relation,

$$\delta p = \frac{\Gamma_{1,0} p_0}{\rho_0} \delta \rho \tag{5}$$

where $\Gamma_1 = (\partial \ln p / \partial \ln \rho)_s$, the derivative being at constant specific entropy s.

The analysis is greatly simplified by the fact that the equilibrium structure is spherically symmetric and time independent. We introduce a spherical polar coordinate system (r, θ, ϕ), where r is the distance to the center, θ is co-latitude, i.e. the angle from the polar axis, and ϕ is longitude. Then the solution is separable in time, and in the angular coordinates (θ, ϕ). The time dependence is naturally expressed as a harmonic function, characterized

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

by an angular frequency ω. The dependence on (θ, ϕ) may be obtained from an analysis of the way in which the angular coordinates enter into the equations. The result is that the expansion function in (θ, ϕ) must be an eigenfunction of the tangential part $\nabla_{\rm h}^2$ of the Laplace operator. This can be taken to be a spherical harmonic,

$$(-1)^m c_{lm} P_l^m(\cos\theta) \exp(\mathrm{i}m\phi) \equiv Y_l^m(\theta, \phi) \tag{6}$$

where P_l^m is a Legendre function and c_{lm} is a normalization constant, such that the integral of $|Y_l^m|^2$ over the sphere is unity. Here l and m are integers, such that $-l \le m \le l$; Y_l^m satisfies

$$\nabla_{\rm h}^2 Y_l^m = -\frac{l(l+1)}{r^2} Y_l^m \ . \tag{7}$$

Some properties of the spherical harmonics were discussed above. Also, it is useful to note that if the oscillation is approximated locally by a plane wave, with horizontal wave number $k_{\rm h}$, then

$$\frac{l(l+1)}{r^2} \simeq k_{\rm h}^2 \tag{8}$$

according to equation (7). This identification is very useful in the asymptotic analysis of the oscillations.

It is convenient, in the mathematical analysis, to express the solution on complex form as is indeed implied by equation (6). The physical variables are obtained by taking the real part of the complex solution. Thus after the separation of variables the pressure perturbation, for example, can be expressed as

$$p'(r, \theta, \phi, t) = \Re[\tilde{p}'(r) Y_l^m(\theta, \phi) \exp(-\mathrm{i}\omega t)]$$

in terms of an amplitude function $\tilde{p}'$ which depends just on r; here $\Re$ denotes the real part. Also, it follows from the equations of motion that the displacement vector can be written as

$$\boldsymbol{\delta r} = \sqrt{4\pi}\,\Re\left\{\left[\tilde{\xi}_r(r) Y_l^m(\theta, \phi)\boldsymbol{a}_r + \frac{\tilde{\eta}(r)}{L}\left(\frac{\partial Y_l^m}{\partial\theta}\boldsymbol{a}_\theta + \frac{1}{\sin\theta}\frac{\partial Y_l^m}{\partial\phi}\boldsymbol{a}_\phi\right)\right]\exp(-\mathrm{i}\omega t)\right\} \tag{9}$$

where

$$\tilde{\eta}(r) = \frac{L}{r\omega^2}\left(\frac{1}{\rho_0}\tilde{p}' - \tilde{\Phi}'\right) \tag{10}$$

and $L = \sqrt{l(l+1)}$; in equation (9) $\boldsymbol{a}_r$, $\boldsymbol{a}_\theta$ and $\boldsymbol{a}_\phi$ are unit vectors in the r, θ and ϕ directions. With this definition $\tilde{\xi}_r$ and $\tilde{\eta}$ are essentially the root-mean-square radial and horizontal displacements.

Given the separation of variables, the equations of stellar pulsation are reduced to a set of four ordinary differential equations for the amplitude functions $\{\tilde{\xi}_r, \tilde{\eta}, \tilde{\Phi}', \mathrm{d}\tilde{\Phi}'/\mathrm{d}r\}$. These must be combined with boundary conditions: two of these ensure regularity at the center, $r = 0$, which is a regular singular point of the equations. One condition enforces continuity of Φ' and its gradient at the surface, $r = R$. Finally, a dynamical condition must be imposed on the surface pressure perturbation. This in its most simple form imposes zero pressure perturbation on the perturbed surface, i.e.

$$\delta p = 0 \qquad \text{at} \qquad r = R \ . \tag{11}$$

Under the assumption of spherical symmetry, the frequencies are independent of m. Formally, m does not appear in the separated oscillation equations; physically, m is related to the equator in the coordinate system chosen, and this choice can have no effect in a spherically symmetric star.

The modes observed in the Sun are of high radial order or degree. In this case it is often possible to neglect the perturbation in the gravitational potential, at least in simplified analyses (Φ' should in general be included in numerical computations). In this so-called Cowling approximation, the order of the equations is reduced to two, greatly simplifying the analysis. In this case, furthermore, equation (10) directly relates the surface pressure perturbation and horizontal displacement. Using also equations (11) and (1), we obtain

$$\frac{\tilde{\eta}(R)}{\tilde{\xi}_r(R)} \simeq \frac{GM}{R^3}\frac{L}{\omega^2}$$

where M is the total mass; from this it follows that at the observed frequencies, and low or moderate degree, the oscillations are predominantly in the radial direction.

What do the frequencies depend on?

Adiabatic oscillations are essentially mechanical phenomena. Thus they depend on the forces in the star, i.e. pressure and gravity. In turn, the pressure is determined by the mass distribution, through the condition of hydrostatic equilibrium in the equilibrium model. Thus, as far as the oscillations are concerned, stellar structure is essentially characterized by the dependence $\rho(r)$ of density on distance to the center. In addition, the oscillations depend on the relation between the pressure and density perturbations, as characterized by Γ_1 (cf equation (5)). It follows that, given $[\rho(r), \Gamma_1(r)]$ for a stellar model, its adiabatic oscillation frequencies can be computed. This pair of variables can be replaced by other, equivalent pairs; since the observed solar oscillations are essentially acoustic modes, a natural choice is (c, ρ) where

$$c = \left(\frac{\Gamma_{1,0} p_0}{\rho_0}\right)^{1/2}$$

is the adiabatic sound speed. Conversely, to the extent that the adiabatic approximation is adequate, observed frequencies provide information only about such mechanical quantities.

Asymptotics of acoustic modes

A great deal of insight into the properties of the observed solar oscillations can be obtained from a simple analysis

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of acoustic waves. The starting point is the dispersion relation for plane sound waves,

$$\omega^2 = c^2|\boldsymbol{k}|^2$$

where $\boldsymbol{k}$ is the wave vector. Separating $\boldsymbol{k}$ into radial and horizontal components k_r and k_h and using equation (8), we obtain

$$k_r^2 = \frac{\omega^2}{c^2} - \frac{L^2}{r^2} \tag{12}$$

where again $L = \sqrt{l(l+1)}$[1]. The interpretation of this equation is entirely in accordance with the discussion accompanying figure 1: with increasing depth and hence increasing sound speed, k_r decreases and hence the wave travels more and more horizontally. The lower turning point $r = r_\mathrm{t}$, where the wave travels horizontally, is reached where $k_r = 0$, i.e.

$$\frac{c(r_\mathrm{t})}{r_\mathrm{t}} = \frac{\omega}{L} \,. \tag{13}$$

For $r < r_\mathrm{t}$, k_r is imaginary and the wave decays exponentially. It follows from equation (13) that the lower turning point is closer to the center, the lower is the degree or the higher is the frequency. Radial modes, with $l = 0$, penetrate the center, whereas the modes of highest degree observed, with $l \gtrsim 1000$, are trapped in the outer 0.2 % of the solar radius.

To obtain a standing wave, i.e. a mode of oscillation, suitable conditions must be satisfied at the surface and at $r = r_\mathrm{t}$. These essentially induce phase changes in the wave which, together with the phase change between r_t and R, must equal an integer times π. It follows that the condition for a standing wave can be expressed as

$$\int_{r_\mathrm{t}}^{R} k_r \mathrm{d}r = (n+\alpha)\pi$$

or, using equation (12),

$$\int_{r_\mathrm{t}}^{R} \left(1 - \frac{c^2L^2}{r^2\omega^2}\right)^{1/2} \frac{\mathrm{d}r}{c} = \frac{\pi(n+\alpha)}{\omega} \,. \tag{14}$$

Here n is the mode order and α (which in general is a function of frequency) accounts for the phase changes at $r = r_\mathrm{t}$ and $r = R$. The observed frequencies of solar oscillation satisfy a relation of this general functional form with reasonable precision. It should be pointed out that equation (14) can be given a more solid justification through a formal asymptotic analysis of the oscillation equations.

The observed frequencies are most often analyzed by comparing them with frequencies computed for solar models. Thus we need to relate differences in frequencies to differences between the properties of the Sun and the model. Let $\delta\omega = \omega_\odot - \omega_\mathrm{mod}$ be the difference between the observed and the model frequencies, $\delta_r c(r) = c_\odot(r) - c_\mathrm{mod}(r)$ be the difference between the solar and model sound speeds, and $\delta\alpha(\omega) = \alpha_\odot(\omega) - \alpha_\mathrm{mod}(\omega)$ be the difference between phase changes in the Sun and model; then it may be shown from equation (14) that

$$S\frac{\delta\omega}{\omega} \simeq \mathcal{H}_1\left(\frac{\omega}{L}\right) + \mathcal{H}_2(\omega) \tag{15}$$

where

$$S = \int_{r_\mathrm{t}}^{R} \left(1 - \frac{L^2c^2}{r^2\omega^2}\right)^{-1/2} \frac{\mathrm{d}r}{c} - \pi\frac{\mathrm{d}\alpha}{\mathrm{d}\omega} \tag{16}$$

$$\mathcal{H}_1(w) = \int_{r_\mathrm{t}}^{R} \left(1 - \frac{c^2}{r^2w^2}\right)^{-1/2} \frac{\delta_r c}{c}\frac{\mathrm{d}r}{c} \tag{17}$$

and

$$\mathcal{H}_2(\omega) = \frac{\pi}{\omega}\delta\alpha(\omega) \,. \tag{18}$$

Thus, apart from the term in $\mathcal{H}_2$, the frequency difference is essentially a weighted average of $\delta_r c/c$. The weight factor has a simple physical meaning: $\mathrm{d}r/c$ is the sound travel time over the distance $\mathrm{d}r$; multiplying by the factor $(\ldots)^{-1/2}$ converts this into the sound travel time, corresponding to the radial distance $\mathrm{d}r$, along the relevant ray. Thus the average is weighted by the local sound travel time along the ray corresponding to the mode, as might indeed have been expected. The term in $\mathcal{H}_2$ is dominated by the change in the near-surface phase shift; thus it contains contributions from the treatment of the near-surface properties of the model and oscillations, as discussed below.

Equation (15) may be fitted to differences between observed and model frequencies. Even this simple type of analysis provides excellent insight into the likely sources of error in the model. An example is illustrated in figure 2. Panel A clearly shows that the scaled differences are predominantly a function of frequency; as discussed above, this indicates that the dominant sources of error in the model are in the near-surface region. However, as shown in panel B, there is a very significant contribution from the term in $\mathcal{H}_1(\omega/L)$, resulting from differences in the internal sound speed between the Sun and the model. Particularly striking is the variation near $r_\mathrm{t} \simeq 0.7R$, i.e. for modes which just penetrate beyond the convection zone, suggesting a relatively substantial and rather localized difference in sound speed in this region (cf equation (17)); this inference is indeed confirmed by more detailed analyses (see the article SOLAR INTERIOR: STANDARD MODELS).

Near-surface problems

The simple assumption of adiabatic oscillations breaks down near the surface, where the local thermal time scale is comparable to the oscillation period. Although it is possible in principle to solve the full set of nonadiabatic oscillation equations, in practice this is greatly complicated by the uncertainty about how to treat the perturbation, induced by the oscillations, in the convective flux. Furthermore, there are other uncertainties in the physics

[1] A more careful asymptotic analysis shows that this should be replaced by $L = l + 1/2$.

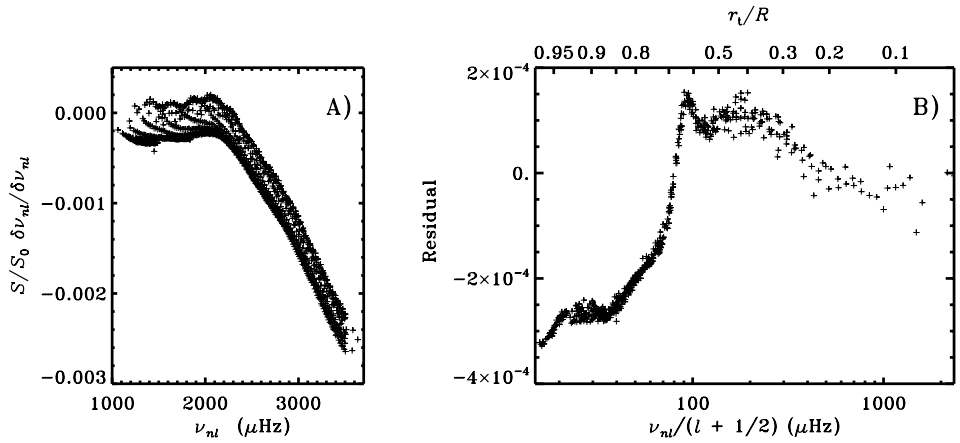

Figure 2. Panel A shows relative differences between observed and model frequencies, scaled by S/S_0, where S is defined in equation (16) and S_0 is its value in the limit $r_t \to 0$. The results are plotted against the cyclic frequency $\nu = \omega/(2\pi)$. Panel B shows the residuals after subtracting the function $\mathcal{H}_2(\omega)$, obtained by fitting the expression (15) to the data shown in panel A; these residuals essentially correspond to $\mathcal{H}_1(\omega/L)$. Here the abscissa is ν/L which is related to the location of the lower turning point, shown on the upper abscissa, by equation (13).

of the near-surface region. The model structure depends on the details of the treatment of the convective flux, usually grossly simplified, and of the convectively induced turbulent pressure which is often neglected. Perturbations in turbulent pressure are also likely to be significant, yet are very uncertain. Finally, the processes responsible for the excitation of the solar oscillations, which may also affect the oscillation frequencies, are likely to be concentrated near the solar surface.

Numerical modelling of this region, including a detailed treatment of convection and its interaction with the oscillations, is becoming computationally feasible, although not yet at a level which allows sufficiently precise predictions of the influence on the frequencies. However, it is still possible under many circumstances to suppress the frequency errors induced by our incomplete understanding of the near-surface layers. Except at high degree, the modes essentially propagate vertically in this region, with a horizontal wavelength that is much larger than the vertical wavelength (cf equation (12)). Consequently, the behavior of the modes, and the direct effect of the near-surface errors, is essentially independent of degree and hence is a function of frequency alone. The influence on the frequency does depend on degree, through the dependence of the penetration depth and hence the fraction of the solar mass which is involved in the oscillation (cf figure 1): compared with low-degree modes at the same frequency, high-degree modes are trapped close to the surface, involving little mass and hence their frequencies are more strongly affected by the near-surface errors. Quantitatively, the effect is a change $\delta_{\rm surf}\omega$ in the frequency, of the form $\delta_{\rm surf}\omega = E^{-1}\mathcal{F}_{\rm surf}(\omega)$, where

$$E = \frac{\int \rho|\boldsymbol{\delta r}|^2 \mathrm{d}V}{M|\boldsymbol{\delta r}(R)|^2} \qquad (19)$$

is a normalized mode inertia, which measures the fraction of the solar mass taking part in the oscillation; $\mathcal{F}_{\rm surf}$ is a function of frequency which depends on the properties of the near-surface layers. This scaling of the near-surface effects is largely equivalent to the asymptotic scaling by S of the frequency shifts in equation (15); in fact, the function $\mathcal{H}_2(\omega)$ in that equation contains a contribution from the near-surface errors, as described by $\mathcal{F}_{\rm surf}$.

In the analysis of observations, it is assumed that the differences between the observed solar frequencies and those computed for a solar model contain a contribution of the form given by $\delta_{\rm surf}\omega$, with an unknown function $\mathcal{F}_{\rm surf}(\omega)$. On the other hand, determination of $\mathcal{F}_{\rm surf}(\omega)$ serves as a diagnostics of the physics of the outermost layers, including possible effects of convection. In fact, as already seen in figure 2, the differences between observed frequencies and frequencies of current models are dominated by a contribution of this form; its physical origin is not fully understood, however.

Variational principle

Equation (15) still suffers from being based on a highly simplified asymptotic analysis. To obtain the full benefit of the very accurate observed frequencies, we need more precise relations between differences in frequencies and differences in solar structure; these may be obtained from the basic equations of adiabatic oscillation.

The starting point is equation (3), which we write as

$$\omega^2\rho_0\boldsymbol{\delta r} = \rho_0\mathcal{L}(\boldsymbol{\delta r}) \ . \qquad (20)$$

Here $\mathcal{L}(\boldsymbol{\delta r})$ is defined by the right-hand side of equation (3); note that ρ', p' and Φ' can in fact be obtained as functions of $\boldsymbol{\delta r}$, from the remaining linearized equations. From equation (20), ω^2 can be expressed as

$$\omega^2 = \frac{\int \boldsymbol{\delta r}\cdot\mathcal{L}(\boldsymbol{\delta r})\rho_0 \,\mathrm{d}V}{\int |\boldsymbol{\delta r}|^2\rho_0 \,\mathrm{d}V} \ . \qquad (21)$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

It may be shown that this is a variational expression: it is stationary to small changes in $\boldsymbol{\delta r}$. This provides the basis for analyzing the effects on the frequencies of changes in the equilibrium model or other aspects of the oscillation equations. Such changes can be expressed formally as a perturbation to the operator $\mathcal{L}$; it follows from the stationarity of equation (21) that the effect on the frequencies can be evaluated from that equation, using the eigenfunctions of the unperturbed operator.

A simple example of such a perturbation is a change in the structure of the equilibrium model. As discussed above, the helioseismic structure of the model can be specified by (c, ρ); consequently, the changes in the model, and hence in the operator $\mathcal{L}$, are characterized by the changes $\delta_r c$ and $\delta_r \rho$ in c and ρ, at fixed r. After some manipulation, the resulting change in the frequencies can be expressed as

$$\frac{\delta\omega}{\omega} = \int_0^R \left[K_{c,\rho}(r)\frac{\delta_r c}{c}(r) + K_{\rho,c}(r)\frac{\delta_r \rho}{\rho}(r) \right] \mathrm{d}r + E^{-1}\mathcal{F}_{\mathrm{surf}}(\omega) \ . \qquad (22)$$

Here the kernels $K_{c,\rho}$ and $K_{\rho,c}$ can be determined from the reference model, corresponding to the unperturbed $\mathcal{L}$; also, in accordance with the earlier discussion, we have included a term in $\mathcal{F}_{\mathrm{surf}}$ accounting for the near-surface errors. Equation (22) forms the basis for inverse analyses to determine corrections to the model sound speed and density. Note that although equation (22) was expressed in terms of (c, ρ), other variables may be used; in particular, if the equation of state of solar matter is assumed to be known, the frequency differences can be expressed in terms of, say, ρ and the abundance Y of helium, providing the basis for determination of the solar envelope helium abundance.

Effect of rotation

So far, we have considered only oscillations of a spherically symmetric star; in this case, the frequencies are independent of the azimuthal order m. Departures from spherical symmetry lift this degeneracy, causing a frequency splitting according to m.

The most obvious, and most important, such departure is rotation. Effects of rotation were already discussed in the introduction. The description provided there can be made somewhat more precise by noting that, according to equations (6) and (9), the oscillations depend on longitude ϕ and time t as $\cos(m\phi - \omega t)$, i.e. as a wave running around the equator. We now consider a star rotating with angular velocity Ω and a mode of oscillation with frequency ω_0 in a frame rotating with the star (see figure 3). Letting ϕ' denote longitude in this frame, the oscillation therefore behaves as $\cos(m\phi' - \omega_0 t)$. The longitude ϕ in an inertial frame is related to ϕ' by $\phi' = \phi - \Omega t$; consequently, the oscillation as observed from the inertial frame depends on ϕ and t as

$$\cos(m\phi - m\Omega t - \omega_0 t) \equiv \cos(m\phi - \omega_m t)$$

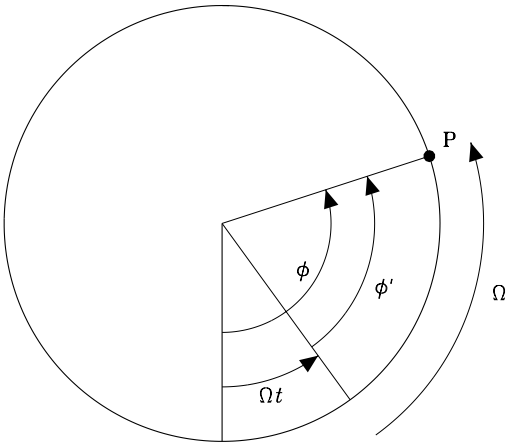

Figure 3. Geometry of rotational splitting, in a star rotating with angular velocity Ω. The point **P** has longitude ϕ' in the system rotating with the star and longitude $\phi = \phi' + \Omega t$ in the inertial system.

where

$$\omega_m = \omega_0 + m\Omega \ . \qquad (23)$$

Thus the frequencies are split according to m, the separation between adjacent values of m being simply the angular velocity.

This simple description contains the dominant physical effects of rotation on the observed modes of oscillation, but it suffers from two problems: it assumes solid-body rotation, whereas the Sun in fact rotates differentially (see DIFFERENTIAL ROTATION); and it neglects the effects, such as the Coriolis and centrifugal forces, in the rotating frame. The effects of differential rotation can be accounted for, roughly speaking, by replacing Ω in equation (23) by a suitable average; a natural expectation is that the appropriate weight is the energy density $\rho|\boldsymbol{\delta r}|^2$ in the mode. To obtain a full description, including also the additional forces in the rotating frame, we must modify equation (3) appropriately. Since the Sun rotates slowly, the centrifugal force and other effects of second or higher order in Ω can be neglected; this includes also the distortion of the equilibrium structure caused by rotation. Then it is relatively simple to write down the required modification to equations (3) and (20), as a perturbation to the operator $\mathcal{L}$. Using again the stationarity of equation (21) we finally obtain the perturbed frequencies on the form

$$\omega_{nlm} = \omega_{nl0} + m\int_0^R \int_0^\pi K_{nlm}(r,\theta)\Omega(r,\theta) r \, \mathrm{d}r\mathrm{d}\theta \qquad (24)$$

where the kernels K_{nlm} can be calculated from the eigenfunctions for the non-rotating model. It might be noted that the rotational splitting $\omega_{nlm} - \omega_{nl0}$ is an odd function of m.

The general expression for the kernels is quite complicated and will not be presented here. However,

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

its basic properties follow the simple discussion given above. In particular, except for modes of low order and low degree, we have approximately that

$$K_{nlm} \propto \rho_0 r |\boldsymbol{\delta r}|^2 \ ;$$

in this limit, the splitting is essentially given by an energy-weighted average of the angular velocity, and hence is dominated by the advection of the mode by the average angular velocity, as in equation (23); the contribution from the Coriolis force is small, in comparison. This also illustrates quite simply how different modes sense the angular velocity: in the radial direction the sensitivity is restricted to the region outside the turning point r_t, whereas in latitude the sensitivity reflects the behavior of the Legendre function P_l^m. It may be shown that P_l^m is essentially confined to the latitude band $\pm \sin^{-1}[(1 - m^2/L^2)^{1/2}]$; thus modes with $m \simeq l$ have substantial amplitude only close to the equator, whereas modes with $m \simeq 0$ extend over all latitudes (see HELIOSEISMIC OBSERVATIONS, figure 2). As already discussed in the introduction, this variation in sensitivity over the range of observed modes permits inversion to infer the angular velocity as a function of r and θ.

Perhaps the most interesting inference concerns the rotation of the solar core. Unfortunately, this is also the most difficult region to probe: only the lowest-degree modes reach the core, and for these the range in m is small, making the observational determination of the rotational splitting difficult. Furthermore, the p modes have relatively small amplitude in the core, reducing their sensitivity to the core rotation, and the effect of rotation is further reduced by geometry, as a result of the small distance from the rotation axis. A similar geometrical reduction in sensitivity holds in the, otherwise dynamically very interesting, region near the polar axis throughout the Sun.

Mode excitation

We have so far discussed only the diagnostic potential of observed frequencies of solar oscillation. However, a condition for observing the modes is that they are excited. Thus we should also consider the possible causes for the oscillations.

'Classical' pulsating stars (see, for example, VARIABLE STARS) owe their pulsations to an intrinsic instability, whereby the star acts as a heat engine, extracting mechanical energy from the radiative or convective flow of energy through the star. In the solar case, such mechanisms appear not to be effective: the modes are intrinsically damped. Instead they are forced stochastically by the vigorous turbulent convection near the top of the convection zone.

Turbulence is a source of acoustic noise, the emission of sound increasing as a high power of the mach number $\mathcal{M} = v_{\rm turb}/c$, where $v_{\rm turb}$ is a typical convective velocity. In models of solar convection, $\mathcal{M}$ is of order unity in the uppermost parts of the convection zone, with intermittent supersonic flows being possible (see SOLAR INTERIOR: CONVECTION THEORY). In particular, very strong flows are associated with the cool downdrafts. Such motion acts as sources of sound waves, which excite the normal modes of the Sun. The resulting mode amplitudes are determined by a balance between the energy input from the forcing and the energy loss through radiative and convective damping. Very roughly, the outcome is that the energy of a single mode of oscillation is approximately equal to the energy of a single convective eddy with a timescale corresponding to the pulsation period. More detailed calculations, based either on simple models of convection or on hydrodynamical simulations, give results that are approximately in agreement with the observed amplitudes.

The stochastic nature of the excitation, and the resulting fluctuations in the mode amplitudes, must be taken into account in fits to determine frequencies and amplitudes from observed time strings of oscillation data. Also, it appears that the localized nature of the source causes asymmetry in the peaks in the power spectra which further complicates the fits. On the other hand, these properties of the observed power obviously carry information about the forcing. The distribution of power is in reasonable agreement with the predictions of stochastic-excitation models. Furthermore, the line asymmetries and properties of high-frequency resonances carry information about the location of the source of the forcing, placing it within the upper few hundred kilometer of the convection zone; this again is not inconsistent with models of the convection zone.

Other aspects

The oscillation frequencies, and other aspects of the observations, carry additional information, some of which is discussed elsewhere. As discussed above, rotation induces a frequency splitting which is an odd function of the azimuthal order m. Departures of solar structure from spherical symmetry gives rise to a frequency splitting which is an even function of m. Such departures might arise, for example, from latitudinal variations in the convective energy transport, or from effects of magnetic fields. More local effects of magnetic fields are observed near sunspots, which absorb and scatter the waves, and in addition are hosts to a separate class of modes (see SUNSPOT OSCILLATIONS AND SEISMOLOGY). Information about local properties of the Sun, including three-dimensional and time-dependent inhomogeneities and flow fields, are becoming available from analyses of the waves that do not assume a modal structure. Also, it has been possible to detect large sunspots on the far side of the Sun; such detections have potentially substantial practical value, in predicting possible solar storms affecting the Earth's environment, once the active region rotates to the near side.

Helium (He)

The second lightest element which, after hydrogen, is the second most abundant in the universe. The most abundant isotope of the neutral helium atom consists of a nucleus made up of two protons and two neutrons around which revolve two electrons. The atomic mass is 4, and the atomic number (i.e. charge on the nucleus) is 2. The nucleus of such a helium atom is also known as an alpha particle. Helium nuclei with only one neutron also exist but are more rare.

In terms of number of atoms, nearly 8%, and in terms of mass, about 25%, of all the directly observed matter in the universe is helium. If, as is generally agreed, the heavier elements have been built up from the lighter ones (starting with hydrogen) in a chain of nuclear reactions, the problem is to account for the observed abundance of helium. Helium is being produced from hydrogen by means of nuclear reactions inside stars, but this process is not adequate to account for the amount of helium actually observed. If the Big Bang theory of the origin of the universe is correct, then the observed quantity of helium could have been produced in the first few minutes of the existence of the universe, while the temperature lay in the region of 10^9 kelvins. The observed abundance of helium is one of many factors that favour the Big Bang theory.

Helix Nebula (NGC 7293)

A planetary nebula in the constellation Aquarius, position RA $22^{h}\ 29.6^{m}$, dec. $-20^{\circ}\ 48'$. It is the nearest planetary nebula to Earth, it has the largest angular size, at $15'$ by $12'$, and its magnitude of 6.5 makes it the brightest (though like all extended objects it does not have a high surface brightness). It is illuminated by its hot thirteenth-magnitude central star. The Helix gets its name from its appearance of a spiral viewed from above; an alternative name is the Sunflower Nebula.

Hell [Höll], Maximilian [Miksa] (1720–92)

Born in Schemnitz, Hungary, became a Jesuit, and worked in Leutschau, Klausenburg and in Vienna where he set up and directed an observatory for Maria Theresa of Austria and Hungary. Somewhat to his own surprise, Hell was invited by Christian VII, king of Denmark, to observe the 1769 transit of Venus from the then Danish island Vardø within the Arctic Circle off the coast of Lapland, all expenses paid. The location was of considerable importance to the accuracy of the ultimate goal of the observations, since Vardø was at an extremity of the distribution of the other observing sites in Manila, Batavia, California, Peking, and Tahiti. J LALANDE was collecting the observations to combine them all into a single accurate value for the distance of the Sun and asked for Hell's data, but Hell reserved their publication until they had been seen by his sponsoring royal patron. LALANDE's suspicions were aroused, and when Hell's observations proved to show inconsistencies with others, he accused Hell of falsifying the data. Rumors circulated that Hell had not even seen the transit and had made up the data while he was in Copenhagen. Hell's scientific reputation was destroyed, although before he died in 1792 he built an observatory in Erlau and worked on the (imaginary) healing properties of magnetism with Franz Mesmer (from whose name the word *mesmerism* is derived). This story forms part of the events of the suppression of the Jesuit Society, in a power struggle in Europe in the eighteenth century between civil, royal and religious forces. In 1835 C L Littrow discovered parts of the original journal that Hell wrote during the event on Vardø, and noted that Hell had indeed altered records of the timing, according to Littrow writing new times in ink of a different color. Hell's low reputation in scientific history was apparently confirmed. In 1883, however, SIMON NEWCOMB visited Vienna, where Hell's manuscripts were kept, and came to a different conclusion. The times had indeed been altered, not after the event but while the observations were being made, correcting smudged ink, and difficulties in writing with a defective pen in the Arctic cold. Nor could Newcomb see changes of color, only a change of shade on drying. Newcomb noted that Littrow's color sensitivity was weak and that he couldn't distinguish the color of Aldebaran. Newcomb fully rehabilitated Hell in a paper called 'On Hell's alleged falsification . . .' in the *Monthly Notices of the Royal Astronomical Society*. There is a crater on the Moon named after Hell; it is not particularly deep.

Hellas Planitia

The official name for the Hellas Basin, the largest impact feature on Mars and indeed the largest in the solar system, centered at 44.3 °S, 66.2 °W. The inner part of Hellas Planitia is around 2100 km across and is surrounded by a rim 2 km high. At its deepest it is 9 km below Mars's average surface level—the greatest depth on the planet. The outer part of the basin extends for about 4000 km. The impact that formed Hellas was probably the last big impact event on Mars, and may have created the uplift of the Tharsis Bulge on the opposite side of the planet.

See also: Mars: surface, Tharsis Montes.

Helmholtz, Hermann Ludwig Ferdinand von (1821–94)

Born in Potsdam, Germany, had a varied career as an army doctor, professor of anatomy and physiology, and professor of physics at Berlin. At the same time as, but independently of, Lord Kelvin, he studied (1854) the source of energy of the Sun. He suggested that instead of radiating by consuming chemical energy, which would be used up in a lifetime of a few thousand years, the Sun was gradually settling under gravity so that the source of its radiation was gravitational potential energy. There was enough potential energy in the Sun to supply its radiation for several million years. Even this was shorter than the age of the Earth as deduced from geological evidence, and the problem was not resolved until the discovery of solar nuclear energy. However, Helmholtz's conjecture about a source of stellar energy has proved to be applicable at the time when stars first settle from interstellar clouds—the cloud's gravitational potential energy heats the star which it forms and ignites its nuclear reactions. The duration of this settling process is called the *Kelvin–Helmholtz timescale*.

Henderson, Thomas (1798–1844)

Born in Dundee, after a career as a lawyer's clerk, appointed as HM Astronomer at the Cape of Good Hope, but soon left because of poor health. Henderson returned to Scotland as the first Scottish Astronomer Royal and, from observations made in South Africa, he was the first person to measure the distance of a star, namely Alpha Centauri, a member of the nearest star system to the Sun, at 4.5 light-years. BESSEL's independent measurements of the star 61 Cygni were, however, published three months earlier.

Henry, Paul (1848–1905) and Henry, Prosper (1849–1903) [known as Frères Henry]

Born in Nancy, the brothers worked together at the Paris Observatory searching for minor planets. Decided to exploit photography to facilitate the search and thus built telescopes at home for the purpose. With the encouragement of the then director of the observatory (Admiral Mouchez), built (1885) a 34 cm photographic refractor; this work was the foundation of the *Carte du Ciel* project to photograph the sky in its entirety. The Frères Henry made half the telescopes used in the international project, led by France. The project took the attention of French astronomy for decades, at a time when astrophysics was developing in America, Britain and Germany. The two brothers, and their lifetime of work together, are commemorated by the single name, Frères Henry, of a close pair of craters on the Moon.

Heracleitus of Ephesus (*c*. 540–*c*. 475 BC)

Greek philosopher, born in Ephesus, thought of the universe as a place of ceaseless change ('becoming'), going so far as to suggest that the Sun was created anew each day. He believed the fundamental element was fire, because it was always changing, and that the Sun and Moon were bowls of fire. So too were stars, at great distances. Eclipses occurred when the bottom of the bowl was turned towards us.

Heraclides of Pontus (*c*. 388–315 BC)

Greek philosopher, born in Heraclea, Pontus, Heraclides was taught by PLATO and ARISTOTLE, and the Pythagoreans in Athens. Although his written works are lost, it is said that he considered the planets to be individual worlds. He was the first philosopher to suggest that the rotation of the Earth would account for the apparent rotation of the stars, even distinguishing between the solar day of rotation and the sidereal day.

Herbig, George Howard (1920–)

American astrophysicist, Herbig was educated and worked in California, mostly at the Lick Observatory, and Hawaii. He is known for his spectroscopic studies of recently formed stars and the interstellar medium, from which he studied the still mysterious diffuse interstellar lines. He found and investigated many Hα emission stars, T Tauri stars, and peculiar stars, all of them different stages of the early history of stars. He and GUILLERMO HARO independently discovered the eponymous *Herbig–Haro objects*, gas clouds now thought to be the result of shocks in the interstellar medium caused by ejected material from unstable young stars. Herbig showed that the lithium abundance is correlated with age in young stars, and he investigated the rotation speeds of stars of different spectral class. From his data it is hypothesized that the slow rotation of the more numerous, less massive stars is associated with the almost universal existence of planetary systems around them.

Herbig–Haro Objects and Exciting Stars

Herbig–Haro (HH) objects correspond to high-velocity material ejected from young stars, which interacts with the environmental gas and with previous ejections, forming a complex shock wave structure. The shock waves heat and ionize the outflowing and the environmental material, which then emits a rich emission line spectrum that is observed over a wide wavelength range.

The sources of HH objects

The stars that eject HH objects in some cases are optically detected, T TAURI STARS and in other cases are infrared sources (not detected optically). Some of the sources are not directly detected even in the infrared, as the infrared emission seen in the source region is spatially offset from a radio emission peak, which is believed to indicate the true position of the source. In such cases, the infrared emission observed close to (but not coinciding with) the RADIO SOURCE is believed to correspond to stellar light which is being scattered by dusty gas which surrounds the star.

It is tempting to think about a possible evolutionary sequence, with the more embedded, optically invisible objects corresponding to earlier stages in the evolution of the young star plus outflow system, and the optically visible T Tauri stars to later evolutionary stages (see also STELLAR EVOLUTION). However, whether or not the central star is visible also depends on the nature of the surrounding environment, and possibly also on the orientation of the system with respect to the plane of the sky.

The production of the jet

One of the main uncertainties in our current picture of HH objects and their sources is the mechanism by which the source produces the observed high-velocity ejections. Figure 1 shows a schematic diagram of the elements which are believed to be present. In the center of the system, there is a star, which is possibly surrounded by a magnetosphere (similar to the MAGNETOSPHERE OF EARTH) extending out to a few times the radius of the star (central circle of the diagram). Around the star there is an orbiting ACCRETION DISK, the material of which slowly drifts in towards the star, eventually becoming incorporated into the star (through a quite complex flow involving the interaction of the stellar magnetosphere with the inner edge of the accretion disk). The star + accretion disk system is surrounded by a flattened, infalling envelope of material belonging to the region of the interstellar medium which is collapsing to form the central star. The material of this infalling envelope is first incorporated into the accretion disk, and then into the central star.

The high velocity ejections (which we see as HH objects) could come directly from the surface of the star (as a stellar wind), but it has still not been possible to come up with an explanation of how to produce a stellar wind with appropriate parameters for explaining the observed HH objects. The currently more favored possibility is that the ejected material might actually come from the inner region of the accretion disk or from the region of interaction between the disk and the stellar magnetosphere.

The high-velocity wind escapes through two oppositely directed channels in the surrounding envelope, forming what is called a bipolar outflow (composed of two jets traveling away from the star in opposite directions). It is still unclear whether these channels are ploughed up by the passage of the jets or whether they are directly produced by the process of gravitational collapse which has formed the star (see also ASTROPHYSICAL JETS).

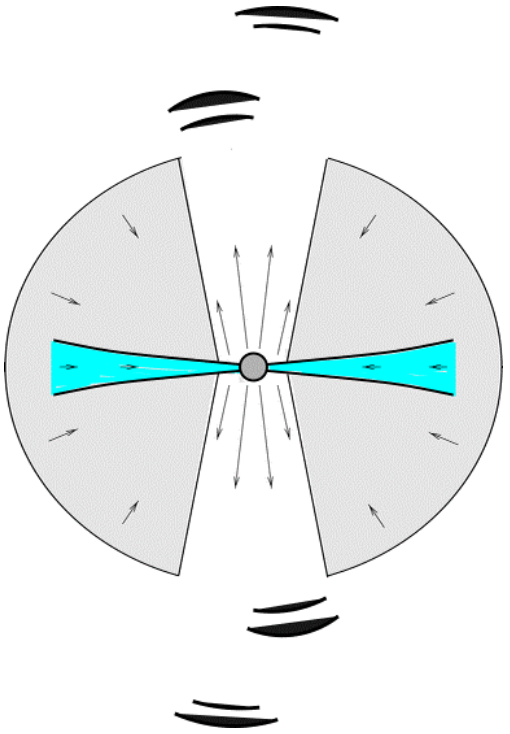

Figure 1. Schematic diagram of a young star–HH object system. The HH objects are the pairs of black arcs at the top and bottom of the diagram. The star + magnetosphere system (central circle) is surrounded by an accretion disk, which is fed by the material from a surrounding, infalling envelope. The star and/or the inner region of the accretion disk produce a wind, which escapes from the system through two oppositely directed 'channels' drilled through the infalling envelope. This collimated wind interacts with previously ejected material and with the surrounding environment, producing a system of shock waves, which we observe as HH objects.

The observational characteristics of HH objects

The region of interaction between the collimated winds ejected from young stars and the surrounding environment (or with previous ejecta) has a number of shock waves that produce an emission line and continuum spectrum. This spectrum has clear differences with the spectra of photoionized regions (showing strong emission lines of neutrals as well as of ionized species) and has been used to identify the class of objects known as HH objects.

HH objects have now been detected over a wide wavelength range, ranging from radio (centimeter) wavelengths to the ultraviolet. The observed continuum emission includes the free–free, two-photon and recombination continua of hydrogen. Emission lines of neutral, singly and doubly ionized species of many of the most abundant elements have also been detected. Ultraviolet and infrared molecular hydrogen emission lines (which are clearly associated with the HH objects) have also been detected. In 2001, observations with the Advanced CCD Imaging Spectrometer on NASA's Chandra X–ray Observatory have revealed x–ray emissions from HH 2, one of the brightest and closest Herbig Haro objects in the Orion Nebula. Previous instruments lacked the resolution and sensitivity necessary to observe these x–rays.

Traditionally, HH objects have been divided into low- and high-excitation objects, depending on the range of ionization states implied by their emission line spectra. High-excitation objects show strong lines of, e.g., singly and doubly ionized oxygen, while the emission of low-excitation objects is dominated by lines of neutral oxygen, neutral and singly ionized carbon, etc. Both the emission line and the continuum spectra have been modeled with reasonable success in terms of the excitation produced by the passage of shock waves with velocities ranging from 20 to 200 km s^{-1} (with the lower velocities corresponding to the low-excitation objects and the higher velocities to the high-excitation objects).

Some of the most interesting characteristics of HH objects are their kinematical properties. The emission line profiles have widths indicating line-of-sight velocities of up to 500 km s^{-1} (in the high-excitation objects). Given the magnitude of these velocities and the fact that most of the detected HH objects are clearly within 1 kpc of the Sun, it is easy to detect the PROPER MOTIONS of these objects.

The proper motions of approximately 10% of all of the known HH objects have now been measured. The first measurements were done with photographic plates (about 20 yr ago), using sequences of plates obtained over a time baseline of decades. In the last few years, proper motions have been measured using higher angular resolution CCD frames, obtained over a period of only a few years. In the recent images obtained with adaptive optics (in ground based telescopes) or with the HST, the proper motion of HH objects can already be detected using images obtained over a period of only a few months. This recent increase in the attainable angular resolution will produce a detailed picture of the time evolution of HH objects. During 2000–2001, spatially resolved spectroscopic observations of a few HH jets were carried out using the Hubble Space Telescope. These observations have unprecedented angular resolution and show details of the jet collimation region and of the shock structures present along the jets.

Even though HH objects have spectra that are not so diverse (allowing a clear identification of the objects) they do show a wide range of quite different morphologies. Many objects show groups of compact emission knots, located in two diametrically opposed regions (or 'lobes') with respect to the central source. The two lobes show proper motions directed away from the source, one of them showing redshifted radial velocities, and the other one being blueshifted.

In other objects, only one of the two lobes is observed. In most of these cases, the observed lobe is blueshifted, indicating that the invisible lobe is the one directed away from the observer. This is probably a result of the fact that the lobe directed away from the observer is hidden by the dense, high-extinction region surrounding the central star.

Many HH objects show only 1–3 knots in each lobe, while others show larger numbers of emission line knots. A few objects show chains of well-aligned knots, extending radially away from the central star. Even though only few good examples of such 'HH jets' are found (approximately 10% of the known HH objects), they have received a lot of attention from both observers and theoreticians, as their organized structures appear to be more straightforward to interpret than the more chaotic structures of other HH objects.

The interpretation of the jet-like HH objects

HH jets have very high Mach numbers (their velocities are 10–100 times higher than their sound speed), and interact with the surrounding environment forming a number of shocks. The leading edge (or 'head') of the jet produces a bow shock, similar to the shock formed around the nose of a supersonic airplane or a bullet.

Actually, in the case of the head of a jet, two shocks are produced: the bow shock, which pushes aside the surrounding environment to make way for the jet material, and the jet shock (also called the 'Mach disk'), which is induced on the jet by the surrounding material. This pair of shocks is called a 'working surface'.

Working surfaces can also be formed in the body of the outflow, and not only at the leading edge. If the velocity with which the material is ejected from the central source varies with time, faster material (ejected at later times) catches up with slower material ejected

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

earlier. This catching up process leads to the formation of two-shock working surfaces similar to the ones formed at the leading edge of the jet.

In HH objects, we observe a series of aligned knots. An example of this kind of structure is shown in figure 2, in which an image of the HH 34 object is shown. This image has been taken with the HST in the light of the red lines of singly ionized sulfur.

From this figure, we see that the successive knots are quite different from each other. Some of them are small, appearing just barely resolved in the HST image, and some of them are quite large, showing a clear, bow-like shape. In larger field of view images of this outflow (obtained with other telescopes), a number of knots at larger distances from the source have also been detected.

The knots along the HH 34 jet are observed to move away from the source at velocities of about 300 km s^{-1}. This motion is observed as a wavelength shift of the emission lines of the object (as a result of the DOPPLER EFFECT), and also directly as a displacement of the positions of the knots in the plane of the sky.

It is interesting that the structure of HH 34 can be reproduced with a numerical solution to the gas-dynamic equations (which describe the motion of a diffuse gas moving at supersonic velocities), if one allows oneself to choose an arbitrary time variability for the velocity with which the material is ejected from the source. For example, one can choose a variability with several sinusoidal modes. Modes with large amplitudes and long periods produce well-separated, large, bright working surfaces traveling down the outflow. Modes with low amplitudes and short periods produce little chains of low-intensity knots.

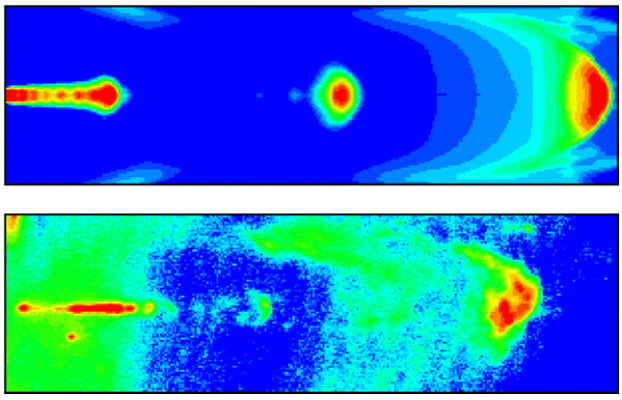

Figure 2. Bottom: HST image of the HH 34 jet, obtained through a filter which isolates the red forbidden lines of singly ionized sulfur ([S II] 6717+6731). The source of the jet is the compact knot close to the left edge of the image. Top: the corresponding intensity map predicted from a numerical model of a jet with a time-dependent ejection velocity with three sinusoidal modes of different periods and amplitudes.

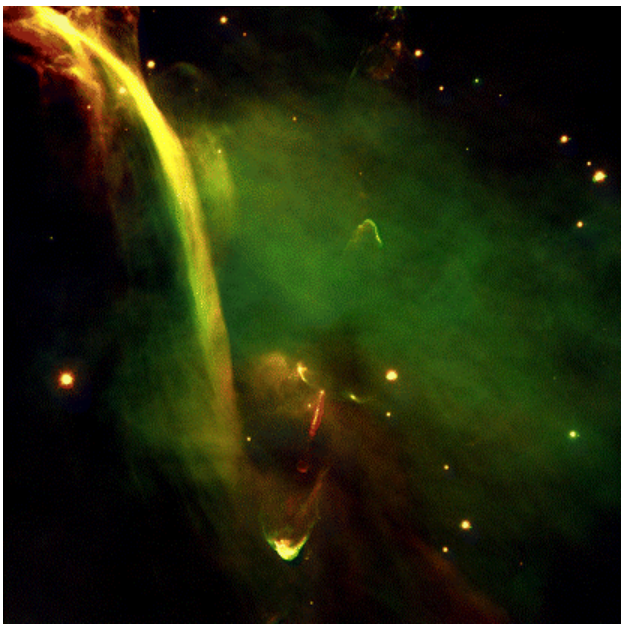

Figure 3. Composite image of HH 34 obtained with the FORSZ instrument of the European Southern Observatory's Very Large Telescope.

Picking three modes of appropriate periods and amplitudes, one can compute models with knots that have morphologies and kinematical properties that strongly resemble the knots along the HH 34 jet. An image (in the red lines of singly ionized sulfur) predicted from such a model is shown in figure 2, from which one can see that structures that resemble HH 34 can indeed be obtained from a model of a jet with a variable ejection velocity.

A recent image of HH 34 is shown in figure 3.

Molecular outflows

In many systems of HH objects, one also observes emission in molecular lines (for example, in lines of CO and NH_3 in radio and millimeter wavelengths), coming from a region that surrounds the HH objects. The molecular emission is also distributed in two lobes, one blue- and one redshifted, with velocities that in general are lower than the ones measured for the associated HH objects. It is possible that this molecular emission corresponds to material from the molecular cloud out of which the young stars are forming, which is being pushed by the stellar outflows. It has also been suggested that the molecular outflows could correspond to a slower, molecular wind, ejected from the outer regions of the accretion disk around the central star.

Recent, high angular resolution observations of molecular outflows obtained with millimeter interferometers show that the situation is really more complex. Some outflows are found to have a broad, low-velocity emission component (which probably does correspond to environmental gas which is being pushed

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

by the HH flow) but also show a high-velocity, central component.

These high-velocity components of molecular outflows have dynamical properties and morphologies which are very similar to the ones of HH jets. It is possible that this molecular emission traces small quantities of environmental gas which has been entrained into the HH jet ejected by the star. Also, the molecular emission might be indicating that the gas associated with the HH ejection is at least partially molecular.

At the present time, the relation between HH objects and the molecular outflows is not clear. The ongoing debate on this subject will have interesting implications for our ideas about the formation and propagation of outflows from young stars.

Bibliography

It is straightforward to find the up-to-date literature on HH objects, as there is an on-line catalog of HH objects ('A general catalogue of Herbig–Haro objects', by B Reipurth), which can be downloaded from the web address:
http://casa.colorado.edu/hhcat/
This catalog gives an extensive list of the literature on the observations of all of the known HH objects. A more or less complete compilation of the literature on the theory of HH objects is given in the paper:

Reipurth and Raga 1999 *The Origin of Stars and Planetary Systems* ed C Lada and N D Kylafis (Dordrecht: Reidel) p 267

Also, there is a monthly 'Star formation newsletter' (edited by B Reipurth) which gives the abstracts of most of the recent papers in the fields of star formation and outflows from young stars. This newsletter is available at the web address:
http://casa.colorado.edu/reipurth/

Hercules

(abbrev. Her, gen. Herculis; area 1225 sq. deg.) A northern constellation which lies between Draco and Ophiuchus, and culminates at midnight in mid-June. The origin of the constellation figure is uncertain, though its name dates back to ancient Greece, where it was identified with the strong man and hero of Greek mythology. Its brightest stars were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest*.

A large but rather inconspicuous constellation, the brightest stars in Hercules are α Herculis (Rasalgethi), a multiple system, consisting of a red (M5) primary, which is a semi-regular variable, magnitude range 2.7–4.0, and a yellow (G5) secondary, magnitude 5.4, separation 4.8″, both of which have a much fainter companion, β Herculis (Kornephoros), magnitude 2.8, which also has an unseen companion, and ζ Herculis, a close binary with yellow (F9 and G7) components, magnitudes 3.0 and 5.7, separation 1.55″, period 34.5 years. There are 12 other stars brighter than fourth magnitude. Other interesting stars include the Mira-type variable S Herculis (range 6.4–13.8, period about 307 days) and the eclipsing binary DQ Herculis (Nova Herculis 1934), one of the brightest novae of the twentieth century, which attainted about magnitude 1.4 before fading to magnitude 14–15.

Other interesting objects include the Great Cluster in Hercules (M13, NGC 6205), the brightest globular cluster in the northern sky, which lies between η and ζ Herculis and, at magnitude 5.9, is just visible to the unaided eye as a faint misty patch, M92 (NGC 6341), another fine globular cluster, magnitude 6.5, and NGC 6210, a ninth-magnitude planetary nebula.

Also in Hercules are Hercules X-1, an x-ray binary, and Hercules A, a powerful extragalactic radio source.

Hercules X-1

Hercules X-1 (Her X-1) is a pulsating x-ray source detected with the first x-ray satellite, UHURU, in 1971. It is an accreting X-RAY BINARY system consisting of a NEUTRON STAR that rotates every 1.24 s while orbiting a 'normal' stellar companion every 1.7 days; the misalignment of the magnetic axis relative to the rotation axis results in a distinctive pulse profile in x-rays. The 1.7 day orbital motion shows up clearly in Doppler shifts of the 1.24 s pulse; the x-ray source shows distinct eclipses every 1.7 days; and a previously known optical variable star HZ Herculis (HZ Her), colocated with the x-ray source, is found to have an identical period. The fact that we see total eclipses implies that our line-of-sight is within a few degrees of the orbital plane. The x-ray source shows sharp eclipses, attesting to its compact size. Variation in optical light by 1.8 magnitudes over the 1.7 day orbital period is attributed to x-ray heating on the side of the companion facing the active neutron star.

In addition to the 1.24 s rotation period and the 1.7 day orbital period, the system has an approximately 35 day 'superorbital' period in which the x-ray emission displays so-called main and short 'on' states separated by relative x-ray quiescence. The (0.2–100 keV) x-ray fluxes are $\sim 2 \times 10^{-9}$ ergs cm^{-2} s^{-1} during main-on state which lasts from 9–12 days; $\sim 6 \times 10^{-10}$ ergs cm^{-2} s^{-1} during the short-on state (5–7 days); and $\sim 1 \times 10^{-10}$ ergs cm^{-2} s^{-1} during the low or quiescent state. However, the 1.7 day optical and UV flux variations attributed to x-ray heating of the companion star continue throughout the 35 days with the optical light curves showing less than 20% change in peak-to-peak amplitude over the 35 day cycle. The optical light curves have a power spectrum that shows power at the sum of the orbital and long-term frequencies, but not in the difference, implying that the long-term variations are due to counter-precession of a tilted, co-rotating ACCRETION DISK. However, the underlying physics that causes the disk to start precessing has not as yet been determined. Her X-1 is one of only a half-dozen known x-ray binaries that show a superorbital period.

Due to its brightness over a broad range of energies and its high inclination, with eclipses of the neutron star, Her X-1 provides an excellent opportunity to study accretion processes onto a compact object which have come to be recognized as an important energy release mechanism in the universe. In addition it allows us to study the characteristics of matter and radiation under extreme conditions: the intense gravitational and magnetic fields of the compact object.

Temporal variations

The 1.24 s pulsations have also been detected in both optical and UV continua. The rms pulsed fraction is of order 0.5% in the UV, two to four times that of the reported optical pulsed fraction. The UV and optical pulses are in phase with the hard x-rays during orbital phases when x-ray dips occur. The lack of UV/x-ray delay indicates that the dips and the UV pulses may originate in the same material near the line of sight.

Absorption dips that last nearly as long as the x-ray eclipse regularly occur before the eclipse (pre-eclipse dips) and occasionally at orbital phase 0.3–0.6 (anomalous dips). The pre-eclipse dips exhibit the characteristic of starting out with the main-on state merged with the first eclipse ingress and progressing toward an earlier orbital phase as the main-on progresses: This pattern has persisted since the discovery of Her X-1 in 1971. The recurrence interval (1.65 days) is somewhat longer than the beat period between orbital and 35 day cycles. Since the pattern of the dips does not drift significantly in orbital phase over many 35 day cycles, it must be tied to the 35 day 'clock'.

The 35 day superorbital period is not coherent; it can vary in length from 19.5 to 21.5 orbital cycles with the most favored length being 20.5 cycles (34.85 days). The turn-on of the main-on state (which defines phase 0.0 of the 35 day cycle) occurs preferentially at orbital phases 0.2 and 0.7 (where orbital phase 0.0 refers to the center of x-ray eclipse). The existence of just these two types of turn-on causes phase jumps between successive 35 day cycles to be integral multiples of 0.5 orbital cycles.

The system has undergone several 'anomalous low' states during which it shows a substantial, unexpected drop in x-ray flux, with no substantial change in absorbing column density; little or no change in UV and optical fluxes; and a noticeable increase in pulse period. With the exception of the increase in pulse period and the degree of x-ray flux reduction these characteristics are similar to those observed during 'normal' 35 day low states.

Study of archival optical data of the variable star HZ Her shows that the system also displays intervals (lasting from months to years) when the 1.7 day optical variations attributed to x-ray heating disappear—which implies that accretion does turn off. A small amplitude modulation ($\sim$0.3 magnitudes) with twice the orbital frequency is observed at this time and is interpreted as the changing light from the distorted companion.

Spectral behavior

The normal star companion fills its ROCHE LOBE and the x-rays are powered by matter spilling over the inner LAGRANGIAN POINT and transferred through an accretion disk onto the neutron star surface. Her X-1 accretes matter at a rate of a few times 10^{-9} solar masses ($M_\odot$) per year. The energy release due to accretion is given by

$$E_{\rm acc} = G M_{\rm NS} \dot{M} / R_{\rm NS} \qquad (1)$$

where $M_{\rm NS}$ and $R_{\rm NS}$ are the mass and radius of the accreting object. The x-ray luminosity may be related to the mass accretion rate, $\dot{M}$, via

$$L_x = f \frac{G M \dot{M}}{R} \qquad (2)$$

where f, of order unity, takes account of possible anisotropy of the radiation. For Her X-1, for a distance

Dirac House, Temple Back, Bristol, BS1 6BE, UK

of 5 kpc, L_x is about 2×10^{37} erg s $^{-1}$ during the main-on state.

At maximum light during the 'normal' main-on state Her X-1/HZ Her shows a nearly constant energy flux per logarithmic frequency interval over a frequency range of 10^{15}–10^{19} Hz. A reduction in x-ray flux during the anomalous low state is not associated with an increase in flux at some other wavelength.

Figure 1 shows the x-ray spectrum of the main-on state obtained with BeppoSax. The pulse-averaged spectrum is a flat power law with a high-energy cut-off and an excess strong thermal blackbody component at low energies (a characteristic of many binary x-ray pulsars). Its unusually high galactic latitude and correspondingly low interstellar absorption ($N_{\rm H} \sim 10^{20}$ cm^{-2}) make Her X-1/HZ Her especially well suited for the study of this soft component. Spectral features around 1.0 and 6.4 keV are attributed to Fe L- and K-shell emission; a feature between 35 and 58 keV is attributed to electron–cyclotron resonance which implies a surface magnetic field of a few $\times 10^{12}$ G. The spectrum changes as a function of pulse phase: the Fe line and thermal emission are strongest during the off-peak of the pulse. The pulse profile changes as a function of energy: the pulse peak shifts and shows less structure below 1 keV. The pulse phaseshift suggests that the soft x-rays are likely reprocessed hard x-rays and the Fe-line emission originates at the reprocessing site.

The ultraviolet spectra of Her X-1 show strong emission lines due to N V, C IV, and He II (figure 2). The Goddard High-Resolution Spectrograph on the Hubble Space Telescope (HST) resolved two moving emission components of the N V emission doublet: a broad emission line that can be attributed to the x-ray illuminated surface of a Keplerian accretion disk and a narrow line associated with the x-ray heated atmosphere of the companion star, HZ Her. The ultraviolet continuum is flatter than normal stellar spectra, presumably due to x-ray heating effects.

Optical spectra of HZ Her show Balmer absorption lines down to the series limit (figure 3). Absorption lines are seen in the spectrum both at minimum and maximum light. Emission lines at He II λ4686 and N III/C III around λ4400 are seen during maximum; those due to He II persist during the minimum. At minimum light the optical spectrum of HZ Her corresponds to a spectral type of A7 ($T_{\rm eff} = 8100$ K). At maximum light the spectral type ranges from B3 to B6 depending on the lines used. The dramatic change in spectral type from minimum to maximum is also attributed to x-ray heating of the side facing Her X-1; the lack of a good match to a single spectral type is attributed to x-ray heating effects. The optical flux is mainly from the x-ray heated star surface with the disk surface contributing less than 15% of the total optical flux.

Pulse and orbital period history

Overall the pulse period of Her X-1 shows a secular decrease or spin-up as is expected for a system accreting mass (and hence angular momentum). However, during anomalous low states the system shows a noticeable spin-down. Correlation between times of low hard x-ray luminosity and episodes of spin-down is predicted by models which suggest that a *decrease* in mass accretion rate causes the Alfvén radius at which material joins the magnetosphere to move out, thereby *increasing* the drag-producing torques of the field lines threading the disk outside the co-rotation radius, leading to spin-down.

The orbital period has been shown to be decreasing at a rate of 2×10^{-8} days yr^{-1}. If all the mass lost by the companion is accreted by the neutron star the mass transfer rate needed to explain the decrease in orbital period is $1.4 \times 10^{-8} M_\odot$ yr^{-1}, nearly an order of magnitude greater than the mass loss rate required to provide the observed x-ray luminosity. Mass loss through a simple self-excited wind also cannot explain the observed period decrease. Braking of the companion star by a magnetically-channelled stellar wind provides a mechanism for the angular momentum loss rate. UV spectra do not show the presence of either P Cygni profiles or modest line shifts indicative of wind flows; however, it is possible that the high x-ray luminosity ionizes the material in the wind flows and thereby precludes spectroscopic detection of a wind.

Open questions

Evolutionary status

X-ray binaries containing neutron stars are classified according to the mass of the 'normal' stellar companion. The high-mass systems (HMXBs) contain massive early-type stars with short lifetimes ($<10^7$ yr). More than half of HMXBs exhibit regular x-ray pulsations (implying magnetic fields of the of order 10^{12} G) with periods from 0.1 to 1000 s. The x-ray emission is caused by matter accreted from the stellar wind of the massive companion. The optical fluxes, due mainly to emission from the massive companion, are high, giving x-ray to optical luminosity ratios in the range 10^{-5} to 10. The low-mass x-ray binaries (LMXBs) contain faint optical companions with long lifetimes of 10^8–10^9 years. The x-ray emission is caused by matter overflowing from the Roche lobe of the companion. The optical light is due predominantly to x-ray heating of the accretion disk, giving x-ray to optical luminosity ratios from 10 to 10^4. With few exceptions, strong pulsations are not seen, implying that LMXBs have relatively weak magnetic fields ($\leq 10^{10}$ G). The Her X-1 system is unusual in that, with an approximately $2M_\odot$ companion, it is the only known 'intermediate'-mass system. It is like the HMXBs in that it exhibits pulses and its optical light is dominated by emission from the companion, but it accretes matter via Roche lobe overflow through an accretion disk like the LMXBs. The location of Her X-1, more than 3 kpc above the Galactic plane, suggests that it is a rather old system like the LMXBs, or that, if it originated in the Galactic plane, the neutron star must have obtained a significant kick from the SUPERNOVA that formed it. The pulses and the cyclotron line feature which attest to the high magnetic field of Her X-1 are difficult to reconcile with theories of STELLAR EVOLUTION which require that the magnetic fields of

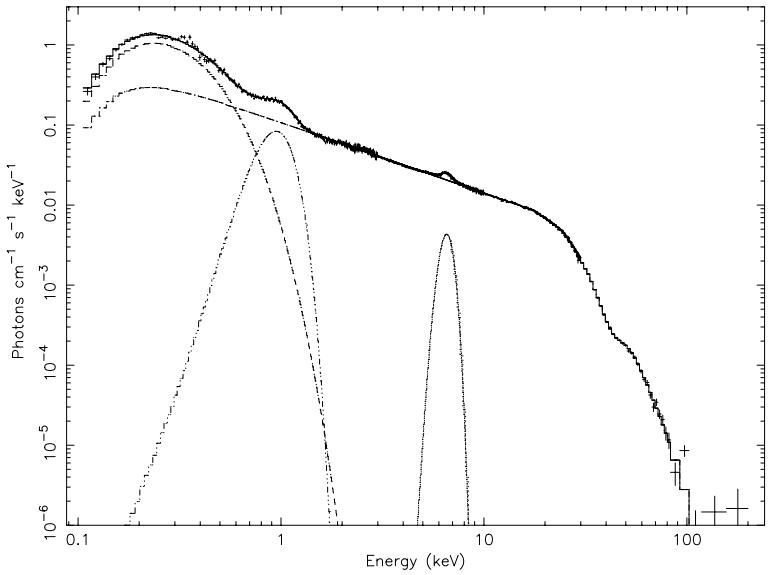

Figure 1. x-ray photon spectrum of Her X-1 taken by BeppoSax with spectral components (blackbody, power-law, Fe L line and Fe K line) indicated by broken curves. Averaged over orbital phases, excluding eclipses and dips.

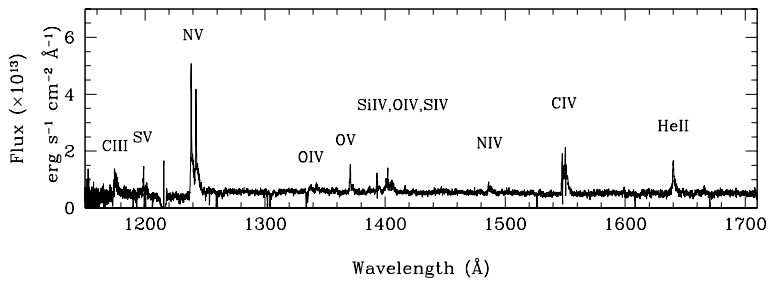

Figure 2. Ultraviolet spectrum of Her X-1 taken with HST/STIS averaged over orbital phases 0.69–0.76.

neutron stars decay over time. The large orbital decay rate is also difficult to reconcile with the relatively low mass accretion rate and lack of evidence for mass loss through a wind.

System mass

The Her X-1 system is considered one of about seven (out of several hundred known) x-ray binaries for which reliable estimates of the component masses exist. However, both methods used to determine the component masses of the system rely on assumptions that have not been independently verified. The mass determinations made utilizing x-ray and optical pulse timing assume that the companion star fills its Roche lobe and that the optical pulses are reprocessed at the inner Lagrangian point of HZ Her. RADIAL VELOCITY measurements are hampered by the uneven heating of the star (the center of light is not the center of mass) and the presence of substantial amounts of gas in the system. Lower limits to the mass of the neutron star ($M_x \geq 1.3 \pm 0.1 M_\odot$) obtained by radial velocity measurements are consistent with the pulse-timing determination ($M_x = 1.3 \pm 0.1 M_\odot$).

The superorbital period

The interpretation of superorbital periods in terms of disk precession has been questioned, because if the disk precession is controlled by the gravitational fields of the neutron and companion stars any induced precession would be damped rapidly because of differential precession within the disk. The preferential turn-ons at orbital phases 0.2 and 0.7 have been attributed to the interaction of a tilted accretion disk with the time variation of the torque induced by the companion star leading to a wobble or 'nodding' motion in the disk. Again the physics that causes the disk to tilt in the first place is not known. Several models have been put forward that attempt to tilt and precess the disk without invoking precession of the neutron star and/or its companion. One viable suggestion is that the behavior attributed to precession is maintained by the influence of the x-ray emission on the structure of the disk; that strong central illumination can maintain disk warping has been shown analytically. Another possibility

is that shadowing of the companion star may lead to transfer of matter with misaligned angular momentum.

Table 1. Properties of Her X-1.

Apparent magnitude m_V	14.7–13.0
Orbital epoch T^0_{orb}	JD2443805.019980(14)
Orbital period, P	1.700 167 720(10)d
Pulse period	1.237 759 653(3)s
$\dot{P}_{orb}$	$-2.0(0.4) \times 10^{-8}$ days yr^{-1}
NS* mass	$1.3(0.1)M_\odot$
CS mass	$2.2(0.1)M_\odot$
CS spectral type	A7-B3/6
Distance, D	5–7 kpc
Inclination of orbit to LOS, i	$87(2)^\circ$
Orbital eccentricity, e	≤ 0.0003
$a_X \sin i$	13 light seconds
x-ray eclipse duration	0.2320(3) days

* NS stands for neutron star; CS stands for companion star. LOS for line-of-sight.

Emission lines

The optical N III and C III emission lines at λ4640 and λ4650 disappear during mid-eclipse as do the O III λ3133 lines in the UV, suggesting that they can be attributed to Bowen fluorescence from the x-ray heated side of the companion star. However, the origin of the high excitation emission line of He II (λ4686) is not clear: the line persists at orbital phase 0.0 when neither the heated side of HZ Her nor the accretion disk are visible. This suggests either an accretion disk corona or an extended source of hot gas in the system.

Bibliography

Over 300 papers deal with direct observations or interpretations of the Hercules X-1/HZ Herculis system. The first discovery paper:

Tananbaum H, Gursky H, Kellogg E M, Levinson R, Schrier E and Giacconi R 1972 Discovery of a periodic pulsating binary x-ray source in Hercules from UHURU *Astrophys. J. Lett.* **174** L143

A follow-up paper:

Giaconni R, Gursky H, Kellogg E, Levinson R, Schreier E and Tananbaum H 1973 Further x-ray observations of Hercules X-1 from UHURU *Astrophys. J.* **184** 227

captured the most prominent behavior and gave the initial interpretation in terms of an accretion-powered, pulsating binary x-ray source.

The twisted, tilted accretion disk was first suggested as an explanation of the 35-d variations in:

Katz 1973 *Nature Phys. Sci.* **246** 87

A comprehensive summary of research on x-ray binaries has been compiled by:

Hermes

An Apollo asteroid discovered by Karl Reinmuth in 1937, provisionally designated 1937 UB. Hermes is the only asteroid to have been given a name without first having received a permanent number and having had its orbit accurately calculated. On 30 October 1937 it passed Earth at a distance of 733 000 km, a close-approach record that stood for over 50 years. The parameters of its orbit are approximate only: mean distance from the Sun 1.64 AU (245 million km), perihelion 0.62 AU, aphelion 2.66 AU, period 2.11 years, inclination 16°, eccentricity 0.62. It has never been seen again, but with an estimated diameter of 900 m and a potential closest-approach distance of 0.003 AU (450 000 km) it remains near the top of the list of potentially hazardous asteroids.

Herrick, Edward Claudius (1811–62)

Bookseller and librarian, born in New Haven, CT, self-educated by association with Yale University academics, and observer of the 9 August 1837 meteor shower, which he identified as the Perseids. With the Leonids in mind (after a brilliant display in November 1833 they proved to be an annual shower, the first identified), Herrick found other August records of meteor showers. In 1839 he confirmed the radiant of the shower as being in Perseus. As a result of his library research, he also identified a third annual meteor shower around 30 April (now called the Lyrids) and, later, a fourth annual shower, in December, the Andromedids (or Bielids, named for their association with Biela's Comet). Herrick had in fact been preceded in the identification of the Perseids as an annual meteor shower by ADOLPHE QUETELET. The two of them had been preceded by anonymous English and German farmers who for generations had referred to the Perseids as the Tears of St Lawrence (martyred on 10 August 258). Feted locally for his discoveries, Herrick became the Yale University librarian, where he wrote obituaries of graduates and faculty, including his own, which he completed a few days before he died in 1862.

Herschel Family

William Herschel (1738–1822), his sister Caroline (1750–1848) and his son John Frederick William (1792–1871) freed astronomy from its preoccupation with the solar system and helped to make the study of the stars, the nebulae and the cosmos as a whole part of mainstream science.

William and Caroline Herschel

William was the third surviving child, and Caroline the fifth, of a humble bandsman in the Hanoverian Guards. William was given as good an education as the family could afford, after which in 1753 he joined his father in the military band, but Caroline's illiterate mother prevented her from learning more than reading and writing.

In 1757, after the defeat of the Hanoverian army by the French, William fled to England, where he scratched a living as a musician, first in the capital and then in the north. His fortunes took a turn for the better in 1766, when he was appointed organist to a fashionable chapel in the spa resort of Bath. Despite his busy life as performer, conductor and teacher of music, William's financial security now allowed him to develop other interests, including astronomy.

In 1772 William visited the family home in Hanover and was dismayed to find Caroline a household drudge. Their father was now dead, and William persuaded his mother and eldest brother to release Caroline so that she could join him in Bath, to pursue a career as a singer. Before long, however, Caroline found William devoting every leisure minute to astronomy. Being self-taught, he did not know that astronomers studied the nature and movements of the familiar bodies of the solar system; instead, from the start he set himself the goal of understanding 'the construction of the heavens'. He realized that to see distant and therefore faint objects he would need telescopes as large as possible, but his funds were limited, and before long he resorted to making his own reflectors with the help of some second-hand tools and Robert Smith's classic treatise on *Opticks*. These early experiments were to culminate in 1781 in two unsuccessful attempts to cast a 3 ft diameter mirror in a foundry set up in the basement of their home. He did, however, successfully build a Newtonian REFLECTOR of 20 ft focal length with 12 in mirrors (see NEWTONIAN TELESCOPE, REFLECTING TELESCOPES); but it was simply slung from a pole and used by an observer perched precariously on a ladder. In 1778 he succeeded in polishing a mirror of 7 ft focal length to a shape of high precision, and soon he was using this systematically to familiarize himself with the night sky.

In 1774 William had opened his first observing book, and on the first page he sketched the ORION NEBULA, remarking that it had changed shape since the drawing reproduced in the book by Smith. In prophetic words he commented that 'perhaps from a careful observation of this Spot something might be concluded concerning the Nature of it'. But he realized that first he must familiarize himself with the brighter stars. While thus engaged he began to collect stars that were double, hoping that they might prove of use in the detection of annual parallax, for GALILEO had suggested long ago that the more distant star of a pair might be used as a quasi-fixed reference point against which to measure the annual movements of the nearer star. On 13 March 1781, while doing this, William came to examine a 'star' in Taurus, and saw at a glance that there was something unusual about its appearance. Re-examining it four days later, he found that it had moved, and was therefore no star but a member of the solar system. Speculations about undiscovered planets were in fact commonplace at the time, but this was unknown to William, who therefore took the object to be a comet.

By this time word of this extraordinary musician had spread in scientific circles, and William's home had been visited by a number of astronomers, including NEVIL MASKELYNE, the Astronomer Royal. William did not know how properly to describe the position of the supposed comet, and Maskelyne's Greenwich instruments were inferior to William's 7 ft reflector and showed nothing unusual about any object in the region he indicated. Eventually Maskelyne identified the object by its motion. It proved to be not a comet, but a primary planet of the solar system (later named Uranus), the first to be discovered since the dawn of history.

William became famous overnight, and his allies (notably Sir Joseph Banks, President of the Royal Society) lobbied King George III—himself a Hanoverian—to make available funds to enable William to give up music and devote himself to astronomy. William was invited to take his 7 ft reflector to Greenwich to be compared with Maskelyne's instruments, and then to the court in London and afterwards to Windsor Castle. Suitably impressed, King George awarded William a modest but adequate pension, if he would settle near Windsor and show the heavens to the royal family when asked.

William accepted, without consulting Caroline, who thus changed overnight from a singer to an assistant astronomer. By the autumn of 1783 William had built a new and larger 20 ft reflector with a stable platform, and with this he began to 'sweep' the sky for NEBULAE, in a campaign that was to take two decades and increase the number of known nebulae from about 100 to 2500. Caroline shared the night watches, sitting at a desk at an open window and recording their observations. Next day she would write up a fair copy, and she later arranged their results for publication. On her spare nights she searched for comets, and she was to discover no fewer than eight. In addition, William had found that Flamsteed's British Catalogue of stars was riddled with errors, and so Caroline prepared an index that would take the user from the catalogued star back to the observations on which the catalogued data were based. This Index was published in 1798 by the Royal Society at its own expense.

In the 1770s William several times observed the Orion Nebula and thought it had altered shape and was therefore small, and so near and truly nebulous. Indeed, any nebula of a uniform milky appearance was, he thought,

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

truly nebulous, while a distant star cluster would appear mottled. In 1784, however, he encountered nebulae that displayed both forms of nebulosity, and this led him to change his mind and conclude that all nebulae were star CLUSTERS, the differences in appearance being in part a reflection of the differences in the distances of the stars concerned.

This being so, the nebulae were clusters of stars, some of them scattered while others were tightly packed. Clustering implied the action of an attractive power or powers (presumably, but not necessarily, gravity), and with time a scattered cluster would become more compressed. This led William to introduce into astronomy the concept of development with time, a scattered cluster being younger than a compressed one. Furthermore, the need to classify the great numbers of specimens of nebulae that he was collecting led him to play the natural historian, a methodology wholly alien to traditional astronomy. This, plus the fact that few other astronomers could so much as glimpse the nebulae about which William was theorizing so freely, made his contemporaries uncertain of how to react to this gifted maverick.

In 1790 William came across what is now classified as the planetary nebula NGC 1514, but which to him was a star surrounded by a shell of nebulosity out of which it was surely condensing. This caused him to change his stance once more and to accept the existence of nebulosity that had not yet condensed into stars, but would in time do so.

William made many other contributions to astronomy, including the discovery of satellites of both Saturn and Uranus. Re-examining DOUBLE STARS after a long interval, he found that in some the two stars had moved in orbit around each other, though he did not have enough information to demonstrate that the force binding them together was gravitational. He published long lists in which stars of almost equal brightness were compared with each other, the intention being that a variation in the brightness of a particular star would reveal itself by disturbing the published comparisons. He investigated the shape of the Galaxy on the assumptions that his telescopes could penetrate to the borders in all directions, and that within the Galaxy the stars were distributed with fair uniformity, so that the number of stars he could see in a given direction was an index of the distance to the border in that direction. He carried out the star counts for a great circle of the sky and published an influential plan of this cross-section of the Galaxy; but in later life he abandoned both the assumptions on which it was based. In 1783 he published the first analysis of proper motions and concluded that the solar system is moving in the direction of Lambda Herculis, though the similarity between his result and that of modern analyses was partly a matter of luck. His experiments with sunlight led him in 1800 to the discovery of infrared radiation.

William also supplemented his income by making telescopes for sale, and many of the crowned heads of Europe were among his clients. For himself he completed in 1789 a monster 40 ft reflector with 4 ft mirrors. But it was cumbersome, the mirrors tarnished easily, and perhaps his own conversion to belief in nebulosity removed the reflector's primary *raison d'être*.

John Herschel

In 1788 William married, with unwelcome consequences for Caroline who found herself thereby displaced in his priorities. In 1792 his son John was born. Where William had been self-taught in astronomy, John was to enjoy a Cambridge education, and by 1815 was embarked on a career as a Cambridge don. His father, however, now in failing health, still had ambitions in astronomy that he could fulfil only through his son, and in 1816 he prevailed upon John to return home and become his astronomical apprentice. The 20 ft with which William had swept for nebulae was now in a poor state, and John was to build another to similar design. In 1821, Caroline came out of retirement to act as an amanuensis to her nephew in his trial sweeps for nebulae.

John's first task, however, was to re-examine his father's double stars, in collaboration with James South, another wealthy amateur who owned two fine equatorials ideal for the purpose. A few years later John was to be one of several astronomers who showed that the attractive force binding together the two members of a binary system was indeed gravitational.

John next used his 20 ft to re-examine his father's nebulae. In William's catalogues the nebulae were classified by type and this made the catalogues unsuitable for systematic re-examination. The problem was solved by Caroline, who had retired to Hanover after her brother's death in 1822. She rearranged the entire 2500 nebulae into a form convenient for John to use when sweeping, a work for which she was awarded the medal of the ROYAL ASTRONOMICAL SOCIETY (in whose foundation John had played a leading part, and of which William had been the nominal first President).

John's re-examination resulted in his 1833 catalogue of 2306 nebulae. It was now time to complete his father's work by surveying the southern skies invisible from England. Taking the 20 ft, an equatorial purchased from South, and one of Caroline's 'comet sweeper' telescopes, he sailed to the Cape of Good Hope where from 1834 to 1838 he engaged in an observational campaign of unparalleled intensity. His results were published in a sumptuous volume in 1847, 'being a completion of a telescopic survey of the whole surface of the visible heavens', for John had examined the entire heavenly sphere with his 20 ft. His return in 1838 marked the end of his career as an observer, and the end too of the Herschels' virtual monopoly of observations of nebulae, for in 1839 the future Lord Rosse at Birr in Ireland completed a reflector with 3 ft mirrors, followed in 1845 by 'the Leviathan of Parsonstown' with its 6 ft mirrors. John did, however, advance astronomy by working at his desk. In particular, *Philosophical Transactions* for 1864 contained his catalogue of over 5000 nebulae and star clusters; the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

great majority had been discovered by him or by his father, and the enlarged version of the catalogue published by J L E Dreyer in 1888 is the NEW GENERAL CATALOGUE OF NEBULAE AND CLUSTERS OF STARS or NGC in widespread use today.

As a theorist John lacked the daring of his father, and he was inhibited too by the obligation he felt always to portray his late father's work in a favorable light, even when he himself had come to a different view. Also, by the mid-nineteenth century the daring, even shocking theorizing of his father had become components of mainstream astronomy. William, Caroline and John had enlarged the science from the study of the solar system to the study of the cosmos.

Alexander Stewart Herschel and John Herschel II

Two of John's sons, Alexander Stewart and John II (both born in South Africa), made their own contributions to astronomy, the former particularly in cometary and meteoric studies. The later members of the family carefully preserved the manuscripts of their forebears, which are now largely in permanent collections, notably the Library of the Royal Astronomical Society.

Hertzsprung, Ejnar (1873–1967)

Danish astronomer, studied chemical engineering and worked as a chemist in St Petersburg before returning to Denmark to take up astronomy, worked in Göttingen and Potsdam with KARL SCHWARZSCHILD, and then at the Leiden Observatory (Netherlands) where he became director. Hertzsprung determined the proper motions of stars, and about a million positions of binary stars, as well as the brightnesses of stars, determining by photography not only their brightnesses, but also their colors (expressed as the ratio of a star's brightness through two different colored pieces of glass). A star's color is connected to its temperature, and its brightness relative to others in a cluster all at the same distance is connected to its absolute magnitude. In 1911 he plotted these quantities in what became known as a color–magnitude diagram for the Hyades star cluster, and discovered the distinction between giant stars and 'main sequence' stars. Two years later HENRY NORRIS RUSSELL plotted an equivalent diagram for stars whose spectral classes were known and which were not in clusters but so nearby that their distances and thus their absolute magnitudes could be determined. A star's spectral class is, like color, connected to its temperature. The spectral class–absolute magnitude diagram also showed the distinction between giants and main sequence stars like the color–magnitude diagram. The two diagrams have the same topography, and collectively are known as the *Hertzsprung–Russell diagram*. (By an accident of history, an apparently independent parallel study of the 'relation between brightness and spectral type in the Pleiades' was undertaken by Hans Rosenberg (1879–1940) of Göttingen, whose overlooked paper contained the first published Hertzsprung–Russell diagram (June 1910).) Hertzsprung also determined the distance to the Small Magellanic Cloud, by use of the statistical parallax of a group of Cepheid stars (triangulating onto the stars over the baseline of the Sun's journey through space over several years). Although he made a mistake, putting the stars a factor of ten too close, possibly through a slip of the pen, it is interesting that the distance, the largest distance of anything known at the time, was so large that a factor of ten too small did not immediately stand out.

Hertzsprung–Russell Diagram

The Hertzsprung–Russell diagram (HR-diagram), pioneered independently by EJNAR HERTZSPRUNG and HENRY NORRIS RUSSELL, is a plot of the star luminosity versus the surface temperature. It stems from the basic relation for an object emitting thermal radiation as a black body:

$$L = 4\pi\sigma R^2 T_{\rm e}^4 \qquad (1)$$

where L is the luminosity (energy emitted per second by the whole radiating surface), σ is the Stefan–Boltzmann constant, R is the radius and $T_{\rm e}$ is defined as the temperature of a hypothetical black body of the same radius R radiating the same total luminosity L. In general, physical temperatures in stellar surface regions closely approximate $T_{\rm e}$, and the place where a photon has 50% probability of radiating directly into space—the photosphere—is well defined. Thus R in equation (1) is also well defined. In red giant and supergiant stars the radius is more uncertain, because they have very extended atmospheres partly out of hydrostatic balance.

The luminosity is customarily expressed in solar units $L_\odot = 3.90 \times 10^{33}$ erg s^{-1} and plotted on a magnitude scale $M_{\rm b} = -2.5 \log L/L_\odot + M_{\rm b,\odot}$, where $M_{\rm b}$ and $M_{\rm b,\odot} = 4.77$ are the bolometric magnitudes of the star and the Sun, respectively.

Every star at every instant of its life has a given L and R and therefore $T_{\rm e}$ which are dictated by the global structure of the star and the physical processes taking place in it. Since the structure of a star is not constant in time because of the continuous energy leakage from the surface (and nuclear fusion), L and $T_{\rm e}$ will change as the star evolves. Therefore a star will describe a path in the HR-diagram which is a function of its mass and chemical composition. It follows that the HR-diagram is a powerful diagnostic of the star's structure and evolution during its whole life.

Different populations of stars have different HR-diagrams: they go from the well-behaved ones of globular clusters, in which almost all evolutionary phases are detectable, to the poor ones of open clusters and associations, where only very few stars beyond the main sequence are visible, to the patchy HR-diagrams of composite stellar populations, in which at least one more dimension is added, namely the past history of stellar formation.

By studying the path in the HR-diagram of single stars and/or the morphology of the HR-diagram of stellar aggregates of different complexities (from clusters to galaxies) we will learn very much not only about how stars are made and evolve but also about many physical properties of the host system.

Passing from observations to theory and vice versa

The observational data are apparent magnitudes and colors in a given photometric system (for instance the classical Johnson UBV system). The colors are defined as the difference $(m_{\Delta\lambda} - m_{\Delta\lambda'})$ between any two magnitudes $m_{\Delta\lambda}$ and $m_{\Delta\lambda'}$ corresponding to the fluxes in the adopted pass-bands $\Delta\lambda$ and $\Delta\lambda'$. Going from apparent magnitudes $m_{\Delta\lambda}$ and colors to luminosities and effective temperatures is not trivial as a number of steps are needed. Determining the absolute luminosity requires distance, color excess, and bolometric corrections. Determining $T_{\rm e}$ is even more indirect. For the few cases for which the radius R is known, $T_{\rm e}$ is derived from its definition via the black body law. In all other cases some measure of the temperature is estimated by at least three different methods: (i) from the entire spectral energy distribution matched by a black body of given temperature; (ii) from the Wien law $\lambda_{\rm max} T = \cos t$, where $\lambda_{\rm max}$ is the wavelength of the maximum intensity of the spectrum; (iii) from suitable relationships between colors and temperature based on preliminary comparison with the black body emission. Each method is affected by some degree of uncertainty. In the same star, these different methods can yield different values of temperature. These are generally close to each other and to the idealized $T_{\rm e}$ defined by equation (1).

From an operational point of view, we start from apparent magnitudes and colors, correct them for extinction if possible, translate apparent magnitudes $m_{\Delta\lambda}$ into absolute magnitudes $M_{\Delta\lambda}$ if the distance is known, derive from $M_{\Delta\lambda}$ the absolute bolometric magnitudes $M_{\rm b}$ applying the so-called bolometric correction (BC), transfer colors into $T_{\rm e}$, and finally compare the resulting HR-diagram with the theoretical counterpart obtained from the theory of stellar structure and evolution. The BC is required to account for the fraction of the flux not detected by the pass-band in use. It is worth recalling here that BCs and color–$T_{\rm e}$ relationships are complicated functions of spectral type, luminosity class and chemical composition X, Y and Z, i.e. the fractional mass abundances of hydrogen, helium and all heavier elements lumped together. The whole procedure can be repeated backward, i.e. starting from theoretical L and $T_{\rm e}$ to predict the corresponding observational magnitudes and colors.

HR-diagram of cluster and field stars

Figure 1 shows the apparent HR-diagrams of two Galactic GLOBULAR CLUSTERS, the metal-rich 47 Tucanae and the metal-poor M55. Each HR-diagram clearly illustrates the properties of assemblies of stars with the same age, chemical composition and distance.

Most of the stars fall along the main sequence (MS) band, running from low to high magnitudes and colors. The bending portion of the top of the main sequence defines the so-called turn-off (TO). Along the main sequence are stars in the core H-burning phase (see below). The remaining stars are distributed in four different loci.

(i) The sub-giant branch (SGB) and the red giant branch (RGB) are so named for the large dimensions of the stars. The sub-giant branch runs nearly horizontally from

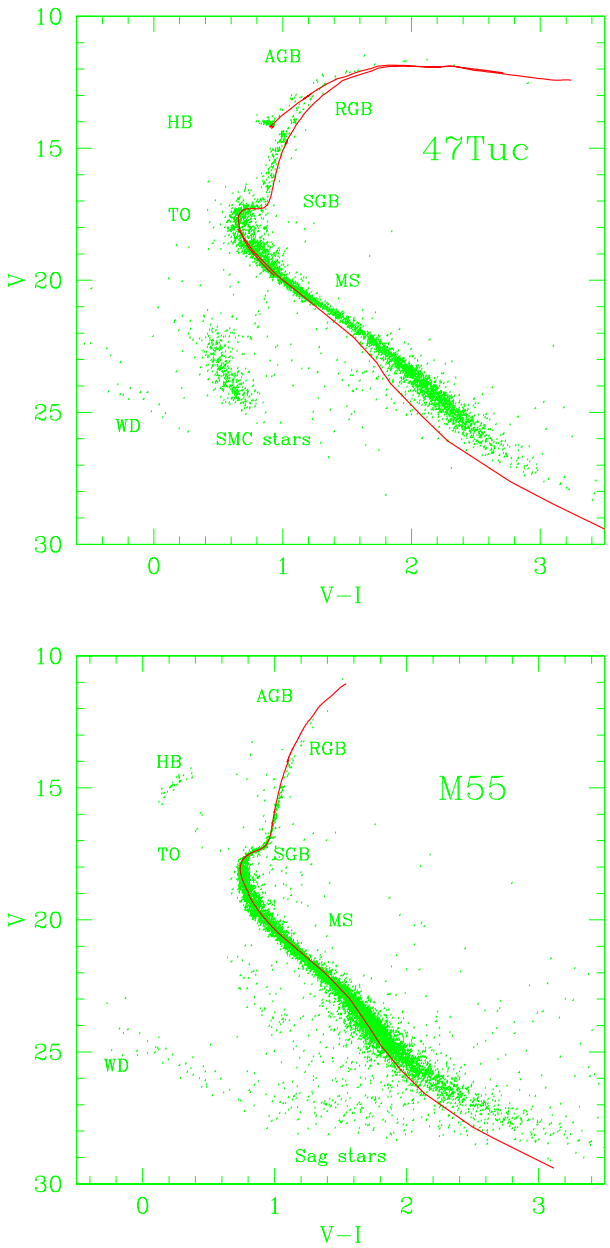

Figure 1. Upper panel: the HR-diagram of the metal-rich Galactic globular cluster 47 Tucanae. Superposed is the isochrone with $Z = 0.008$ and age of 10 Gyr. Lower panel: the same but for the metal-poor Galactic globular cluster M55. The superposed isochrone has metallicity $Z = 0.0004$ and age of 14 Gyr. In these figures, V is visual and I an infrared bandpass. Courtesy of M Zoccali.

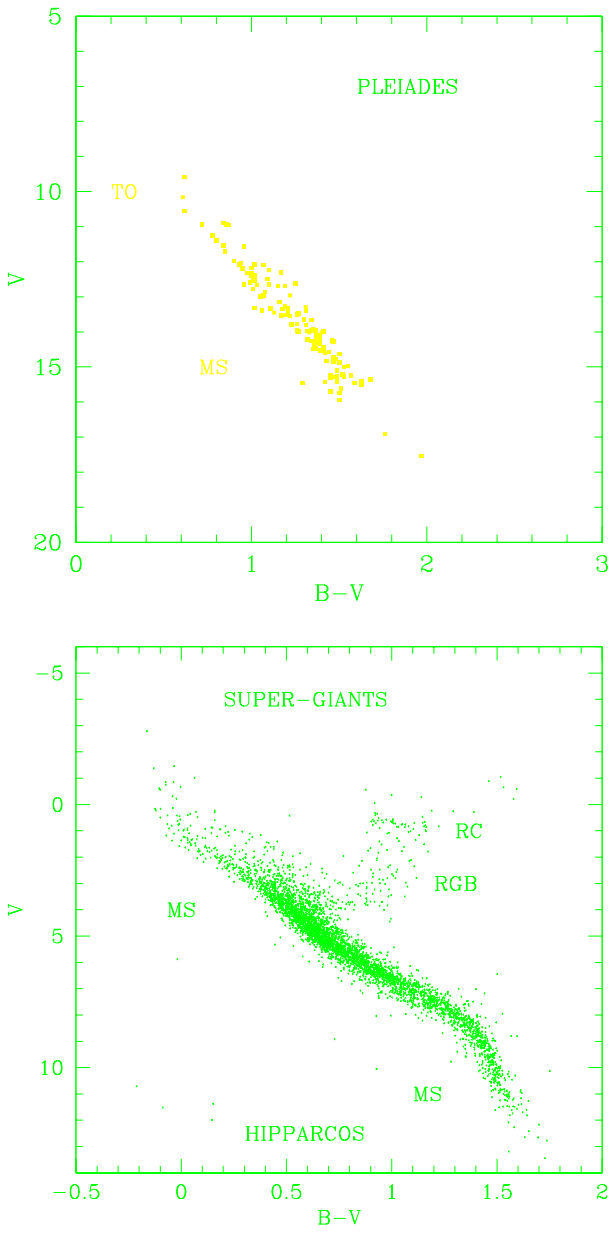

Figure 2. Upper panel: the HR-diagram of the Pleiades. Lower panel: field stars in the solar vicinity (within 50 pc of the Sun) after Hipparcos.

the turn-off to the bottom of the red giant branch. This is nearly vertical for metal-poor clusters (M55), whereas it has a pronounced curvature for metal-rich clusters (47 Tucanae). For the latter, the brightest red giant branch stars in the V-passband are not the reddest ones. The subgiant and red giant branch stars are in the shell H-burning phase prior to core He ignition.

(ii) The group of stars slightly bluer than the red giant branch and crowding into a clump in the case of 47 Tucanae, or significantly bluer and more dispersed (a sort of blue tail) in the case of M55, both correspond to the so-called horizontal branch (HB). This was so named originally because, in many intermediate-metal clusters, the corresponding feature defines a broad, essentially horizontal distribution in V. As it happens, with due allowance for the BC, even dropping blue

Dirac House, Temple Back, Bristol, BS1 6BE, UK

horizontal branches like that of M55 are indeed remarkably horizontal. Horizontal branch stars are burning helium in the core.

(iii) Just above the red giant branch and with a merging path are the few asymptotic giant branch (AGB) stars. They are in post core He-burning stages ('double shell source' stage) prior to the ejection of their envelopes to become first planetary nebulae (PNe) and later white dwarfs (WDs).

(iv) Finally, there is the fainter sequence of white dwarf stars that are the end product of globular cluster stars' evolution. The white dwarf sequence is nearly parallel to the main sequence, but about 12 mag fainter, and nicely corresponds to a line of constant radius (see below). The white dwarf sequence was rarely visible in the past and became clearly detected only with the advent of modern ground and space telescopes.

To complete the star census, it is worth recalling that in both panels of figure 1 contamination by fore- and background stars is clearly visible. In the case of 47 Tucanae the blob of stars fainter than the main sequence but brighter than the white dwarf sequence are stars of the Small Magellanic Cloud (SMC), displaced in this part of the HR-diagram because of the large distance. In the case of M55, the stars blurring the main sequence band on both sides are those of the Sagittarius galaxy against which M55 is observed. Situations like this are common to other HR-diagrams and must be kept in mind for a correct interpretation to be obtained.

The upper panel of figure 2 shows the HR-diagram of the Pleiades, a sparsely populated open cluster, in which only the main sequence is visible. Finally, the lower panel of figure 2 shows the recent HR-diagram of field stars in the solar vicinity (within 50 pc of the Sun) observed by the Hipparcos satellite. The novelty of this diagram with respect to many previous versions of it is that for the first time all these stars have distances measured with the greatest accuracy. One may easily identify the main sequence band, the sub-giant branch, the red giant branch, a clump of red stars hereafter known as the 'red clump' (RC), and finally the sequence of white dwarfs.

Why do we have such different HR-diagrams? What are the physical causes driving the evolution of stars and determining the morphology of the HR-diagram? Can we infer from their properties important parameters such as the age of the stars in order to set limits on the age of the universe? What can we learn from HR-diagrams about the past history of galaxies? Answering these questions is the aim of the following sections.

Basic physics of stellar interiors

Looking at the Sun as a prototype star, convincing arguments indicate that it has been radiating energy at nearly the same rate for several billion years (at least 4.6 Gyr), thus making clear that several conditions have always been satisfied.

Hydrostatic equilibrium

If the complex structure of the Sun (or a star in general) is reduced to a self-gravitating isotropic sphere of gas of constant mass, this means that gravitational pull is balanced by differential gas pressure. Neglecting all other forces but those due to gravity and pressure, at each layer of radial distance r the conditions of hydrostatic equilibrium and mass conservation are

$$\frac{\mathrm{d}P}{\mathrm{d}r} = -\frac{GM_\mathrm{r}}{r^2}\rho \qquad \text{and} \qquad \frac{\mathrm{d}M_\mathrm{r}}{\mathrm{d}r} = 4\pi r^2 \rho \tag{2}$$

where M_r is the mass contained in the sphere of radius r and ρ is the local density. It can easily be checked that even a very small departure from hydrostatic equilibrium would imply a variation of the star radius over the free-fall time scale

$$t_\mathrm{ff} = 2\left(\frac{R^3}{GM}\right)^{1/2} = 3.2\times 10^3 \left(\frac{R}{R_\odot}\right)^{3/2}\left(\frac{M}{M_\odot}\right)^{1/2} \tag{3}$$

which in the case of the Sun is about 1 h. We will assume hydrostatic or quasi-hydrostatic equilibrium from now on.

Thermal equilibrium

This demands that the energy leakage from any spherical surface within the star is balanced by continuous supply from an internal reservoir. In other words the following equation must be satisfied once we have a quasi-static star:

$$\frac{\mathrm{d}L_\mathrm{r}}{\mathrm{d}r} = 4\pi r^2 \rho \epsilon \tag{4}$$

where L_r is the luminosity emitted by the sphere of radius r and ϵ is the amount of energy per unit mass and time generated inside it by all sources. What can produce the 3.90×10^{33} erg s^{-1} of the Sun's luminosity and do it for about 4.6 Gyr, or, in general, the luminosities of any other star over its whole life? These questions, taken together, limit the candidate mechanisms to gravitational contraction and nuclear fusion.

Gravitational energy

According to the virial theorem for a system in hydrostatic equilibrium, any variation of the gravitational potential by contraction goes to increasing the internal energy and liberating (radiating) an equal amount of energy. An estimate of the thermal energy of a star is soon derived from the virial theorem and gravitational potential energy Ω:

$$E_\mathrm{T} \simeq -\frac{1}{2}\Omega \simeq \frac{1}{2} q \frac{GM^2}{R} \tag{5}$$

with $q = 3/2$ (a numerical factor accounting for the mass distribution). Supposing that the whole internal energy is radiated away at the rate L (luminosity), the duration of this source is

$$t_\mathrm{K} = \frac{3}{4}\frac{GM^2}{RL} = 2\times 10^7 \left(\frac{M}{M_\odot}\right)^2 \frac{L_\odot}{L}\frac{R_\odot}{R}\ \mathrm{yr}. \tag{6}$$

Dirac House, Temple Back, Bristol, BS1 6BE, UK

Thus, gravitational contraction and hence internal energy could power the Sun for about 20 million years. This is too short compared with the time scales of biological and geological evolution on the Earth. Similar considerations apply to any other type of star.

Nuclear fusion

Thermonuclear reactions in stellar interiors are indeed the main source of energy (see STELLAR INTERIORS: THERMODYNAMICS). The fusion of light nuclei into more massive nuclei (for instance $4 \times {}^1\mathrm{H}$ into $1 \times {}^4\mathrm{He}$ in main sequence stars) provides the required amount of energy for a very long time. To get positively charged nuclei to fuse together despite their electrical repulsion, they must approach each other closer than about 10^{-13} cm, which is the range of the strongly attractive nuclear forces (roughly the nuclear radius R_N). This means that the positive Coulomb potential energy $V_\mathrm{cou} = Z_1 Z_2 e^2/r$ for $r \geq R_\mathrm{N}$ suddenly drops to large negative values for $r < R_\mathrm{N}$. At R_N V_cou is at a maximum and of the order of 1 MeV (peak of the so-called potential barrier). At the temperatures and densities of stellar interiors, the relative kinetic energy of random thermal motions is only $E_\mathrm{k} \simeq 10^3$ eV and therefore no reactions should occur. However, thanks to QUANTUM MECHANICS, even in this case there is a finite albeit small probability of barrier crossing and reactions take place. The energy liberated by each fusion event is

$$\Delta E = \Delta M c^2 \tag{7}$$

where ΔM is the mass difference between the combined mass of the original nuclei and that of the fused nucleus. In the case of four ${}^1\mathrm{H}$ fusing into one nucleus of ${}^4\mathrm{He}$, the ${}^4\mathrm{He}$ nucleus has a mass of $3.97 m_\mathrm{p}$ (m_p is the proton mass). Therefore an amount of mass equal to $0.03 m_\mathrm{p}$ has been converted into energy and liberated to form the compound nucleus. This energy amounts to 6.3×10^{18} erg (g of matter)$^{-1}$. Similarly, when three ${}^4\mathrm{He}$ fuse to form a nucleus of ${}^{12}\mathrm{C}$, the energy liberated per gram is about 0.61×10^{18} erg. Remarkably, H fusion liberates roughly 10 times more energy than He fusion. We will see that this corresponds to the observed fact that main sequence stars are about 10 times more numerous than all post-main sequence stars. Fusion of light nuclei into heavier ones liberates energy up to the synthesis of ${}^{56}\mathrm{Fe}$, which has the largest binding energy per nucleon $\Delta M\, c^2/A$ (A is the mass number). Above this, not only is the electrical repulsion between nuclei so strong that in practice no nucleus has enough energy to cross the barrier but also the binding energy starts decreasing. This means that energy must be supplied to nuclei from the thermal reservoir in order to make them fuse. This fact limits the maximum number of large-scale fusion steps that may occur inside a star. Each of these requires a minimum temperature (and density) to occur, which means a minimum mass of the star (or its inner core).

H burning

Fusion of ${}^1\mathrm{H}$ into ${}^4\mathrm{He}$ occurs through two channels called the PP chain and the CNO cycle. The PP chain in its simplest version is a sequence of reactions: first ${}^1\mathrm{H}({}^1\mathrm{H}, \mathrm{e}^+\nu){}^2\mathrm{H}$ where two protons react to form deuterium plus a positron and a neutrino, followed by ${}^2\mathrm{H}({}^1\mathrm{H}, \gamma){}^3\mathrm{He}$. The first two reactions must occur twice in order to produce two ${}^3\mathrm{He}$ nuclei. Finally, these fuse through ${}^3\mathrm{He}({}^3\mathrm{He}, 2\,{}^1\mathrm{H}){}^4\mathrm{He}$. In total, four protons are fused into one nucleus of ${}^4\mathrm{He}$. The initial reaction can occur at about 1×10^6 K, but the last one requires temperatures greater than about 10×10^6 K. The individual reactions are very slow and a very small fraction of nuclei have enough energy to overcome the electrical repulsion. Even so, in a star like the Sun every second 6×10^{14} g of H are converted into 5.96×10^{14} g of He and 4×10^{12} g of matter are transformed into energy. The CNO cycle proceeds through a different mechanism. The initial step is a nucleus of ${}^{12}\mathrm{C}$ reacting with a proton to give rise to a series of reactions whose net result is the transformation of $4 \times {}^1\mathrm{H} \rightarrow 1 \times {}^4\mathrm{He}$, leaving all other species unchanged. The CNO cycle requires significantly higher temperatures and it is much more sensitive to temperature than the PP chain. In the CNO cycle $\epsilon_\mathrm{CNO} \propto T^{20}$; in the PP chain $\epsilon_\mathrm{PP} \propto T^5$. Main sequence stars more massive than about $1.5 M_\odot$ generate their nuclear energy via the CNO cycle at temperatures larger than 17×10^6 K.

He burning

The next step is the non-simultaneous fusion of three ${}^4\mathrm{He}$ according to ${}^4\mathrm{He} + {}^4\mathrm{He} \rightarrow {}^8\mathrm{Be} + {}^4\mathrm{He} \rightarrow {}^{12}\mathrm{C} + \gamma$. It is accompanied by the reactions ${}^{12}\mathrm{C}({}^4\mathrm{He}, \gamma){}^{16}\mathrm{O}$ and ${}^{12}\mathrm{O}({}^4\mathrm{He}, \gamma){}^{20}\mathrm{Ne}$. He burning, called the 3α process, requires high temperatures ($T > 100 \times 10^6$ K) and takes place only after stars have exhausted the central H content and formed a central core of pure He. The threshold mass of the He core depends on the physical state of the gas. In the electron degenerate material of the central regions of low mass stars (up to about $2.2 M_\odot$) the minimum mass is about $0.5 M_\odot$, which immediately sets also a gross lower limit for a star to be able to ignite He in the core. All low mass stars in the range $0.5 < M/M_\odot \leq 2.2$ undergo explosive He ignition because core contraction proceeds to degeneracy before the ignition temperature is reached. Stars more massive than $2.2 M_\odot$ ignite helium without becoming electron degenerate and do it when the He core mass is only $\simeq 0.3 M_\odot$.

Later burnings stages

The following principles influence the occurrence of later burning stages beyond the 3α process. (i) Higher and higher threshold temperatures and densities are required; this implies that minimum values of the core mass must be reached by the stars. (ii) The amount of liberated energy decreases so that the duration of later burning stages becomes shorter and shorter. (iii) Nuclear burning can only proceed up to the formation of an iron core. (iv) With increasing core density the gas becomes more and

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

more electron degenerate. (v) Ignition of a nuclear burning stage in a degenerate gas is potentially explosive and may lead to complete disruption of the star. (vi) External causes (for instance mass loss by stellar wind) may prevent a star from reaching the required core mass for a certain burning stage to occur.

Following core He exhaustion, in stars more massive than about $10M_\odot$ carbon is ignited at temperatures of about 500×10^6 K. Two nuclei of ^{12}C are fused into a variety of heavy elements, for instance $^{12}C(^{12}C, \gamma)^{24}Mg$, or $^{12}C(^{12}C, n)^{23}Mg$, or $^{12}C(^{12}C, ^4He)^{20}Ne$ etc. After core C exhaustion, at temperatures of about 1×10^9 K, high-energy thermal photons begin to break up ^{20}Ne by the reaction $^{20}Ne(\gamma, ^4He)^{16}O$, followed by $^{20}Ne(^4He, \gamma)^{24}Mg$. The core of the star consists now mainly of ^{16}O and ^{24}Mg. When the temperature reaches 2×10^9 K, oxygen burning begins. Although it is schematically indicated by $^{16}O(^{16}O, ^4He)^{28}Si$, because the most important product is ^{28}Si, many other elements are generated such as Mg, S and P and copious γ, p, n and α particles are liberated. Finally, at temperatures of about 3×10^9 K, Si burning occurs through a complex network of nuclear reactions briefly indicated by $^{28}Si + ^{28}Si \rightarrow ^{56}Ni$. Although these advanced stages involve the same physics of thermonuclear reactions encountered in previous stages, they are characterized by photo-dissociation and radiative captures that transform the nuclear material into its most stable form. The process is started by $^{28}Si(\gamma, ^4He)^{24}Mg$. The liberated ^{4}He nuclei induce a long series of reactions such as $^{28}Si(^4He, \gamma)^{32}S$, $^{32}S(^4He, \gamma)^{36}Ar$, $^{36}Ar(^4He, \gamma)^{40}Ca$, ..., $^{52}Fe(^4He, \gamma)^{56}Ni$. The nuclear sequence is terminated with Si-burning and the formation of the most stable nuclei.

Lifetime of a nuclear phase

Let f_i be the mass fraction of the star in which the temperature is high enough to burn a certain nuclear fuel i (hydrogen, helium, carbon, etc), X_i the fractional mass abundance of it and E_i the energy released per gram of matter by the corresponding complex of nuclear reactions. The duration t_i of the phase is given by

$$t_i \simeq E_i \, f_i \, X_i \frac{M}{L}. \tag{8}$$

In the case of H burning, inserting $E_H = 6.0 \times 10^{18}$ erg g^{-1}, $f_H = 0.1$, $X_H = 0.7$ (typical values) and the mass and luminosity of the Sun we obtain $t_H \simeq 7$ Gyr. In the case of He burning for which $E_{He} = 0.6 \times 10^{18}$ erg g^{-1}, $f_{He} = 0.2$, $X_{He} \simeq 1$, and a star with the same mass and luminosity as those in the horizontal branch phase (see case F in table 2), we obtain $t_{He} \simeq 10^8$ yr.

Main sequence stars obey the mass–luminosity relationship $L \propto M^\alpha$ with $\alpha = 3.5$–4 (in reality a core mass–luminosity relationship applies to all evolutionary phases). Therefore, the nuclear lifetime of any evolutionary phase depends on the star mass or core mass. If we limit ourselves to the case of main sequence stars for which the lifetime is the longest, $f_H \simeq 0.1$ and $X_H = 0.7$ we obtain the approximate relation

$$t_H \simeq 10^{10} \left(\frac{M}{M_\odot} \right)^{-\alpha+1} \text{ yr}. \tag{9}$$

More precise H-burning lifetimes are given in table 1. They vary from a few million years for very massive stars ($100M_\odot$) to many hundreds of billions of years for stars of very low mass ($0.1M_\odot$). For stars like the Sun the H-burning lifetime is about 10 Gyr.

The energy production by nuclear sources is regulated by the stellar luminosity (and ultimately by the opacity of the material); therefore the whole history of a star can be viewed as a series of slow nuclear burning stages alternating with periods of fast gravitational contractions causing the increase in the central (mean) temperature to the threshold value for the next nuclear step to occur. As a consequence t_K and t_N are also the time scales over which a star changes its properties (L, T_e, etc).

Equation of state

To a high degree of precision, stellar interiors are in conditions of local thermodynamic equilibrium so that radiation is described by the Planck law, particles obey the appropriate law of statistical mechanics and the interaction between matter and radiation is governed by the Kirchhoff law.

The structure and evolution of a star are particularly sensitive to the equation of state governing the pressure P as a function of density ρ, temperature T and molecular weight μ of the particles. Matter in stellar interiors is composed of ions and/or nuclei (complete ionization) and electrons, immersed in a bath of photons. Each component contributes to the total pressure $P = P_r + P_i + P_e$.

The functional dependence $P(\rho, T, \mu)$ for each component depends on the quantum number density of particles with momentum p (an isotropic distribution of momenta is supposed). Quantum statistics predicts that fermions (protons, neutrons, electrons etc) and bosons (photons) have different number-momentum distributions $n(p)$. However, for all particles but photons, $n(p)$ reduces to the classical Maxwell–Boltzmann law when the mean inter-particle separation is much greater than the de Broglie wavelength $\lambda_B = h/p$ (h is the Planck constant). Therefore, there will be a certain density at which the quantum behavior shows up. This condition is known as the onset of degeneracy. Because of their small mass and hence long λ_B, electrons are the first particles to become degenerate. Protons, neutrons and nuclei in general reach degeneracy only at densities comparable with nuclear densities (10^{15} g cm^{-3}), which occurs only in very peculiar situations that are ignored here. In the case of photons, considered as relativistic, zero-mass particles, the quantum $n(p)$ must always be used. Based on these considerations, the equation of state for the various components is found by integrating over the corresponding functions $n(p)$. The results are as follows.

Table 1. Typical parameters of main sequence stars and core H-burning lifetimes.

$M/M_\odot$	$\log L/L_\odot$	$\log T_e$	$R/R_\odot$	T_c	ρ_c	M_c/M	M_e/M	Energy	t_H
30.0	5.11	4.60	6.6	37	3.3	0.61	0	CNO	5.7×10^6
15.0	4.29	4.49	4.7	33	5.8	0.49	0	CNO	1.2×10^7
9.0	3.60	4.37	3.5	31	9.9	0.41	0	CNO	3.0×10^7
5.0	2.76	4.23	2.3	27	20.9	0.32	0	CNO	1.1×10^8
3.0	1.91	4.09	1.7	24	40.3	0.25	0	CNO	3.7×10^8
2.0	1.25	3.36	1.4	21	65.7	0.19	0	CNO	1.1×10^9
1.0	−0.16	3.75	0.9	14	97.5	0	0.1	PP	9.7×10^9
0.5	−1.39	3.59	0.4	9	70.1	0	0.3	PP	8.7×10^{10}
0.3	−1.90	3.56	0.3	8	106.4	1	1.0	PP	1.7×10^{12}

The surface temperature T_e is in K; the central temperature T_c is units of 10^6 K; the central density ρ_c is in g/cm^3. The fractional masses M_c/M and M_e/M show the extension of the convective core and external convective envelope respectively. t_H is the lifetime in years of the core H-burning phase.

The photon pressure P_r depends only on the gas temperature:

$$P_r = \frac{1}{3}aT^4 \qquad \text{where} \quad a = \frac{8\pi^5 k^4}{15c^3h^3} = 7.564 \times 10^{-15} \text{ erg cm}^{-3} \text{ K}^{-4}. \tag{10}$$

There is no density dependence, because the number of photons is not conserved owing to continuous emission and absorption, a result already predicted by classical thermodynamics.

At ordinary low densities (no electron degeneracy) ions and electrons have the equation of state

$$P_g = P_i + P_e = \frac{k}{\mu_i m_p}\rho T + \frac{k}{\mu_e m_p}\rho T = \frac{k}{\mu m_p}\rho T \tag{11}$$

where k is the Boltzmann constant, m_p is the proton mass, and μ_i, μ_e, μ are the mean molecular weights of just ions, just electrons and the mixture of the two, respectively. The mean molecular weights of a fully ionized gas with abundance mass fractions X, Y and Z are

$$\mu_i = \frac{4}{4X+Y} \qquad \mu_e = \frac{2}{1+X} \qquad \mu = \frac{1}{2X + 0.75Y + 0.5Z}. \tag{12}$$

At increasing density (and decreasing temperature), electrons become degenerate. The equation of state is very complicated. It acquires a simple form only in the extreme cases of fully degenerate, non-relativistic electrons ($kT \ll m_e c^2$, thermal energy much smaller than the electron rest energy) and fully degenerate, relativistic electrons ($kT \gg m_e c^2$), for which we have

$$P_e = \frac{h^2}{20m_e}\left(\frac{3}{\pi}\right)^{2/3}\left(\frac{\rho}{\mu_e H}\right)^{5/3}$$

or

$$P_e = \frac{ch}{4}\left(\frac{3}{8\pi}\right)^{1/3}\left(\frac{\rho}{\mu_e H}\right)^{4/3}. \tag{13}$$

The first and second equations are for non-relativistic and relativistic electrons, respectively. The lower power of ρ in the latter expression is due to the electrons' velocities saturating at the speed of light c. In both cases the pressure of degenerate electrons does not depend on temperature but only on density.

Studying the equation of state in many stellar environments we learn that P_r is important in massive stars, and among main sequence stars electron degeneracy is important only in the low-mass ones. In more advanced evolutionary phases, electron degeneracy progressively becomes the dominant central source of pressure.

The lack of temperature dependence in the equation of state of fully degenerate electrons bears very much on stellar structure. If for any reason the temperature starts increasing, for instance by deposition of energy from nuclear reactions commencing in a degenerate gas, the equation of state does not provide a compensating expansion to quench the instability, and the temperature increases even further, thus making nuclear energy release even stronger. Thermal runaway soon occurs. In many circumstances a thermonuclear explosion occurs, tearing the star apart.

Energy transport

There are three mechanisms for the transport of heat inside a star: (i) the random thermal motion of individual electrons and/or ions that interacting with each other transport energy from hot to cold regions (thermal conduction); (ii) The continuous absorption, emission, scattering of photons with the same effect (radiative transfer). In both cases the link between flux of energy and temperature gradient is derived from the same principles. (iii) The third is the large-scale motions of fluid elements, in which rising blobs of hot, less dense gas and sinking blobs of cool, denser gas transfer energy from hot to cold regions of a star. This mechanism is called convection.

Radiative transfer

Based on simple dimensional arguments, the flux density of heat along the radial direction r due to propagation of photons with velocity c, frequency-averaged mean free path $\tilde{l}$ and heat capacity per unit volume $C = \mathrm{d}U/\mathrm{d}T =$

$4aT^3$, where U is the internal energy density aT^4, is given by

$$\frac{L_r}{4\pi r^2} = -\frac{1}{3}c\tilde{l}\frac{dU}{dT}\frac{dT}{dr} = -\frac{1}{3}c\tilde{l}4aT^3\frac{dT}{dr}$$

or

$$\left(\frac{dT}{dr}\right)_R = -\frac{3\rho\kappa}{4acT^3}\frac{L_r}{4\pi r^2} \qquad (14)$$

where the mean free path $\tilde{l}$ has been averaged over all frequencies of the black body spectrum to account for the frequency dependence of the absorption, emission and diffusion processes. In doing so, the frequency-averaged mean free path can be expressed in terms of the so-called Rosseland opacity $\kappa = 1/\rho\langle\tilde{l}\rangle$ and the fundamental equation for radiative transport is obtained.

The above equation can be interpreted in the following way: given a certain temperature gradient (and opacity κ) implied by the mass and pressure balance, the luminosity L_r is determined. The steeper the temperature gradient and the lower the opacity, the higher is the luminosity.

Convective transport

Can the radiative temperature gradient be arbitrarily steep? The answer is no, because when the gradient becomes steeper than the local adiabatic value, convection sets in and a different temperature gradient is built up. However, for the very outer layers in which a more complicated treatment is required, thanks to the high thermal capacity of convective elements in all but distended giant envelopes, the real temperature gradient is nearly identical to the adiabatic one and the following approximation holds:

$$\left(\frac{dT}{dr}\right)_C = \frac{\gamma - 1}{\gamma}\frac{T}{P}\frac{dP}{dr} \qquad (15)$$

where $\gamma = c_p/c_v$, i.e. the ratio of the specific heats at constant pressure and constant volume for the gas under consideration.

Where is convection?

Performing some algebraic manipulations, we may express the radiative gradient as $(d\ln T/d\ln P)_R \propto \kappa L_r P/M_r T^4$, where the luminosity–mass ratio L_r/M_r has been introduced. Neither $\kappa P/T^4$ nor L_r/M_r is constant throughout a star. It can be shown that the ratio $P/T^4 \propto P/p_r$ is nearly constant, whereas κ greatly varies throughout a star. In the outer layers κ is very large because of ionization, while L_r/M_r reaches a nearly constant value. Therefore we expect the external layers of a star to be often in convective conditions. In contrast, in the internal regions, while the opacity decreases to a minimum (electron scattering), the ratio L_r/M_r increases in a way that depends on the temperature sensitivity of the nuclear energy source. It follows that low-mass stars with $\epsilon_{PP} \propto T^5$ have radiative cores, whereas massive stars with $\epsilon_{CNO} \propto T^{20}$ have convective cores. Later burning stages (helium, carbon, etc) will always occur in convective conditions. Table 1 contains a few characteristic parameters for main sequence stars of different mass.

Central values

Useful analytic expressions for the central density, pressure and temperature of main sequence stars in which the equation of state is that of a perfect gas (no radiation pressure and no degeneracy) are

$$\rho_c = 1.4\frac{M}{R^3}\ \text{g cm}^{-3} \qquad P_c = 1.1\times10^{16}\frac{M^2}{R^4}\ \text{dyn cm}^{-2}$$

$$T_c = 2.3\times10^7\mu\frac{M}{R}\ \text{K} \qquad (16)$$

where mass and radius are in solar units. Along the main sequence, the density decreases and the temperature and pressure increase with the star's mass.

Sketching the evolution of solar-type stars

Stars in the mass range $(0.7–1.5)M_\odot$ are those we see today in old globular clusters and old open clusters and therefore they are of primary interest in interpreting the HR-diagram. Table 2 contains some data for the various phases we are going to describe below, limited to the case of low-mass stars such as the Sun. Representative post-main sequence paths in the HR-diagram are shown in the upper panel of figure 3. The paths illustrated are for low-metal stars with abundances more like those in globular clusters. In broad terms their evolution is similar to that of stars of solar-like compositions; in detail, they differ.

Protostars

STAR FORMATION is by far the most uncertain aspect of stellar theory. Based on observations, we know that stars form in dense, cold molecular clouds, in which various kinds of instability combine to trigger fragmentation and collapse of gas into small entities of stellar size (protostars). This stage is reached when trapping of energy by increasing opacity supplies pressure support against gravity and the condition of hydrostatic equilibrium is established. During this very short-lived phase the sole source of energy is gravitational contraction. The star is cool and red but very extended in radius (large luminosity). To avoid confusion with the later stages of evolution, neither this nor the next, pre-main sequence phase is illustrated in figure 3.

Pre-main-sequence

Once hydrostatic equilibrium is established, the contraction slows down but it continues until the central temperature is high enough to initiate nuclear burning. The star, fully convective, slides down the Hayashi line, i.e. the locus in the HR-diagram of fully convective objects in hydrostatic equilibrium. No star cooler than this limit can exist. On the Hayashi line and prior to main sequence stage, light elements such as ^{2}H, ^{7}Li, etc are all burned. T-TAURI STARS located at the right of the main sequence are associated with the pre-main sequence phase. Their phenomenology is quite complicated, because there is simultaneous infall of material onto the star (disk accretion) but also strong ejection of material in the form of winds (bi-polar flows). It takes another several million years before the star settles down on the main sequence where quiet H burning takes place.

A1, collapse; A2, protostar in hydrostatic equilibrium; B1, pre-MS (minimum luminosity on the Hayashi line); B2, pre-MS (maximum luminosity before the MS); C1, start of the MS phase; C2, end of the MS phase; D, post-MS (bottom RGB); E, tip of RGB and He flash; F, core He-Burning and HB (mid-stage); G, AGB phase; H, WD. Age in years, temperature in kelvins, density in g cm^{-3}, radius in solar units.

Main sequence

During this phase H burning produces enough energy to balance the luminosity (the star is said to be in thermal equilibrium). The nuclear production is a strong function of temperature (PP chain versus CNO cycle, the first one in the case of the Sun). Gravity is balanced by differential gas pressure (the ideal gas law in this case). The H content in the center decreases until it eventually reaches zero. Heat is carried out by radiative transport.

Post-main-sequence

When the H content becomes zero in a small central sphere, the tiny He core contracts and H burning begins in a shell surrounding the core. Gravitational contraction in the core makes it electron degenerate. The star leaves the main sequence and moves toward low T_e at nearly constant L. This phase corresponds to the sub-giant branch in the HR-diagram. The external convection penetrates very deeply into the star. The energy generated by the H-burning shell and the increased opacity force the star to expand to large radii and once the Hayashi line is reached to climb along it at nearly constant T_e but increasing luminosity. The star is in the red giant branch phase.

Red giant branch and He flash

The outward migration of the H-burning shell makes the He core grow in mass and it slowly increases temperature until the threshold limit for He burning is reached. Since the core is electron degenerate, (i) this occurs when the core has acquired a certain value of the mass and (ii) He ignition is explosive but does not disrupt the star (He flash). Core degeneracy is removed and the star begins to burn helium relatively quietly in a convective core. The mass of the He core at the He ignition stage is nearly independent of the initial mass and chemical composition of the star. The He core mass at the He flash stage is $M_{\rm Hefl} \simeq 0.5M_\odot$.

Core He burning and horizontal branch

During the brightest stages along the red giant branch mass loss by stellar wind occurs; this removes part of the envelope's mass. According to current estimates of the efficiency of mass loss and theoretical lifetimes during the brightest stages of the red giant branch, little mass is lost by stars more massive than about $1M_\odot$, whereas about 20% of the mass is lost by stars of about $0.8M_\odot$. While burning helium in the core, the star settles on the horizontal branch. The luminosity is now much lower than that at the tip of the red giant branch and T_e is higher than the corresponding value on the Hayashi line. The range in T_e covered by HORIZONTAL BRANCH STARS depends on the amount of mass ($\Delta M_{\rm RGB}$) lost at the tip of the red giant branch and several structural details that cannot be described here. Suffice it to recall that at given $\Delta M_{\rm RGB}$ and initial mass, T_e of horizontal branch models is higher for decreasing metallicity and increasing age. Since core H ignition occurs in He cores of nearly the same mass, the horizontal branch luminosity is nearly constant and the duration of central He burning is also nearly constant (a few 10^8 yr).

Asymptotic giant branch phase and planetary nebula ejection

When helium is exhausted, the C–O core contracts again and becomes strongly electron degenerate. In order to ignite carbon in such conditions, the core mass has to grow to about $1.4M_\odot$, which is not possible because the total mass of these stars is smaller than this. The star continues to evolve thanks to the He- and H-burning shells that force it to expand and to settle again on the Hayashi line along which it moves, with the luminosity increasing and mass being lost by the stellar wind. The novelty with this phase is that the He-burning shell is thermally unstable due to the high temperature dependence of the 3α reactions and its very small thickness (the so-called Schwarzschild-Harm instability). The He shell goes through a series of paroxysmal activity alternated with periods of quiescence, which causes periodic expansions and contractions of the overlying envelope. This likely enhances the efficiency of stellar winds till the whole envelope is lost. In total an additional 10% of the star mass is stripped away, revealing the hot inner regions with temperatures in excess of about 10^5 K. The overall duration of the asymptotic giant branch

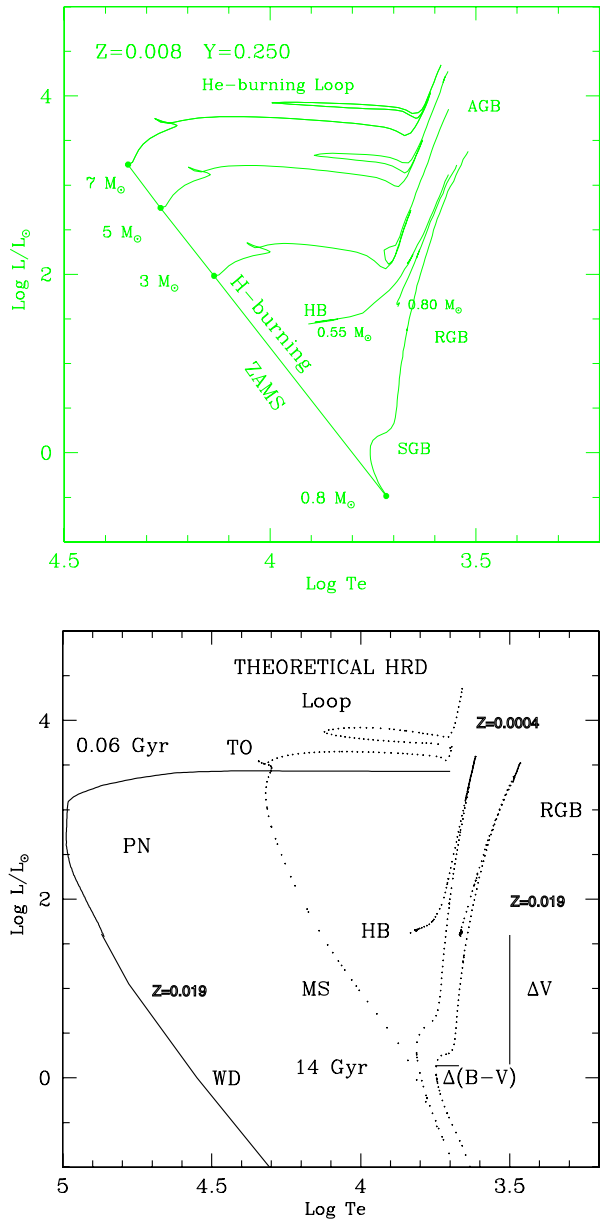

Figure 3. Upper panel: evolutionary tracks of different mass. The composition is $Y = 0.250$ and $Z = 0.008$. Lower panel: Isochrones of different age and metallicity Z as indicated. Note that a large range of T_e is covered in this panel.

phase is only a few 10^6 years. The newly expelled gas illuminated by the very hot central objects interacts with the surrounding material lost in previous stages. This is the origin of the so-called PLANETARY NEBULAE (PN), which takes about 10^4 years to disperse into the interstellar medium.

White dwarfs

As the planetary nebula disperses, the He- and H-burning shells surrounding the inert C–O core are extinguished, leaving a WHITE DWARF. This remnant is supported by electron degeneracy. Gravitational contraction is almost ineffective as a source of heat and therefore no nuclear fuel (C and/or O) can be ignited. The internal temperature is a few 10^8 K. The radius of the star is small, only a few thousand km (the radius of the Earth). The luminosity rapidly decreases to small values. The source of energy is mainly the thermal energy stored in the ions (the kinetic energy of degenerate electrons cannot be tapped). After an initial phase of rapid cooling, the white dwarf will take a long time to radiate stored energy away. As a consequence of the strong degeneracy, the white dwarf has a fixed radius determined by its mass. Decreasing its luminosity by losing energy, the white dwarf will move towards lower T_e, sliding down its line of constant radius (see the lower panel of figure 3.

A counterintuitive rule

In general, exhaustion of central fuel tends to make a star brighter and cooler (shift in the HR-diagram to the right and upward), whereas ignition of a new central fuel tends to make it fainter and hotter (shift in the HR-diagram to the left and downward).

What about other stars?

We deliberately omit here objects with masses comparable with those of giant planets ($M < 0.01M_\odot$) and brown dwarfs ($0.01M_\odot < M < 0.08M_\odot$) that never become hot enough in their cores to ignite the PP chain. In contrast, stars more massive than $0.08M_\odot$ all ignite core H burning on the main sequence.

$0.08M_\odot \leq M \leq 0.5M_\odot$

These stars are very long lived, lasting several hundred billions of years. Those with mass $\leq 0.3\,M_\odot$ are also fully convective. In any case they will never become hot enough to ignite helium in the core. If no other cause intervenes they will become helium white dwarfs.

$0.5M_\odot \leq M \leq 2.2M_\odot$

Their evolution is that thoroughly described in the previous section so that no other details are given here, but for mentioning the transition from PP chain to CNO cycle, which occurs at about $1.3M_\odot$ and is accompanied by the transition from radiative to convective core H burning.

$2.2M_\odot \leq M \leq 8M_\odot$

The major novelty here is that central He ignition takes place in a non-degenerate core. Therefore, there is no red giant branch to climb and no He flash. After core H exhaustion the stars go back to the Hayashi line, ignite He burning in the core, spend some time there and then go back towards high T_e (going around a loop) to settle on the core He-burning band. This is nearly parallel to but brighter and cooler than the MS band (see the isochrone of 0.06 Gyr, whose turn-off mass is about $7M_\odot$, shown in the lower panel of figure 3). Following exhaustion of central helium, the stars, now made of a C–O core surrounded

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

by He- and H-burning shells, expand once more to the Hayashi line, experiencing the asymptotic giant branch phase on the way. Stars with mass up to about $6M_\odot$ will become C–O white dwarfs after the planetary nebula phase. Stars more massive than $6M_\odot$ may reach the stage of C ignition in the extremely degenerate C–O core while in the asymptotic giant branch phase. The consequent thermonuclear runaway will disrupt the whole star in a SUPERNOVA EXPLOSION. No remnant is left.

$8\,M_\odot \leq M \leq 100M_\odot$

This is the range of massive stars that are able to proceed through the whole series of nuclear burning stages up to the formation of the iron core. While the evolution of their cores is relatively straightforward, the path in the HR-diagram is more uncertain because these stars are heavily affected by mass loss by stellar wind. In brief, stars less massive than about (30–40)$M_\odot$ evolve in the HR-diagram in a way quite similar to that of stars of lower mass ($\simeq 7M_\odot$) as described in the previous section. These stars should eventually explode as type II supernovae while shining as red super-giants. The situation is uncertain for more massive objects for which all evolutionary phases seem to occur at high T_e, the whole H-rich envelope being lost by mass loss. They probably explode as another type of supernova. In any case the final fate of all massive stars is core collapse triggered by photodissociation of iron, electron capture and neutronization of matter in the central core. The core collapse induces a supernova explosion which leaves a compact remnant: either a NEUTRON STAR of $1.4M_\odot$ or a BLACK HOLE of larger mass depending on details of the collapsing core's physical structure.

Tracks or isochrones?

In cluster HR-diagrams, stars lie on isochrones (loci of constant age but varying mass). How large is the mass range $\Delta M_{\rm iso}$ spanned by stars in all post-main sequence phases of an isochrone or, equivalently, how much does an isochrone depart from the evolutionary sequence with the turn-off mass $M_{\rm TO}$? The answer lies in relation (8) and the short duration of all post-main squence phases, a time of the order of $0.1t_{\rm H}$ or so. Therefore, for any practical purpose the total lifetime can be approximated by $t = t_{\rm H} + t_{\rm He} = (1 + 0.1)t_{\rm H}$. Differentiating this relation and performing a little algebra, we obtain the approximate relation (to be used only for illustrative purposes)

$$\Delta M_{\rm iso} \simeq 0.045 M_{\rm TO}. \tag{17}$$

Except for massive stars, say above $10M_\odot$ (where $\Delta M_{\rm iso}$ is significant), this mass spread is small. Therefore, over ample ranges of $M_{\rm TO}$ and hence ages, isochrones are almost identical to the evolutionary track of the star just leaving the main sequence: compare the upper and lower panels of figure 3. In any case, accurate age determinations are ultimately possible only by using detailed isochrones.

Interpreting the HR-diagram of star clusters with single stellar populations

STAR CLUSTERS are assemblies of stars for which one can reasonably assume the same initial composition $[X, Y, Z]$, same age (within a narrow range), same distance and finally the same initial mass function (IMF). Therefore, they constitute useful examples of a single STELLAR POPULATION whose properties bear very much on understanding the HR-diagram of any type of stellar population from clusters to galaxies, the latter conceived as convolutions of many single stellar populations.

Single stellar populations are governed by the so-called fuel consumption theorem: the contribution of stars in any post-main sequence phase to the integrated luminosity of a single stellar population is directly proportional to the amount of fuel burnt during that stage. In other words the fuel consumption theorem explains how and why stars distribute themselves along a given isochrone with number frequencies that vary with the position (evolutionary phase). In other words it explains why clusters of different age and chemical composition have different HR-diagrams.

The turn-off mass $M_{\rm TO}$ of a single stellar population with age t is defined as the mass of the star at the stage of central H exhaustion. Stars with mass $M_i < M_{\rm TO}$ are still on the main sequence, whereas those with $M_i > M_{\rm TO}$ are in later evolutionary stages. In other words, the turn-off is the stage at which stars leave the main sequence, venture towards later stages and eventually die. The rate at which this occurs is given by

$$b(t) = \Phi(M_{\rm TO})|\dot{M}_{\rm TO}| \text{ stars yr}^{-1} \tag{18}$$

where $\Phi(M_i) = AM_i^{-1+x}$ is the IMF and $\dot{M}_{\rm TO}$ is rate at which the turn-off mass decreases at increasing age. Therefore, $b(t)$ is the evolutionary flux of the single stellar population and does not depend on the particular evolutionary stage. It is the speed at which stars enter and leave any evolutionary phase. In other words, the number of stars N_j in the jth post-main sequence phase is

$$N_j = b(t)t_j \tag{19}$$

where t_j is the lifetime of the phase.

The integrated bolometric luminosity $L_{\rm T}$ can be separated into the contribution from main sequence stars and from all the others:

$$L_{\rm T} = \sum_i^{\rm MS} L_i + \sum_j^{\rm PMS} N_j \langle L \rangle_j \tag{20}$$

where L_i is the luminosity of single MS stars and $\langle L \rangle_j$ is the mean luminosity of the post-main sequence jth phase. Denoting by M_i the lower mass limit of the IMF, and using the mass–luminosity relation $L(M) = \beta M^\alpha$, the contribution from main sequence stars becomes

$$\sum_i^{\rm MS} L_i = \int_{M_i}^{M_{\rm TO}} L(M)\Phi(M)\,{\rm d}M \sim \frac{A\beta}{\alpha - x}(M_{\rm TO}^{\alpha-x} - M_i^{\alpha-x})$$

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

$$\sim \frac{A\beta}{\alpha - x} M_{\rm TO}^{\alpha - x} \tag{21}$$

and that of post-main sequence stars

$$L_{\rm PMS} = \sum_{j}^{\rm PMS} b(t) t_j \langle L \rangle_j = b(t) \sum_{j}^{\rm PMS} F_j \tag{22}$$

where $F_j = t_j \langle L \rangle_j$ is the nuclear consumption during phase j, after which the theorem is named. $F_j = m_j^{\rm H} + 0.1 m_j^{\rm He}$ where $m_j^{\rm H}$ and $m_j^{\rm He}$ are the amounts of hydrogen and helium burnt (in solar units). It follows from the above equations that the contribution to $L_{\rm T}$ by post-main sequence stars increases with the number of stars in the phase and its duration.

Given a cluster with age t, total bolometric luminosity $L_{\rm T}(t)$ (in solar units) and total number of stars $N_{\rm T}$, the theory of single stellar populations predicts–explains the number of stars expected–observed in each post-main sequence evolutionary phase. Indeed relation (17) can be rewritten as

$$N_j = \frac{b(t)}{L_{\rm T}(t)} L_{\rm T}(t)\, t_j = B(t) L_{\rm T}(t) t_j. \tag{23}$$

It can be shown that $B(t)$ is nearly independent of the IMF and constant over a large range of ages. It goes from 5×10^{-10} to 2×10^{-11} for ages lying between 10^7 and 10^{10} yr. To fully appreciate the potential of this result let us consider the asymptotic giant branch stars, for which theory predicts a lifetime of a few 10^6 yr (say 5×10^6 yr in round numbers). It follows that $N_j \simeq 10 \times 10^{-5} L_{\rm T}(t)$, which means that 10 asymptotic giant branch stars are expected in a cluster with $L_{\rm T} = 10^5\, L_\odot$, in agreement with real clusters. If the total luminosity is a factor of 10 less, almost no asymptotic giant branch stars are expected to be seen. The asymptotic giant branch phase is still there, but the corresponding stars could be easily missed for statistical reasons.

Age of star clusters

Globular clusters

Determining the age of globular clusters is a complex game which requires a knowledge of many parameters, such as the helium content Y, metallicity [M/H], CNO abundance [CNO/H], distance modulus and reddening.

Abundance of helium

Direct spectroscopic measurements of helium abundance are not possible because the stars of globular clusters are too cool. The abundance is derived from several indirect methods which yield the value $Y = 0.235 \pm 0.005$.

Metallicity

By this quantity one usually refers solely to the iron content expressed in the standard notation $[{\rm Fe/H}] = \log(N_{\rm Fe}/N_{\rm H}) - \log[(N_{\rm Fe}/N_{\rm H})_\odot]$, where N_x denotes the number density of atoms of any species. The majority of globular clusters have [Fe/H] ranging from -1.0 to -2.3 dex with a typical uncertainty of 0.15 dex. The observation of HR-diagrams showing sequences of virtually undetectable width indicates a uniform abundance of heavy elements within the stars of a particular cluster.

Abundances of α-elements

An important question that has arisen in recent years is whether the abundances of elements such as C, N, O, Mg with respect to Fe have always been like those observed in the Sun, i.e. $[{\rm X}_i/{\rm Fe}] = 0$ in the standard notation, or whether instead they had supersolar values $[{\rm X}_i/{\rm Fe}] > 0$ for $[{\rm Fe/H}] \leq -1$. Current observations yield $[{\rm X}_i/{\rm Fe}]$ from 0.3 to 1.0 for low metallicities. The overabundance is different for different elements. We will refer to it as the [C,N, O, Mg/Fe] versus [Fe/H] relation.

Reddening

Since there are many globular clusters with low color excess ($E_{B-V} \leq 0.1$) spanning a broad range of metallicities (up to $[{\rm Fe/H}] = -1$), reddening is not a serious problem in finding the intrinsic color of the turn-off.

Distances

The distance scale of globular clusters is perhaps the topic of major controversy. There are three ways to derive globular cluster distances.

(1) *Subdwarfs*. The nearby subdwarfs (metal-poor stars with halo kinematics located on a sequence parallel to but fainter than the main sequence) close enough to have measurable parallaxes allow us (i) to derive absolute M_V so that accurate testing of theoretical zero-age main sequences at varying [Fe/H] in the low-metallicity regime is possible; and (ii) to tie the relative cluster distances to the local distance scale, under the assumption that these stars are similar to unevolved stars in globular clusters.

(2) *RR Lyrae.* Modern determinations of the distance modulus reduce to comparing the apparent magnitudes of the RR LYRAE STARS or equivalently horizontal branch stars with the corresponding absolute visual magnitudes. There are several independent methods to obtain the absolute visual magnitudes of RR Lyrae stars, M_V(RR), which ultimately lead one to assess whether or not a correlation between M_V(RR) and [Fe/H] exists and try to fix the slope and zero point of this relation. The zero point is of critical importance for determining the age of the oldest clusters, whereas the slope $\Delta M_V({\rm RR})/\Delta[{\rm Fe/H}]$ bears very much on the age–metallicity relation, i.e. whether or not the age of globular clusters becomes younger at increasing [Fe/H].

(3) *White dwarfs.* This method rests on fitting the theoretical white dwarf-cooling sequences to the observational position of white dwarfs in the HR-diagram.

The second parameter

The HR-diagram of globular clusters can be ranked as a function of the metallicity [Fe/H]. Generally, metal-rich globular clusters have cool RGBs and red horizontal branches, while the opposite is true in metal-poor globular

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

clusters, in which very extended, blue horizontal branches are observed. This rule is, however, broken by a number of globular clusters whose metallicities are identical (as far as we can tell) but whose horizontal branches are different. As a matter of fact, we have metal-poor globular clusters with red horizontal branches. This opens the gate to the so-called second parameter problem: in addition to metallicity another important parameter helps to determine the morphology of HR-diagrams. Several second parameters have been suggested, among which are the helium content, the [C, N, O, Mg/Fe] versus [Fe/H] relation, the age or finally a subtle combination of all of them.

Methods for determining the age

An essential prerequisite is that HR-diagrams of extremely good photometric quality with precision down to a tenth of a magnitude are available. If so, ages can be derived from the following.

(1) In the isochrone fitting method all the above ingredients are simultaneously necessary. These ages are therefore subject to the highest uncertainty.

(2) The ΔV method rests on the fact that the turn-off magnitude becomes fainter as a cluster ages, while the horizontal branch luminosity is virtually constant. ΔV is the magnitude difference between the turn-off and the horizontal branch at the turn-off color. The method is independent of reddening and to some extent of distance, but it requires an assumption for the helium abundance. The disadvantage is that not all globular clusters possess RR Lyrae stars, and some horizontal branches are not horizontal. Furthermore, the turn-off is often almost vertical, thus making the identification of the turn-off magnitude very uncertain. Finally, there is the effect of the controversial relations $M_V(\mathrm{RR}) - [\mathrm{Fe/H}]$ and $[\mathrm{C, N, O, Mg/Fe}] - [\mathrm{Fe/H}]$.

(3) The $\Delta(B - V)$ method is based on the color difference between the turn-off and the base of the red giant branch. This color difference decreases as the cluster age increases. Within a certain approximation, the method is independent of distance, reddening, photometric zero point, helium abundance and, to first order, variations in [Fe/H]. Among others, the major uncertainties are with the transformations from T_e to colors, and the [C, N, O, . . . /Fe] ratios, all these affecting the turn-off color.

Ages, age spread, and age–metallicity relation

The absolute ages, the age spread at given metallicity and the mean age–metallicity relation of globular clusters are significant for COSMOLOGY and GALAXY FORMATION. The oldest globular clusters set a firm lower limit on the age of the universe, the age spread and age-metallicity relation constraining the time scale and mechanism of halo formation. Because of this, an impressive body of literature exists on the age subject. Since even a short summary of the vivid debate is not possible here, we limit ourselves to stating that over the years the following alternative scenarios have emerged.

(1) The age of globular clusters peaks at about 16 ($\pm$2) Gyr, with wings going down to 10 Gyr and up to 20 Gyr. The spread in age is large, and the most metal-rich globular clusters are also the youngest objects. It follows that the age is the second parameter and halo formation occurred on a long time scale.

(2) Globular clusters are younger than above. Only the most metal-poor globular clusters (presumably the oldest objects) may have ages near 15 Gyr, and, finally, ages below 12 Gyr and above 20 Gyr appear to be unlikely. Furthermore, there is no substantial body of evidence that the age is the dominant second parameter nor for a significant spread in age among clusters of given metallicity.

(3) Globular clusters are even younger. Their age is about 12$\pm$2 Gyr. This result is ascribed to improvements in the equation of state and other details of the input physics that cannot be discussed here.

(4) Remarkably, most of the ages for globular clusters estimated before the Hipparcos mission fell in the range 14–18 Gyr (with exceptions), whereas most of those after Hipparcos are in the range 10–14 Gyr. The age spread and mean age–metallicity relation are still debated.

(5) Going deeper into the reason for the discordant results, this can always be reduced to knowing the distances of globular clusters. Most of the uncertainty stems from a difference in distance modulus of $\simeq$0.25 mag, which is the typical uncertainty with which the magnitudes of horizontal branch, turn-off, main sequence and white dwarf stars are known (from both theory and observations). Amazingly, an uncertainty of about 0.05 mag would immediately imply an uncertainty of $\simeq$1 Gyr. Although we cannot firmly choose between 10–14 and 14–18 Gyr, the first option is certainly to be preferred.

Old open clusters

Old open clusters, whose ages range from say 1 to 7–8 Gyr, trace most of the history of the Galactic disk. Therefore, the correct ranking as a function of age, chemical composition and kinematic properties, is of paramount importance for understanding the process of star formation in the Galactic disk. Furthermore, old open clusters have turn-off masses between $1M_\odot$ and $2M_\odot$. Therefore, they probe the stellar structure in that mass range, in which during the main sequence phase the transitions from radiative to convective cores, i.e. from PP chain to CNO cycle, occur. Later they see the transition from bright red giant branches as in M67 to much less evident red giant branches as in the Hyades. The techniques used to interpret the HR-diagrams of open clusters are similar to those of GCs. However, the much smaller number of stars present in each open cluster and their sparse spatial distribution make the identification of the main sequence, red giant branch, He-burning band—here called the red clump to distinguish it from the classical horizontal branches—much more difficult. The small total number of stars and the fuel consumption theorem cause the red giant branch, red clump, and asymptotic giant branch to be populated by

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

only by a handful of stars (if any at all). The contamination by foreground objects blurs the main sequence and turn-off. In reality the whole HR-diagram is often immersed in a bath of contaminating stars. Despite these uncertainties, ages and the age–metallicity relation are derived. The ages go from 0.9 Gyr for NGC 2477 to 8 Gyr for NGC 6791. As far as the age–metallicity relation is concerned, it runs at nearly constant metallicity close to the solar value.

Young, rich clusters of the Magellanic Clouds
Young clusters with physical properties (luminosity, total mass, shape, etc...) comparable with those of globular clusters are no longer formed in our own Galaxy so that testing the theory of STELLAR EVOLUTION with the same accuracy as for globular clusters is not feasible. In the Milky Way, young clusters such as the Hyades, h+χ Persei and many young associations contain so few stars that only the main sequence is visible. One is forced to combine HR-diagrams for a chosen age class, but spurious inhomogeneities due to different chemical composition are easily introduced. Luckily, the MAGELLANIC CLOUDS (satellites of the Milky Way) are rich in objects of this type. Because of the large number of stars contained in these clusters, it is possible to make meaningful comparisons even for the shortest-lived evolutionary phases. The classical workbench for this kind of study is the cluster NGC 1866 in the LMC. This cluster, whose total mass is estimated to be in the range (3.6–5) $\times$ $10^5 M_\odot$, is well populated throughout the various evolutionary phases, exhibits an extended loop of giant stars and is rich in Cepheids, for which membership is less of a problem. The classical estimates of the turn-off mass and age of NGC 1866 are $5M_\odot$ and 70 $\times$ 10^6 yr, respectively. The existence of Cepheids among the other giant stars of the cluster allows us to check the mutual consistency between properties derived from stellar models and pulsational theory. Corresponding attempts in our own galaxy have always been hampered by the uncertainty in the cluster membership of the Cepheid stars (always the distance problem).

Star formation history of galaxies from their HR-diagrams

Figure 4 shows two HR-diagrams for field stars in different astrophysical environments: (i) the Galactic bulge (upper panel), and (ii) an external galaxy (lower panel). Although they seem to greatly differ from each other, they share many points in common. In HR-diagrams such as these, the interpretation by means of single stellar populations we have used for single clusters, no matter whether old or young, no longer applies. Indeed, these HR-diagrams are the results of many stellar populations spanning ample ranges of ages, chemical compositions and distances, suffering different amounts of extinction and reddening, and maybe having different IMFs. Finally, we remind the reader that owing to the complex nature of these HR-diagrams, in addition to the key parameters characterizing the stellar populations, the number density of stars in each

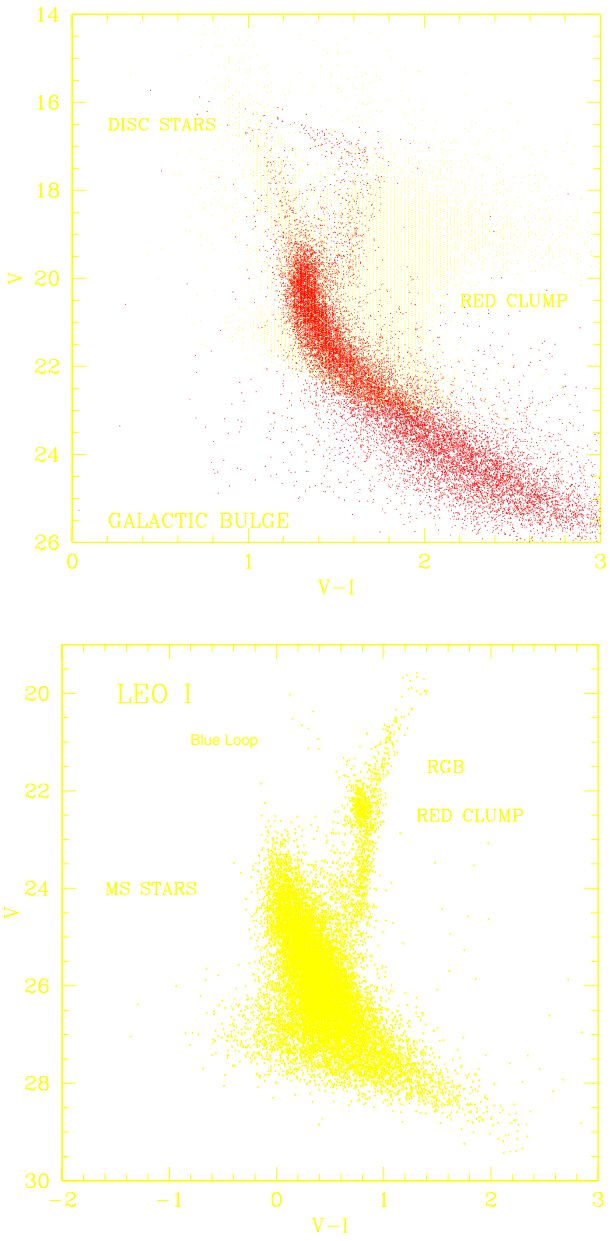

Figure 4. Upper panel: the HR-diagram toward the Galactic center as observed through one of the Baade windows. The dark areas are HST data, whereas the gray areas are ground-based data. Lower panel: the HR-diagram of the dwarf spheroidal galaxy Leo I in the Local Group.

subarea is related to the past history of star formation and structural properties of the host galaxy. Because of this, much interest has recently been given to deciphering the past star formation and chemical enrichment and structure of the population generating such complex HR-diagrams. Various sophisticated techniques aimed at unraveling the parameters in question have been designed. In the following we will briefly analyze the two HR-diagrams

shown.

Galactic bulge

This is the HR-diagram of stars observed towards the Galactic center through one of the Baade windows. In this HR-diagram there are stars coming from different regions along the line of sight: the stars in the bulge itself (the intrinsic depth and extinction of the bulge combine to blur their magnitudes and colors) and the stars belonging to different zones of the disk, each of these at a different distance, affected by a different degree of extinction and containing a different total mass in stars. The only easy thing to say is that main sequence stars of the disk are responsible for the blue plume along the main sequence band, whereas disentangling all the others requires an iterative comparison between simulations of the HR-diagram based on a model mass distribution, star formation rate, and chemical enrichment in both the bulge and the disk, the extinction law along the line of sight and the observed HR-diagram. Neglecting all details of the techniques used, the study of a number of such HR-diagrams has led to the following provisional picture about the various components.

(i) A two-component system (disk and spheroid) is sufficient, with no compelling evidence for the so-called thick disc.

(ii) The majority of stars belong to the disk. They are rather metal rich ($0.008 \leq Z \leq 0.02$) and relatively old (7–4.5 Gyr). The star formation rate exponentially declined with a time scale of about 2.5 Gyr. The Disc has a mass distribution with vertical scale height $z = 230$–250 pc and radial exponential profile with scale length $h_0 = 3.5$–4.5 kpc.

(iii) There is another much younger and thinner component ($z_0 = 100$ pc; $h_0 = 4.5$ kpc) with $Z = 0.015$–0.020, age from 5.0 to 2.0 Gyr and constant star formation rate.

(iv) The spheroid seems to contain two populations: a very old, metal-poor halo component ($Z = 0.0004$–0.005), age of 16–10 Gyr), with a star formation rate exponentially decreasing over a time scale of about 3.0 Gyr, and a younger metal-rich bulge component with $Z = 0.005$–0.02, an age of 10–5.0 Gyr and star formation rate exponentially decreasing with time scale of 2.5 Gyr.

(v) Ratios of the components are halo: intermediate disk = 1:1, bulge: intermediate disk = 7:9, young disk:intermediate disc = 1:10.

(vi) There seems to be a sharp increase in the number star density, a sort of stellar ring, centered at about 3.5 kpc from the galactic center with $\sigma = 0.5$ kpc.

(vii)The mass distributions along three lines toward the bulge are not the same. Does this suggest that the bulge has a bar?

(viii) Finally, the bulge, in addition to the main component of old stars, also seems to contain younger stars (age of about 8–9 Gyr and $Z = 0.005$–0.03), perhaps associated with formation of the bar.

External galaxy: Leo I

This is the HR-diagram of the LOCAL GROUP dwarf spheroidal (dSph) galaxy Leo I. In this case the distance and extinction are less of a problem as they are the same for all stars. Details of the galaxy's structure are not considered here, because the data refer to the galaxy as a whole. Leo I is a metal-poor galaxy (estimated [Fe/H] $= -2$) at a distance of about 300 kpc. Its HR-diagram shows very broad main sequence–turn-off and subgiant regions with no evidence of discontinuities, a compact broad red clump, a large red giant branch, an inconspicuous horizontal branch if any at all and a V-shaped structure above the red clump. The majority of stars in the red arm of the V-shaped structure are red giant branch objects (low mass) with a smaller fraction made of more massive core He-burning objects in the red stages of the loop. The blue arm is stars of the same evolutionary phase but on the blue side of the loop. All these features together suggest that star formation in Leo I extended from 10–15 Gyr ago to less than 1 Gyr ago and proceeded in a rather smooth fashion. The lack of a prominent horizontal branch and the low metallicity suggest that very little star formation took place earlier than $\simeq$10 Gyr ago.

Field stars have been studied in other galaxies of the Local Group going from the Magellanic Clouds, M31 and M32 to many dwarf irregulars (dIrr) and dSph, and their star formation and chemical enrichment histories have been derived. Several interesting preliminary conclusions are possible. (i) No two galaxies of the Local Group have the same star formation history. (ii) The LMC and SMC had dominant episodes of star formation starting only several Gyr ago. An old component is, however, present. (iii) Many dIrr have old populations (NGC 6822). (iv) No galaxy is composed exclusively of stars older than 10 Gyr. (v) Some galaxies have only a small fraction of stars older than 10 Gyr (Leo I). (vi) Some galaxies had nearly constant star formation rate up to the recent past followed by strong activity (Sextans A). (vii) Others had recurrent episodes of varying intensity separated by periods of quiescence (Carina). (viii) The second parameter problem is common throughout the Local Group. Many low-metallicity galaxies have red horizontal branches. This suggests that their oldest stars are indeed younger than the oldest globular clusters.

> Motion in the HR-diagram is the outward and visible sign of an inward nuclear turmoil

Herzberg Institute of Astrophysics

The Herzberg Institute of Astrophysics (HIA) is the Institute within the NATIONAL RESEARCH COUNCIL of Canada responsible for providing astronomical facilities, and developing related instrumentation and software for Canadian researchers. The Institute was established in 1975, and now operates 1.8 m and 1.2 m optical telescopes at the DOMINION ASTROPHYSICAL OBSERVATORY close to Victoria, BC, as well as a 26 m radio telescope, a seven-antenna synthesis telescope and two telescopes dedicated to monitoring the solar radio flux at the DOMINION RADIO ASTROPHYSICAL OBSERVATORY near Penticton, BC. HIA also supports NRC's international partnerships in the 3.6 m optical infrared CANADA–FRANCE–HAWAII TELESCOPE and the 15 m submillimeter JAMES CLERK MAXWELL TELESCOPE on Mauna Kea, Hawaii, and the Gemini twin 8 m optical infrared telescopes on Mauna Kea and on Cerro Pachon in Chile. The Institute has about 100 staff.

Herzberg, Gerhard (1904–)

Molecular spectroscopist, born in Hamburg, Germany, winner of the Nobel prize for chemistry (1971) 'for his contributions to the knowledge of electronic structure and geometry of molecules, particularly free radicals', specifically methylene, a molecule having a carbon with a hydrogen on either side, since identified in nebulae and other interstellar objects. Herzberg's first application for a job as an astronomer, to Germany's Hamburg Observatory, was turned down with the advice that 'there is no point in thinking of a career in astronomy unless one has private means of support', and he turned to engineering, and atomic and molecular physics. At Göttingen, Herzberg worked under Max Born and James Franck, and at Bristol, on the quantum mechanics of molecules, work that he continued in Darmstadt. In 1934, he was dismissed from his job there because his wife was Jewish, and emigrated to Saskatoon in Canada. After a brief period at the University of Chicago and the Yerkes Observatory, he returned to Canada to establish a laboratory for fundamental research in spectroscopy, now known as the Herzberg Institute. He identified the water in Comet Kohoutek, and in 1980 discovered triatomic hydrogen.

Hesiod (eighth century BC)

Greek epic poet who described his cosmology in *Theogeny*, the birth of the gods, which he derived from Babylonian mythology. In his family tree of the gods, Chaos (the yawning gap between Earth and Heaven) produced Erebus (the Abyss) and Night, who produced Ether and Day. At the same time, Earth produced the Heavens, Mountains, and Sea. The Heavens and Earth then produced Cronos. This family tree was mimicked by his structural model of the universe, divided into Heaven, Ether, Chaos, Earth, Erebus, Tartarus and surrounded by the Ocean. The cosmology is completely pre-scientific but Hesiod's is the earliest surviving reference to the Pleiades.

Hess, Harry Hammond (1906–69)

Geophysicist, born in New York City, professor of geology at Princeton, led Project Mohole, the first expedition to drill through the Earth's oceanic crust to the mantle beneath, theorized that spreading of mid-ocean ridges was the source of new mantle-derived continental material. Also a lunar geologist.

Hess, Victor Franz (1883–1964)

Physicist, born in Waldstein Castle, near Peggau in Steiermark, Austria, Nobel prizewinner in physics (1936, shared with CARL ANDERSON) 'for his discovery of cosmic radiation'. In a distinguished career in atomic, nuclear and atmospheric physics, Hess held positions in Vienna, Graz, New Jersey, Washington, DC, and Innsbruck. In 1911–13 he discovered 'ultra-radiation' (cosmic radiation), and later founded the station at the Hafelekar mountain (altitude 2300 m) near Innsbruck for observing and studying cosmic rays.

Hevelius, Johannes [Jan Hewelcke] (1611–87)

German astronomer and instrument-maker, born in Danzig, now Gdansk, Poland. Hevelius was an accomplished instrument-maker and engraver. Influenced by TYCHO BRAHE in subject and instrumentation, he erected in Danzig what must have been then the world's finest observatory Stellaburgum (cf Brahe's Uraniborg), destroyed by fire in 1679. He made several large telescopes and some of the last large, open-sighted instruments, to which he introduced the vernier scale for reading the scales and determining star positions. He wrote a book on instruments, the *Machina Coelestis* (1673) and his widow Elisabeth posthumously published his catalog of star positions, *Prodromus Astronomiae* and his celestial atlas *Firmamentum Sobiescianum* (1687, 1690). The atlas introduced the constellations Canes Venatici, Lacerta, Leo Minor, Lynx and Vulpecula cum Ansere (the fox and the goose, now known simply as Vulpecula), and named Scutum Sobiescianum (now simply Scutum, the shield) after the King of Poland, John Sobieski. Two constellations that Hevelius introduced did not survive—Mons Maenalus and Cerberus. *Selenographia*, his atlas of the Moon, dubbed the gray flat regions as maria but his crater names were superseded by those of RICCIOLI. He discovered four comets, and was one of the first to observe the transit of Mercury.

Hewish, Antony (1924–)

Radioastronomer, born in Fowey, Cornwall, Nobel prizewinner for physics (1974) for pioneering research in radio astrophysics, and the discovery of pulsars. After working in war-time radar development, he was educated and worked at Cambridge where he became professor of radioastronomy and led the Mullard Radio Astronomy Observatory from 1982–8. First worked on the scintillation or twinkling of radio 'stars', which he used to investigate the properties of the plasma clouds in the ionosphere. Extended this to identify scintillation due to the solar wind and built a radio telescope to use this technique to obtain very high angular resolution observations of radio sources. By a stroke of good fortune the observational requirements were precisely those needed to detect pulsars and it was with this telescope that Hewish's graduate student, JOCELYN BELL, noticed them.

Hey, James Stanley (1909–90)

English radioastronomy pioneer, made three fundamental discoveries in radio astronomy. Working on radar during the second World War, he discovered radio interference from solar storms (at first thought to be enemy 'jamming' of radar). It is surprising that he should have found this emission serendipitously, since solar radio emission had been sought without success by several scientists since Hertz discovered radio waves in 1888 (Thomas Edison, Oliver Lodge, J Scheiner and C Nordham). Then in attempting to detect and predict V-2 rockets he saw the radar reflections from meteor trails. Finally, from Richmond Park (a government military research laboratory) he detected Cygnus A as interference behind meteor trail reflections, the first recognized discrete source of radio waves. Became Chief Scientific Officer at the Royal Radar Establishment at Malvern, and constructed one of the two first variable-spacing radio interferometers.

Hidalgo

An asteroid discovered by Walter Baade in 1920, designated (944) Hidalgo. It was the first known Jupiter-crossing asteroid, having an orbit that takes it from 2.01 AU, near the inner edge of the main belt, to 9.69 AU, just beyond the mean distance of Saturn, in a period of 14.15 years. Hidalgo's mean distance from the Sun is 5.85 AU (875 million km); its diameter is uncertain but is about 40 km. Its highly inclined (42°) and eccentric (0.66) orbit suggests that it may be a large extinct cometary nucleus. It is a D-type object, indicating a dark surface.

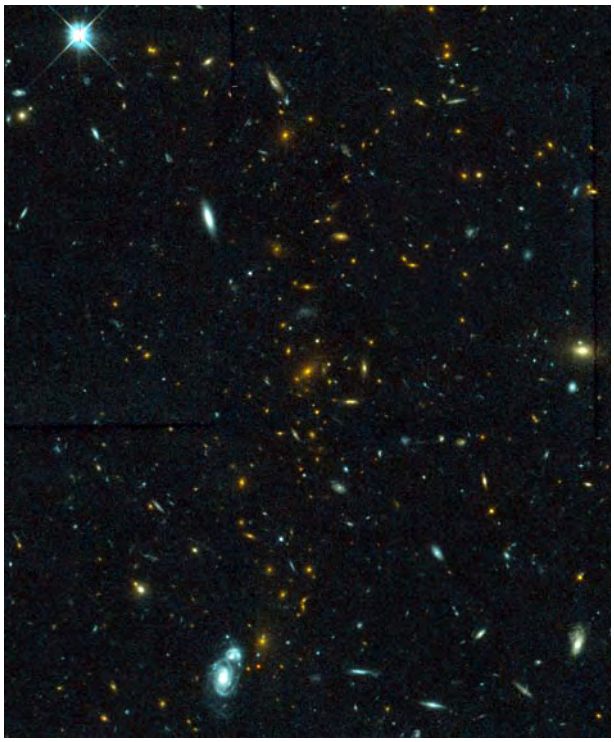

Figure 1. The distant cluster MS1054–03 at a redshift of 0.83. This is the most distant cluster found with the Rosat satellite. The image was taken with the Hubble Space Telescope (courtesy van Dokkum, Franx, ESA and NASA). The cluster is easily recognized by the high density of red galaxies. These galaxies appear red because of the high redshift of the cluster. **This figure is reproduced as Color Plate 7.**

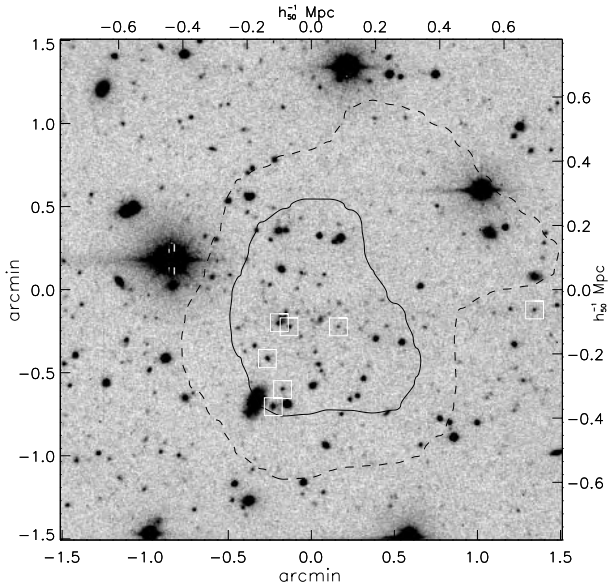

Figure 2. The most distant x-ray cluster RXJ0848.9+4452 at a redshift of 1.26. The contours show the x-ray emission, overlaid over an optical image of the cluster (courtesy P Rosati). The confirmed cluster members are indicated with boxes. Many more galaxies are expected to be member of this cluster.

High-z Clusters

CLUSTERS OF GALAXIES are the largest and most massive structures in the universe, held together by gravity. Their density is more than a thousand times the average density of the universe, and they are filled with galaxies, hot gas and dark matter.

It is very interesting to study clusters of galaxies out to the largest distances and highest REDSHIFTS. The most distant clusters are so far away that the light has traveled for a large fraction of the age of the universe, and we are therefore looking back in time when we study these clusters.

It is very hard to find the high redshift clusters. The oldest method relies on deep optical images taken of the sky. The clusters can be recognized as small concentrations of very faint galaxies. The Palomar Sky Survey was used to find clusters, but it is very hard to find clusters beyond a redshift of 0.4. Other techniques have been more efficient at finding higher redshift clusters. Powerful RADIO GALAXIES can reside in clusters, although most of the clusters found in this way are not very rich.

One of the most efficient ways of finding high redshift clusters is based on their x-ray emission. The hot gas that fills clusters emits strongly in x-rays. This x-ray emission is so bright that it can be seen out to redshifts of 1 and higher. An example of such an x-ray cluster is shown in figure 1. This cluster, MS1054–03, was discovered with the Einstein satellite in a deep survey on part of the sky. All x-ray sources in the survey were carefully identified in the optical by Isabella Gioia and collaborators. Finally, optical spectroscopy with the 10 m W M Keck telecope showed that this was the most distant cluster discovered with the Einstein satellite. It has a redshift of 0.83, and the universe was less than half its present age when the cluster emitted the light we observe.

The most distant cluster found in this way is RXJ0848.9+4452, which was first detected by the Rosat satellite, and identified as a cluster at a redshift of 1.26 by Rosati and collaborators. The image is shown in figure 2. The cluster is as massive as nearby ABELL CLUSTERS. The optical emission is quite faint because the light of the galaxies has been shifted to the infrared by the high redshift. Images in the infrared are necessary to find such high redshift clusters. Surprisingly, this cluster has been found to have a very close neighbor, at the same redshift. The second cluster had been found serendipitously by an infrared survey of the sky. This pair of clusters forms a 'supercluster'.

Now that large samples of clusters at high redshifts have been found, we can determine whether the clusters change with time, and whether the galaxies inside clusters change with time. The first question to answer is whether the number of clusters is different at high redshift. Many theoretical models predict that clusters

form 'hierarchically', which means that large clusters grow by the accumulation of smaller clusters. Some of these theories predict that the most massive clusters should not exist, or be very rare at redshifts of 1. Interestingly enough, the cluster MS1054–03 is so massive that its existence at a redshift of 0.83 poses problems for some theories. In general, there is no strong evidence that the number of clusters changes with redshift. The newest results indicate, however, that the most massive clusters are somewhat rarer at high redshift.

The high redshift clusters are also very suitable for studying the evolution of the galaxies inside the clusters. In the nearby universe, rich clusters are dominated by S0 galaxies and elliptical galaxies, and have only a small fraction of spiral galaxies at their center. Only recently has it become possible to obtain images of high redshift clusters with a quality good enough to undertake such studies. The very sharp images taken with the Hubble Space Telescope are of comparable quality to the earlier images taken of low redshift clusters.

Studies by Dressler and co-workers have demonstrated that the fraction of SPIRAL GALAXIES is significantly higher in clusters at a redshift of 0.5. Figure 3 shows the center of the cluster CL0939+4713 at a redshift of 0.41. The high fraction of spiral galaxies in the center of this cluster is obvious. Generally, high redshift clusters have far fewer S0 galaxies than low redshift clusters. These galaxies are the most common type of galaxy in low redshift clusters. They have probably been added to the low redshift clusters from the outside. Before they fall into the clusters, they look like spiral galaxies. When they fall in, they lose their gas, and appear as S0 galaxies soon after.

At even higher redshifts, the evidence for merging between galaxies becomes stronger. It has been speculated for a long time that ELLIPTICAL GALAXIES form by collisions of less massive galaxies. After two galaxies collide, they quickly merge together and form a new galaxy. If the two galaxies contain no or little gas, they will form a regular elliptical after the mergers.

It has always been difficult to find such mergers in clusters. However, a recent study of the rich cluster MS1054–03 shows that 18% of the member galaxies are mergers. These colliding galaxies are shown in figure 4. It is likely that the mergers evolve into elliptical galaxies or S0 galaxies. This is direct evidence that galaxies evolve through merging. (See also GALAXIES: INTERACTIONS AND MERGERS.)

The mergers and the conversion of spiral galaxies into S0's may very well explain why galaxies in clusters are very different from galaxies outside clusters. Understanding the origin of this effect is one of the goals of studies of distant cluster galaxies. By observing these clusters, astronomers can directly see what happened to the galaxies in the distant past.

Marijn Franx

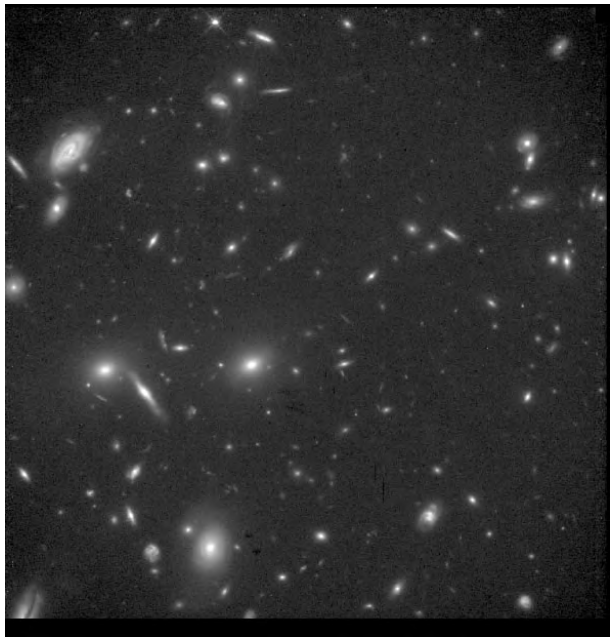

Figure 3. The central part of the distant cluster CL 0939+4713, imaged with the Hubble Space Telescope (courtesy A Dressler and NASA). The center contains many spiral galaxies, unlike clusters nearby. Many of these spiral galaxies look disturbed.

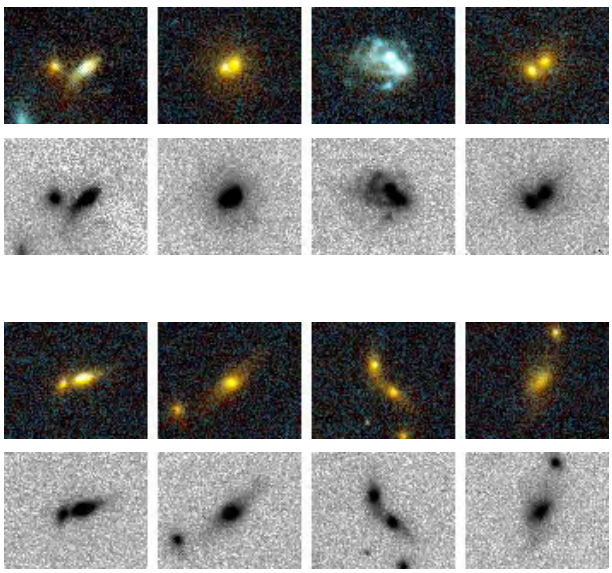

Figure 4. Mergers in the distant cluster MS1054–03 (courtesy van Dokkum, Franx, ESA and NASA). These galaxies have been confirmed to be cluster members. They are classified as mergers. Some show tidal arms, others double nuclei, or faint extensions due to the collisions of galaxies. Such mergers may have been much more prevalent in the past. **This figure is reproduced as Color Plate 8.**

High Altitude Observatory

The High Altitude Observatory (HAO), in Boulder, CO, established in 1940, is dedicated to research in solar and solar-terrestrial physics with emphasis on solar–variability and its impact on the Earth. HAO is a division of the National Center for Atmospheric Research, sponsored by the National Science Foundation and operated by the University Corporation for Atmospheric Research, Boulder, CO. HAO's program includes visiting scientists, advanced education, workshops, development of ground- and space-based instruments, operation of observing facilities, distribution of data to the scientific community and numerical modeling. HAO conducts its research in strong cooperation with the university community, NASA and NOAA, and with many research centers worldwide.

High Energy Astrophysical Observatory (HEAO)

Series of three NASA orbital observatories. HEAO-1, launched in August 1977, successfully completed the most accurate all-sky survey of x-ray sources up to that time. Discovered the 'Cygnus Superbubble' created by a series of supernovae. HEAO-2 (later known as EINSTEIN), launched in 1978, was the first true x-ray astronomy satellite. HEAO-3, launched in September 1979, carried a gamma ray spectrometer and two cosmic ray detectors. It observed spectral lines produced by electron–positron annihilation from the direction of the Galactic centre.

High Energy Transient Experiment (HETE) 2

A US–French satellite launch in October 2000. Its prime objective is to carry out a multiwavelength study of gamma ray bursts with ultraviolet, x-ray and gamma ray instruments. It will be able to localize bursts to within several arcseconds. The first HETE was lost due to a Pegasus launch failure in 1996.

On September 21, 2001, HETE detected a rare optical afterglow of a gamma-ray burst in the constellation Lacerta. The source was relatively close, only about 5 billion l.y. from Earth. The opportunity to see the afterglow in optical light provides crucial information about what is triggering these mysterious bursts, which scientists speculate to be the explosion of massive stars, the merging of neutron stars and black holes, or possibly both.

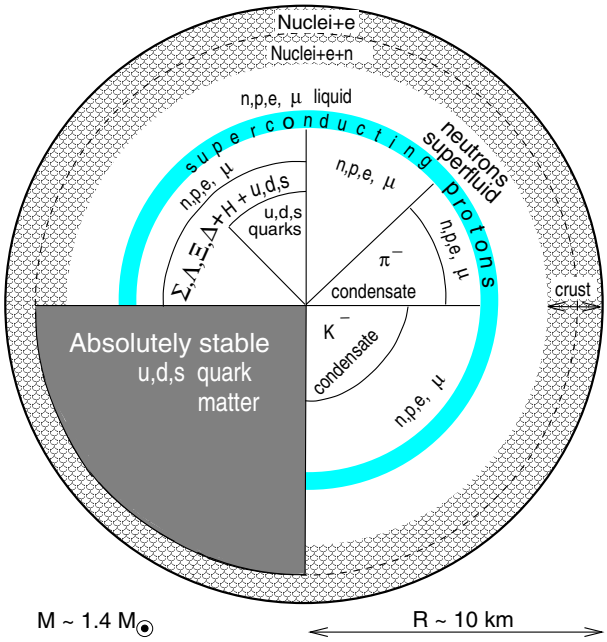

Figure 1. Competing structures and novel phases of high-density matter predicted by theory to make their appearances in the cores ($R \lesssim 8$ km) of neutron stars.

High-density Equation of State of Neutron Stars

The enormous gravitational pull that binds NEUTRON STARS compresses most of their matter to densities that are up to an order of magnitude higher than the mass density of atomic nuclei, 2.5×10^{14} g cm^{-3}. This provides a high pressure environment in which numerous subatomic particle processes, ranging from the generation of new BARYON particles ($\Sigma, \Lambda, \Xi, \Delta$), to QUARK deconfinement, to the formation of (π^- or K^-) boson condensates and H (dibaryon) matter, are expected to compete with one another, and novel phases of matter, like the quark–gluon plasma state being sought at the most powerful terrestrial particle colliders, could exist (figure 1). There are theoretical suggestions of even more exotic processes at supernuclear densities such as the formation of absolutely stable strange quark matter, a configuration of matter even more stable than the most stable atomic nucleus, iron.

No matter which physical processes are actually realized in the dense interiors of neutron stars, each one manifests itself in the high-density equation of state (EoS) that is pressure as a function of total energy density, $P(\epsilon)$, of neutron stars (figure 2).

Neutron stars are objects of highly compressed matter so that the geometry of SPACETIME is changed considerably from flat space. Thus models of such stars are to be constructed in the framework of Einstein's GENERAL THEORY OF RELATIVITY combined with theories of high-density matter. The connection between both is provided by Einstein's field equations (G denotes the gravitational constant, and $\mu, \nu = 0, 1, 2, 3$),

$$G^{\mu\nu} = 8\pi G T^{\mu\nu}(\epsilon, P(\epsilon)), \tag{1}$$

which couples the Einstein curvature tensor, $G^{\mu\nu}$, to the energy–momentum density tensor, $T^{\mu\nu}$, of neutron star matter. The tensor $T^{\mu\nu}$ contains the EoS of neutron star matter, which is derivable from a given stellar matter Lagrangian $\mathcal{L}_m(\{\chi\})$. In general, $\mathcal{L}_m$ is a complicated function of the numerous baryon ($\chi = \mathrm{p, n}, \Sigma, \Lambda, \Xi, \Delta$), meson ($\chi = \pi^-, \mathrm{K}^-$) and quark ($\chi = \mathrm{u, d, s}$) fields predicted to make their appearance in the cores of neutron stars (figure 1). Once $\mathcal{L}_m$ is specified, models for the EoS then follow according to the scheme

$$\frac{\partial \mathcal{L}_m}{\partial \chi} - \partial_\mu \frac{\partial \mathcal{L}_m}{\partial(\partial_\mu \chi)} = 0 \Rightarrow P(\epsilon). \tag{2}$$

In general, equations (1) and (2) are to be solved simultaneously since the particles move in curved spacetime whose geometry, determined by Einstein's field equations, is coupled to the total energy density of the matter fields. For neutron stars, however, the deviation from flat spacetime over the length scale of the nuclear force, ~1 fm, is practically zero up to the highest densities reached in the cores of such stars (some 10^{15} g cm^{-3}). This circumstance divides the construction of models of neutron stars into two distinct problems. Firstly, the effects of the short-range nuclear forces on the properties of neutron star matter are described in a local inertial frame, where spacetime is flat, by the parameters and laws of many-body physics. Secondly, the coupling between the long-range gravitational field and the matter is then taken into account by solving Einstein's field equations for the gravitational field, which leads to the global properties of neutron stars.

Hyperon population

In the most primitive conception, high-density neutron star matter is constituted of only neutrons. Such matter, however, constitutes a highly excited state relative to neutron star matter which will therefore quickly transform, via the weak reaction

$$\mathrm{n} \rightarrow \mathrm{p} + \mathrm{e}^- + \bar{\nu}_\mathrm{e}, \tag{3}$$

into its chemically equilibrated state, made up of neutrons (n), protons (p) and electrons (e^-). NEUTRINOS do not accumulate (i.e. $\mu^{\bar{\nu}_\mathrm{e}} = 0$), because of their extremely small cross sections in neutron star matter. In this way the stellar matter develops Fermi seas of degenerate neutrons, protons and electrons, each one being filled up to the highest possible energy level determined by

$$\mu^\mathrm{n} = \mu^\mathrm{p} + \mu^{\mathrm{e}^-}. \tag{4}$$

Equation (4) is a special case of the general relation

$$\mu^\chi = B^\chi \mu^\mathrm{n} - q^\chi \mu^{\mathrm{e}^-}, \tag{5}$$

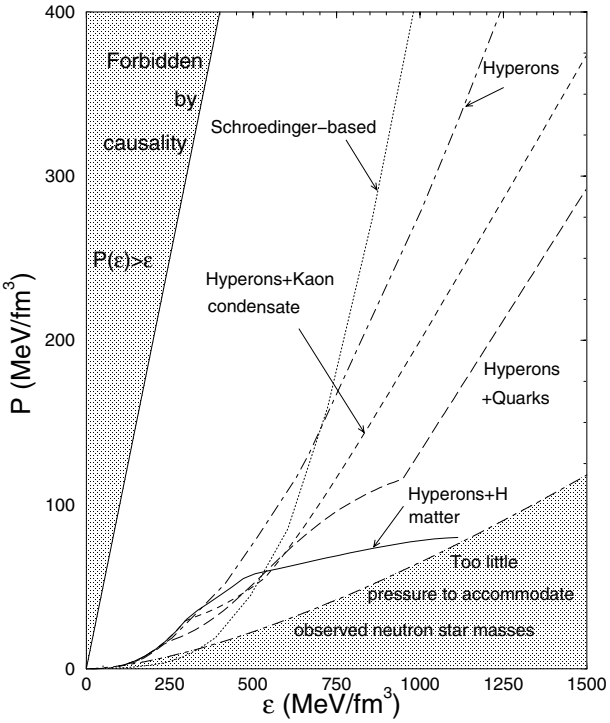

Figure 2. Models for the EoS of high-density neutron star matter. Constraints from causality and observed neutron star masses are indicated.

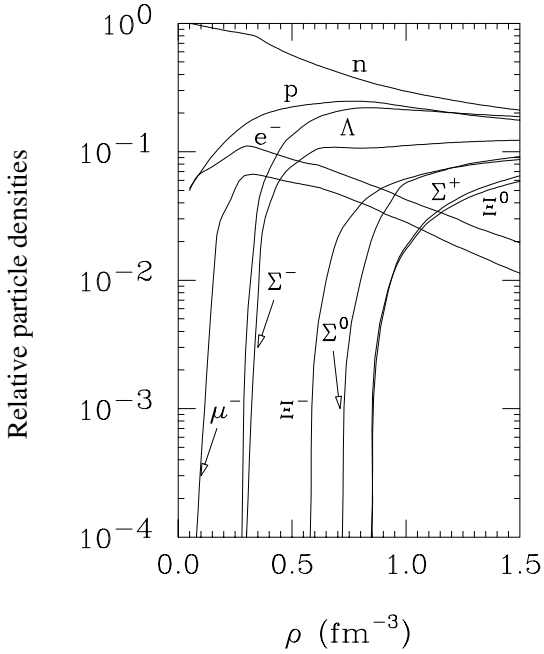

Figure 3. Baryon composition of neutron star matter.

which holds in any system characterized by two conserved charges. These are, in the case of neutron star matter, electric charge q^χ, and baryon number charge B^χ. Applied to the Λ hyperon ($B^\Lambda = 1$, $q^\Lambda = 0$), for instance, equation (5) leads to

$$\mu^\Lambda = \mu^{\rm n}. \tag{6}$$

Ignoring particle interactions, the chemical potential of a given particle χ follows from

$$\mu^\chi = \omega(k_{F_\chi}) \equiv \sqrt{m_\chi^2 + k_{F_\chi}^2}, \tag{7}$$

where $\omega(k_{F_\chi})$ is the energy–momentum relation of a free relativistic particle moving with Fermi momentum k_{F_χ}. Substituting (7) into (6) leads to ($m_\Lambda = 1116$ MeV, $m_{\rm n} = 939$ MeV)

$$k_{F_{\rm n}} > \sqrt{m_\Lambda^2 - m_{\rm n}^2} \sim 3\ {\rm fm}^{-1} \Rightarrow \rho_{\rm n} \equiv \frac{k_{F_{\rm n}}^3}{3\pi^2} \sim 2\rho_0. \tag{8}$$

That is, neutrons begin to transform into Λs at baryon number densities around twice the density of nuclear matter, $\rho_0 = 0.16\ {\rm fm}^{-1}$. This value is only slightly altered by the inclusion of particle interactions, as can be seen from figure 3.

Aside from chemical equilibrium, the condition of electric charge neutrality constitutes another characteristic feature of neutron star matter, as any net charge per particle Z/A in excess of around 10^{-36} would prevent gravity from binding neutron star matter. This too leads to decisive constraints on the particle Fermi momenta, which follow from the charge neutrality condition

$$\sum_{\chi={\rm p},\Sigma,\ldots;{\rm e}^-,\mu^-} q^\chi \frac{k_{F_\chi}^3}{3\pi^2} + \rho_M \Theta(\mu^M - m_M) \equiv 0. \tag{9}$$

The last term in equation (9) accounts for the electric charges carried by condensed mesons of type M, of which only the π^- or, alternatively, the currently more favored $\rm K^-$ come into question.

Figure 3 shows a representative sample composition of neutron star matter assumed to consist of only neutrons, protons and hyperons. The interactions are computed, following the scheme in equation (2), in the framework of relativistic nuclear field theory, where the motion of the particles is described by the coupled field equations

$$\begin{aligned}
({\rm i}\gamma^\mu \partial_\mu - m_\chi)\psi_\chi(x) &= \sum_{M=\sigma,\omega,\pi,\ldots} g_{M\chi} M(x)\psi_\chi(x), \\
(\partial^\mu \partial_\mu + m_\sigma^2)\sigma(x) &= \sum_{\chi=p,n,\Sigma,\ldots} g_{\sigma\chi}\bar{\psi}_\chi(x)\psi_\chi(x),
\end{aligned} \tag{10}$$

plus additional equations for the other meson fields ($M = \omega, \pi, \rho, \ldots$). Evidently, the free-particle case is recovered by setting the meson–baryon coupling constants $g_{M\chi} = 0$. Equations (10) are to be solved in combination with conditions (5) and (9) for the fields $\psi_\chi(x)$ and $M(x)$. This can be accomplished in the framework of different many-body approximations, of which the relativistic Hartree

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

(mean-field) approximation is the simplest approach, followed, with increasing level of complexity, by the relativistic Hartree–Fock (RHF) and relativistic Brueckner–Hartree–Fock (RBHF) approximations. In the Hartree and RHF approximations the coupling constants $g_{M\chi}$ are chosen such that the theory accommodates the bulk properties of nuclear matter at saturation density ρ_0. These are the binding energy $E/A = -16$ MeV, effective nucleon mass $m_{\rm N}^*/m_{\rm N} = 0.79$, incompressibility $K \simeq 265$ MeV, and the symmetry energy $a_{\rm s} = 32$ MeV. Of the five, the value for the incompressibility of nuclear matter carries the largest uncertainty. Its value is currently believed to lie in the range between about 180 and 280 MeV. In sharp contrast to Hartree and RHF, the RBHF approximation makes use of meson-exchange models for the nucleon–nucleon interaction, whose parameters are adjusted to the nucleon–nucleon scattering phase shifts in free space and the deuteron's properties, so that all nuclear matter properties are computed self-consistently.

Once the fields $\psi_\chi(x)$ and $M(x)$ are computed, models for the EoS of high-density neutron star matter follow from the energy–momentum tensor $T^{\mu\nu} = T^{\mu\nu}(\psi_\chi)$,

$$\epsilon = T^{00}, \qquad P = \frac{1}{3}\sum_{i=1}^{3} T^{ii}. \tag{11}$$

The neutron star matter composition shown in figure 3 is computed for the relativistic Hartree approximation, with the associated EoS illustrated in figure 2. Three general physical features emerge. (1) The electric charges add up to zero at each density, as required by electric charge neutrality. (2) The generation of μ^- and Σ^- replaces high-energy electrons at the top of the electron Fermi sea. (3) The generation of baryons with isospin orientations opposite to the neutron's (e.g. Σ^+, Ξ^0) renders neutron star matter more isospin symmetric, that is closer equality between the number of neutrons and protons. All three features are essential for neutron star matter to settle down in the lowest energy state.

Another access to the derivation of the EoS is provided by Schrödinger-based treatments. These are based on phenomenological models for the two (v_{ij}) and three (v_{ijk}) nucleon interaction, eventually supplemented with relativistic corrections. The Hamiltonian thus is of the form

$$H = \sum_i^N \left(\frac{k_i^2}{2m}\right) + \sum_{i<j}^N v_{ij} + \sum_{i<j<k}^N v_{ijk}, \tag{12}$$

with N ($\sim 10^{57}$) the number of nucleons. The method adopted to solve the many-body Schrödinger equation $H|\Psi\rangle = E|\Psi\rangle$ is based on the variational approach, where the variational parameters contained in the wave function $|\Psi\rangle$ are varied to minimize the energy per baryon for a given density, i.e.

$$E(\rho) = \min \frac{\langle\Psi|H|\Psi\rangle}{\langle\Psi|\Psi\rangle}. \tag{13}$$

The energy density, $\epsilon(\rho)$, and pressure, $P(\rho)$, are then given by

$$\epsilon(\rho) = \rho(E(\rho) + m_{\rm N}), \quad P(\rho) = \rho^2 \frac{\partial}{\partial\rho} E(\rho), \tag{14}$$

which can be combined to the EoS in the form $P(\epsilon)$. The dotted curve in figure 2 is an example of an EoS derived in this framework.

Condensation of K^- mesons
Once the reaction

$$e^- \rightarrow K^- + \nu_e \tag{15}$$

becomes possible in neutron star matter, it is energetically advantageous for the matter to replace the fermionic electrons with the bosonic K^- mesons. Whether or not this actually happens depends on the effective mass of the K^- and the value of μ^{e^-} in neutron star matter, as can be seen from the threshold condition

$$m_{K^-}^* \equiv \mu^{K^-} = \mu^{e^-}, \tag{16}$$

which follows from equation (5). Calculations indicate that $m_{K^-}^*$ may become as small as $m_{K^-}^* \simeq 200$ MeV in neutron star matter above a few times ρ_0. Such mass values lie in the vicinity of μ^{e^-} so that the threshold condition for the onset of K^- condensation could indeed be fulfilled. A sample EoS of K^- condensed neutron star matter is shown in figure 2. Reaction (15) is followed by

$$n + e^- \rightarrow p + K^- + \nu_e, \tag{17}$$

with the neutrinos leaving the star as described above. By this conversion the nucleons in the cores of newly formed neutron stars can become half neutrons and half protons. The relatively isospin symmetric composition of neutron star matter achieved in this way resembles the one of atomic nuclei, which are made up of roughly equal numbers of neutrons and protons. Neutron star matter is therefore referred to, in this picture, as nucleon star matter.

H-dibaryons
Another boson that could make its appearance in high-density neutron star matter is the H-dibaryon, a doubly strange six-quark composite with baryon number two. Since its first prediction in 1977, the H-dibaryon has been the subject of many theoretical and experimental studies as a possible candidate for a strongly bound exotic state. In neutron star matter, which, as known from figure 3, may contain a significant fraction of Λ hyperons, pairs of them could combine to form H-dibaryons, which could give way to the formation of H-matter at densities somewhere between $3\rho_0$ and $6\rho_0$, depending on the in-medium properties of the H-dibaryon. The condensation could be accompanied by a pronounced softening of the EoS (solid curve in figure 2) of such matter. If indeed formed, H-matter may not form a permanent component of neutron star matter but, because of its instability against compression, could trigger the conversion of neutron star matter into hypothetical strange star matter (see below).

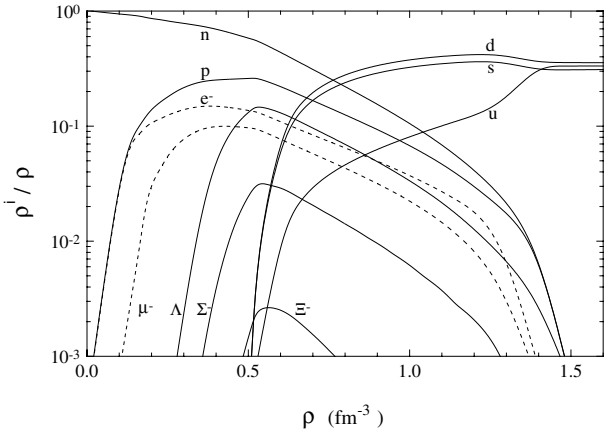

Figure 4. Sample composition of neutron star matter accounting for quark deconfinement.

Quark deconfinement

It has been suggested already back in the 1970s that, because of the extreme densities reached in the cores of neutron stars, neutrons and protons may melt, creating the quark–gluon plasma state being sought at the most powerful terrestrial heavy-ion colliders. At present one does not know from experiment at what density the expected phase transition to quark matter occurs, and one has no conclusive guide from lattice QCD simulations either. From simple geometrical considerations it follows that neutrons and protons begin to touch each other at densities of $\sim(4\pi r_{\rm N}^3/3)^{-1} \simeq 0.24$ fm^{-3}, which, for a characteristic nucleon radius of $r_{\rm N} \sim 1$ fm, is less than twice ρ_0. Above this density, therefore, it appears plausible that the nuclear boundaries of neutrons and protons dissolve and that the quarks, formerly confined inside neutrons and protons, begin to populate free states outside of the nucleons. More than that, since the mass of the strange quark is only $m_{\rm s} \sim 150$ MeV, high-energetic up and down quarks are expected to readily transform to strange quarks at about the same density at which up and down quark deconfinement sets in, giving way to the formation of three flavor (u,d,s) quark matter at densities just a few times ρ_0. A sample composition of such matter is shown in figure 4, and its associated EoS is illustrated in figure 2.

Diquark condensation and color superconductivity

Very recently it was discovered that strong correlations between up and down quarks may exist which could lead to the formation of colored diquark pairs in high-density matter. These pairs, carrying integer spin, could form a Bose condensate in cold ($T < 50$ MeV) and dense ($\rho > 3\rho_0$) quark matter which ought to exhibit color superconductivity. Both the magnitude of the gap and the critical temperature associated with the color superconductive phase were estimated to be on the order of ∼100 MeV, about two orders of magnitude larger than the gaps associated with neutron and proton superfluids. Future theoretical studies may reveal whether these features will have their correspondence in a more complete treatment of QCD at finite baryon number density.

Absolutely stable strange quark matter

So far it was assumed that quark matter forms a state of matter higher in energy than atomic nuclei. This most plausible assumption, however, may be quite deceiving because, for a collection of more than a few hundred u,d,s quarks, the energy per baryon (E/A) of quark matter can be equally well below the energy of the most stable atomic nucleus, ^{56}Fe, whose energy per baryon is $M(^{56}\mathrm{Fe})c^2/56 = 930.4$ MeV, with $M(^{56}\mathrm{Fe})$ the mass of the ^{56}Fe atom. The EoS of strange quark matter can be represented mathematically as $P = (\epsilon - 4B)/3$ (bag constants $B \sim 80$ MeV fm^{-3}). This implies a surface density of $\epsilon = 4B \sim 6 \times 10^{14}$ g cm^{-3} for stars made up of such matter which distinguishes them from neutron stars made up of conventional matter.

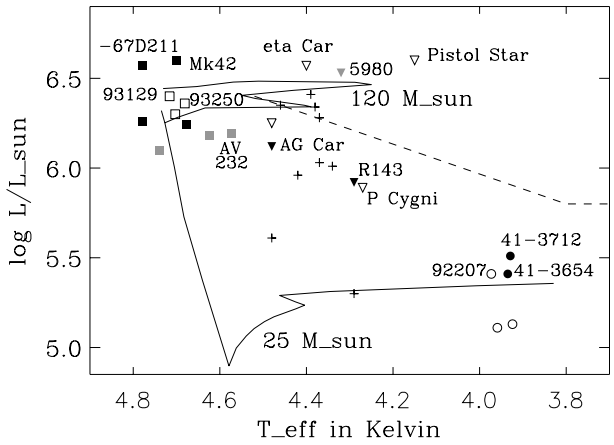

Figure 1. The Hertzsprung–Russell diagram of the most luminous stars. Stars of spectral type O and luminous blue variables are represented by squares and triangles, respectively. Open symbols correspond to the Galaxy, solid symbols to the Large Magellanic Cloud and grey symbols to the Small Magellanic Cloud. To avoid confusion the diagram does not include other hot and very luminous stars of spectral type WN detected recently in the 30 Doradus region of the LMC, which are similar to Mk42. The crosses represent the most luminous stars of the young stellar cluster in the very center of our galaxy. Circles correspond to A supergiants (open symbols, galaxy; solid, M31). Although they are a factor of 10 fainter in bolometric luminosity, objects of this kind are the brightest 'normal' stars in visual light. The theoretical main sequence and stellar evolutionary tracks (labelled by the stellar mass) are given as solid curves. The dashed curve is the 'Humphreys–Davidson limit' discussed in the text.

High-luminosity Stars

The most luminous stars in galaxies are of extraordinary astronomical importance. With the new generation of 10 m class ground-based telescopes and with the large observatories in space such as the HST they can be studied as individuals in galaxies out to 20 Mpc distance including the VIRGO and FORNAX GALAXY CLUSTERS. The quantitative analysis of their spectra yields important information about distances, chemical composition and evolution of galaxies.

In recent years galaxies at extremely large distances, billions of light-years distant, have been detected. Because of their large REDSHIFTS ($z \simeq 3$–4) these galaxies show their ultraviolet light shifted to optical wavelengths. Spectroscopy with 10 m class telescopes reveals that the radiation of these galaxies is dominated by the contribution of the most luminous stars which are usually very hot and emit mostly in the ultraviolet. Using the knowledge obtained about this extreme population of stars in our own Galaxy and the galaxies of the LOCAL GROUP it is, at least in principle, possible to investigate the physics of GALAXIES AT HIGH REDSHIFT belonging to an early phase of the evolution of the universe.

The spectral analysis of the most luminous stars is difficult and complex. The physical reason for the complexity is precisely this prodigious luminosity and the correspondingly large energy and momentum density of their intrinsic radiation field, which dominates the thermodynamics and hydrodynamics of the interior structure and the entire atmospheres. Extreme departures from local thermodynamic equilibrium (LTE), which require the extensive effort of non-LTE radiative transfer and model atmospheres for the spectral analysis, result from this dominating role of the radiation field. In addition, very strong stellar winds are initiated and maintained by the absorption of photon momentum through ionic species of the atmospheric plasma. Through these winds a significant amount of the stellar mass is lost and recycled back to the interstellar medium during the lifetime of these stars.

Figure 1 shows the HERTZSPRUNG–RUSSELL DIAGRAM (HRD) of the most luminous stars known so far in the Milky Way and the nearby galaxies of the Local Group.

The spectral type O3—the most luminous hydrogen burning stars

Luminous stars are usually formed in giant and dense molecular clouds as the most massive objects of very young stellar clusters. Typical examples are the clusters in the CARINA Nebula of the Milky Way and in the TARANTULA NEBULA of the Large Magellanic Cloud. After birth these objects are very hot. Their atmospheric effective temperatures are about 50 000 K. With masses of about a hundred solar masses or more their luminosities are in the range between one and three million solar luminosities. The energy production leading to these enormous luminosities is central nuclear hydrogen burning in the CNO cycle. The interior hydrostatic equilibrium is kept mostly through radiation pressure which may be the cause for pulsational instability. The nuclear lifetime in this stage is very short, roughly 2.5 million years. It is almost independent of the stellar mass in these extreme conditions dominated by electron scattering in the STELLAR INTERIOR.

It is not so easy to detect these most luminous objects in our Milky Way by conventional photometric techniques. Interstellar reddening and extinction and the fact that stellar colors measured in the optical part of the electromagnetic spectrum depend only very weakly on temperature as soon as $T_{\rm eff}$ is above 35 000 K make it impossible to identify these stars by photometry only. The only reliable way is spectroscopy. For optical spectroscopy the criterion for the most luminous and most massive very young stars in the stage of central hydrogen burning is the extreme weakness or complete absence of neutral helium lines relative to strong lines of singly ionized helium. The corresponding spectral type is O3. O3 stars are the hottest, most luminous and most massive stars known. Figure 2 shows how the relative strength of neutral to ionized helium lines changes between spectral types O3, O5 and O6.5 corresponding to a temperature range from 50 000 K to 41 000 K. However, there might be a significant intrinsic spread in effective temperature and luminosity among the

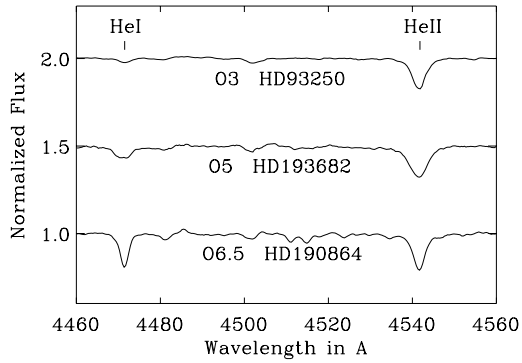

Figure 2. He I and He II spectral lines in the optical spectra of O stars. At spectral type O3 the He I lines are very weak.

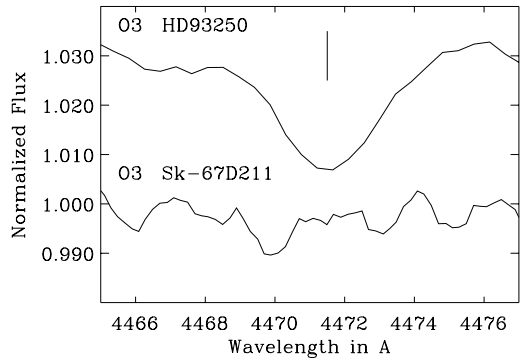

Figure 3. Enlarged plot of the He I 4471 line in two O3 stars (the vertical bar indicates a line depression of 0.01 in units of the continuum). While the line can still be recognized in the galactic object HD93250 ($T_{\rm eff} \simeq 50\,000$ K, $\log L/L_\odot \simeq 6.3$), it is absent in the spectrum of Sk-67D211, one of the hottest, most luminous and most massive stars in the Large Magellanic Cloud ($T_{\rm eff} \simeq 60\,000$ K, $\log L/L_\odot \simeq 6.6$). (See Puls *et al* 1996 *Astron. Astrophys.* **305** 171.)

O3 stars. This is indicated by figure 3 which compares high signal-to-noise spectra of two O3 stars.

The ultraviolet spectra of O3 stars are dominated by strong and broad stellar wind lines superimposed on a forest of narrow photospheric lines mostly of highly ionized iron. Figure 4 shows the UV spectrum of the possibly most massive star in our galaxy.

The signatures of the same UV stellar wind lines are also found in the optical spectra of galaxies at high redshift (figure 5), indicating that the ultraviolet light of these objects is dominated by the emission of the population of the most massive stars.

The evolution of the most luminous stars—the Humphreys–Davidson limit

During central hydrogen burning O stars evolve towards lower effective temperature in the HRD. However, how far they evolve to the right in the HRD is obviously a function of luminosity. The corresponding observational border line in the HRD is called the 'Humphreys–Davidson limit'. The physical reason for the occurrence of this limit is the strong stellar mass loss which peals off the outer stellar layers and leads to a more or less bare contracting stellar core evolving to the helium burning main sequence at very high temperatures before the star has the chance to become a red supergiant (see RED GIANT STARS). Since the strength of mass loss is a function of luminosity (see below), the Humphreys–Davidson limit has a certain slope in the HRD for luminosities larger than 6×10^5 solar luminosities. Objects with lower luminosity pass through the stage of the red supergiants and return to the blue on their way to the helium main sequence.

Close to the Humphreys–Davidson limit the most luminous stars enter an extremely unstable phase of their evolution. They become 'LUMINOUS BLUE VARIABLES' (LBVs). These objects show very strong stellar winds, a significant variability of their brightness and sometimes dramatic eruptions, where significant amounts of stellar mass are ejected and the stellar properties change dramatically. The most famous examples of this group are η Carinae and P Cygni. During such eruptions the luminosity stays constant, but the radius increases substantially and the effective temperature drops. As a result of this process LBVs in outburst become much brighter in visual light. η Carinae, for instance, suddenly became one of the brightest stars in the southern sky during the late 1830s. Something similar happened with P Cygni in the 17th century.

Before and after the LBV phase or when evolving towards or away from the red supergiant phase the most luminous blue stars are spectroscopically identified as blue supergiants with characteristic emission lines in their optical and IR spectra caused by their stellar winds. These 'normal supergiants' are extremely useful as extragalactic distance indicators (see below). The evolution of the most luminous stars comes to an end when they have lost most of their hydrogen envelope through winds and eruptions and appear as bare helium stars on the helium burning main sequence. Still suffering from extremely strong stellar winds these objects show very broad pronounced emission lines of helium, nitrogen or carbon in their optical spectra. They appear as 'WOLF–RAYET STARS'. After this evolutionary stage they explode as SUPERNOVAE.

The cluster of luminous stars in the Galactic center

There is a long-standing debate as to what is the source of luminosity of the central few parsecs of our Galaxy. Using adaptive optics combined with imaging spectroscopy in the infrared it has become clear that the center of the Milky Way is populated by young stellar clusters of very luminous and very massive stars which are only a few million years old and fully account for the bolometric Lyman ionizing luminosities observed. The most luminous objects are evolved blue supergiants close to the evolutionary stage of Wolf–Rayet stars. Their striking spectroscopic characteristic is the strong emission in the He I 2.06 μm line transition in the IR (see figure 6).

Luminosities and temperatures of the brightest objects are indicated in figure 1.

The optically brightest 'normal stars', the wind momentum–luminosity relationship and the determination of extragalactic distances

Massive stars with luminosities below the Humphreys–Davidson limit evolve at (roughly) constant luminosity towards the red supergiant stage and then back towards hotter temperatures. These blue supergiants are the brightest 'normal' stars in visual light, where 'normal' means that they do not suffer from strong eruptions such as those of the LBV. The reason for their enormous visual brightness is that with decreasing atmospheric temperature during the evolution away from the O star domain an increasing fraction of the total luminosity is emitted in visual light as a consequence of Wien's law of radiation. The A supergiants shown in figure 1 have absolute magnitudes M_v of about -9 mag. Only LBV in outburst or supernovae can become brighter in visual light. Consequently, such objects are ideal for study as individuals in distant galaxies to provide information about chemical composition and distance.

One of the most interesting aspects of the recent work on normal blue supergiants is the detection that the strengths of their stellar winds are strongly correlated with stellar luminosity (see figure 7). A careful analysis of the hydrodynamics of radiation-driven winds leads to the prediction that for each supergiant spectral type the mechanical momentum of the stellar wind flow, which is the product of the mass-loss rate $\dot{M}$ and the maximum velocity v_∞, should be strongly dependent on stellar luminosity. This prediction has been confirmed by the detailed spectral analysis of stellar winds of O, B and A supergiants. Figure 8 gives an example for A supergiants (the figure shows wind momenta multiplied by the square root of the stellar radius in units of the solar radius, since this is exactly the quantity predicted to depend on luminosity or—for A supergiants—on absolute visual magnitude). The fact that the relationship holds in this range of extremely high absolute visual magnitudes is very encouraging for the use of A supergiants as extragalactic standard candles. The idea is to determine their wind momenta from spectroscopy and then to use the wind momentum–luminosity relationship observed and calibrated in the Milky Way and in galaxies of the Local Group to determine extragalactic distances. First estimates come to the very encouraging conclusion that with the use of spectrographs attached to 10 m class telescopes the method will allow accurate distance determinations out to galaxies as distant as 20 Mpc.

High-redshift Quasars

The enormous luminosities of QUASARS allow their detection at great distances; the highest-redshift quasars have excited particular interest because they reveal information about the conditions in the universe at a very early epoch. In a single generation the volume of the universe encompassed by the most distant known object has increased by a factor of approximately 40. We have now observed quasars that existed within about a billion years of the Big Bang.

Historical perspective

Quasars were first identified as a discrete class of objects in 1960. Their combination of strong radio emission, substantial brightness variations, and unusual optical spectra (a series of broad, unidentified emission lines superposed on a smooth continuum) was unprecedented; these 'radio stars' were thought to represent an exotic stage of STELLAR EVOLUTION. Maarten Schmidt's decoding of the spectrum of 3C 273 in 1963 (see BRIGHT QUASAR 3C 273) revealed that the redshift[1] (z) of the source was 0.158; his interpretation of the spectrum removed quasars from the realm of our Galaxy and placed them in the distant regions of the universe, and made quasars, by a substantial factor, the most luminous known objects. Within a year the largest quasar redshift exceeded the highest measured galaxy redshift[2]. For more than 30 years the largest redshift belonged to quasars; their reign as the most distant known objects ended in 1997 with the Hubble Space Telescope-aided discovery of a $z = 4.92$ gravitationally lensed galaxy.

Table 1 lists the objects that have at one time possessed the largest known quasar redshift. It is clear that the study of the distant universe has not proceeded at a steady rate; there was a rapid increase in the mid-1960s (note the spectacular discovery of 3C 9), a hiatus of 9 years from 1973–1982, and a spate of discoveries of $z > 4$ quasars in the late-1980s. A particularly striking aspect is the change in the discovery technique for high-redshift quasars; before 1985 all the 'highest-redshift' quasar identifications were initially based upon radio detections, while all subsequent listings in the table were found purely from optical observations. The definition of what constitutes a high-redshift quasar obviously changes with time. For the past decade this term has been applied to quasars with redshifts larger than four; in July 1998 61 quasars have been identified with $z > 4$.

[1] The redshift of a photon is defined by

$$z = \frac{\lambda_{\text{observed}}}{\lambda_{\text{emitted}}} - 1.$$

For an object at redshift 1, the observed wavelengths of all the radiation have been increased by a factor of two over the emitted wavelengths.

[2] In 1961 R Minkowski capped a distinguished career by obtaining a spectrum of the radio galaxy 3C 295 ($z = 0.46$) on his last night of observing.

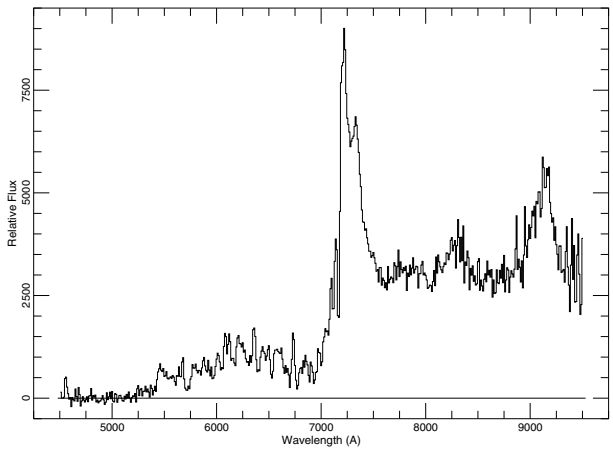

Figure 1. The spectrum of PC 1247+3406, the quasar with the highest known redshift ($z = 4.90$). The strongest emission line is Lyman α; the line at $\lambda = 9150$ Å is produced by C IV. The sharp drop in the continuum at wavelengths below the Lyman α emission line is absorption produced by intervening material.

Figure 1 displays the spectrum of PC1247+3406, the quasar with the highest known redshift ($z = 4.90$); this observation is a typical example of a high-redshift quasar spectrum. The most prominent feature is the Lyman α emission line; it is produced by the transition from the first excited state to the ground state in hydrogen, and has a rest wavelength of 1216 Å. At a redshift of 4 this feature is shifted from the far-ultraviolet to the red region of the optical spectrum. The second strongest emission line is that of thrice-ionized carbon (a doublet with rest wavelengths of 1548 and 1550 Å).

Redward of the Lyman α line the spectrum is relatively smooth and flat, but as one traverses the line to the blue, there is a dramatic decrease in the flux. At a redshift of 4 the level of the 'red continuum' is about twice that of the 'blue continuum'; in the highest-redshift quasars this drop becomes nearly a factor of four. High spectral resolution data show that the apparent decrease in the continuum level is actually due to a multitude of discrete absorption lines. This absorption is produced by individual 'clouds' of material along the line of sight; the strongest transition is Lyman α, and thus this region of the spectrum is referred to as the 'LYMAN α FOREST'. A second discontinuity frequently appears in the spectra of high-redshift quasars at a rest wavelength of ≈900 Å; in figure 1 it occurs at an observed wavelength near 5400 Å. This feature is the Lyman series limit, and is caused by a path through a neutral hydrogen column density of $\geq 10^{17}$ cm^{-2}.

Surveys for high-redshift quasars

The identification of high-redshift quasars presents a difficult challenge, as one can see from the nearly quarter-century lag between the initial quasar redshift and the discovery of the first $z > 4$ source. It is usually impossible to determine whether an image of an object, taken with a ground-based telescope, is a star or a quasar (remember that the word 'quasar' is derived from 'quasi-stellar'). Attempts to locate $z > 4$ quasars using radio observations were not successful (until quite recently). To discover high-redshift quasars with optical telescopes, a number of obstacles must be overcome (see also QUASISTELLAR OBJECTS: SURVEYS).

- High-redshift quasars are rare. On average there is one $z > 4$ quasar brighter than an R magnitude of 20 for every ≈15 square degrees of sky. Even in the regions of lowest stellar density (near the galactic poles), this amount of sky would contain approximately 10 000 stars of similar brightness.
- High-redshift quasars are red. At a redshift of 4, most of a quasar's light below 6000 Å is absorbed by intervening material. Photographic emulsions, the primary detector for wide area surveys, tend to be most sensitive in the blue. As one moves to higher redshifts, the bulk of a quasar's luminosity is observed in the near-infrared, where the background produced by the night sky is much higher than the AIRGLOW in the blue and visible regions of the spectrum.
- High-redshift quasars are faint. Only a small fraction of $z > 4$ quasars can be detected in the Palomar Sky Survey, which has served as the primary optical database for the second half of this century.

This sounds like a hopeless task indeed, until one notes that the optical spectrum of a high-redshift quasar is very different from the principal source of confusion, stars. In contrast to stars, whose spectral energy distribution is generally relatively smooth, high-redshift quasars possess a series of strong emission lines as well as broad and deep absorption features.

The explosion in the level of computational ability available to individual investigators in the 1980s led to a revolution in high-redshift quasar research. Using data obtained from either red-sensitive photographic plates or electronic detectors such as CCDs, it became possible to digitize large-scale surveys, find and characterize all objects using automated software packages (see SOFTWARE: DIGITAL SKY SURVEYS), and sift through the myriads of stars for the 1-in-10 000 source.

The vast majority of high-redshift quasars have been identified with optical telescopes. Discovery techniques include

- **Multicolor imaging.** The colors of all objects in a given region of sky are determined from images taken through a set of filters. The colors of stars fall along a well-defined locus of points in multidimensional color space, whereas high-redshift quasars lie significantly (often more than a magnitude) away from the stars. For example, if one performs a survey with the BRI filter set, the Lyman α emission line in a $z = 4.4$ quasar will fall near the center of the R filter. The $(B - R)$ color of the quasar will be extremely red (line-enhanced R emission compared to the Lyman α forest/Lyman-limit system depressed B flux) while the $(R - I)$ color will be moderately blue. Stephen Warren and his collaborators employed a multicolor technique to identify the first $z > 4$ quasar. To date about 60% of the $z > 4$ quasars have been found using multicolor photometry, including PC 1247+3406.
- **Slitless spectroscopy.** Multicolor imaging can be thought of as very low resolution spectrophotometry (spectral resolution of ≈5). Observing a large region of sky through a dispersive element (commonly referred to as the 'objective prism' technique) will produce spectra of all sources in the field with the spectral resolution defined by the instrumental configuration and the atmospheric seeing. This has the advantage over mulitcolor imaging in that all of the data are obtained at once as well as at considerably higher (≈50) spectral resolution at the cost of reduced sensitivity and higher source confusion (the spectrum from an individual object covers a much larger region of sky than does an image). Approximately one-sixth of the known high-redshift quasars have been found via this technique.
- **Variability.** It has been known since the discovery of the first quasars that they could exhibit spectacular variations in brightness; it is now believed that virtually all quasars display fluctuations of the 10–30% level on a timescale of years. Several high-redshift quasars have been identified by monitoring programs.
- **Serendipity.** In the summer of 1987 Patrick McCarthy and collaborators discovered a redshift 4.41 quasar (then the second largest redshift) while obtaining a spectrum

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of a RADIO GALAXY (the quasar was near the radio source and was in the spectrograph entrance aperture). This supposedly once-in-a-lifetime event was repeated a few years later with the identification of a $z = 4.21$ quasar.

Although optical investigations have produced the vast majority of high-redshift quasar identifications, other regions of the electromagnetic spectrum may provide substantial contributions in the near future. In 1994 Patrick Henry and collaborators identified a high-redshift quasar based on x-ray observations with the ROSAT satellite (this was the first $z > 4$ object that was not discovered through optical observations), and in 1998 the x-ray discovery redshift limit was raised to 4.45 with the identification of an $R \approx 23$ quasar. The latter observation was made possible because of the high accuracy (2 arcsec) of the x-ray positions; this level of positional accuracy will be met or exceeded by future x-ray missions.

RADIO ASTRONOMY, which was the prime source of the first two decades of high-redshift quasar work, has for the most part contributed very little to the discovery of $z > 4$ quasars, but this too may be changing. In 1997 Isabel Hook and Richard McMahon found a $z = 4.72$ quasar in a radio survey; this object was later shown to be a strong x-ray source as well. Large-scale radio surveys (e.g. the FIRST project with the Very Large Array) currently underway will within the next few years undoubtedly produce a multitude of high-redshift quasar candidates.

The SLOAN DIGITAL SKY SURVEY, which will image one-quarter of the sky (the North Galactic Cap) in five optical filters, should have an enormous impact on our understanding of high-redshift quasars. The filters were selected so that a multicolor identification technique will identify high-redshift quasars brighter than an R magnitude of ≈22; this should produce a sample of more than 1000 $z > 4$ quasars, an increase of nearly a factor of 20 over the number of currently known high-redshift quasars.

Scientific programs

The next decade will see an enormous increase in the observational database on high-redshift quasars; what are the important scientific issues that will be addressed? Since these objects are seen at such large redshifts, the radiation we detect was created billions of years ago when the state of the universe was quite different from the current conditions; standard cosmological models predict that the most distant quasars are seen when the universe was considerably less than 10% of its current age, the density was approximately 200 times that of the current value, and the temperature of the cosmic background radiation field was 16 K.

- **Constraints on cosmological models.** Soon after the discovery of the $z > 4$ population, George Efstathiou, Martin Rees and Edwin Turner pointed out the consequences of the existence of black holes of a billion solar masses within a billion years of the Big Bang. These objects provide one of the key constraints on theories of galaxy formation.
- **Quasar evolution.** Within a few years of the discovery of quasars, it was shown that they were a rapidly evolving population of objects; their co-moving number density out to a redshift of one was proportional to $\approx (1 + z)^6$ (or, from a chronological viewpoint, the number density of quasars has dropped by a factor of 50–100 in the past several billion years). Patrick Osmer published a study in 1982 suggesting that this rise with redshift did not continue indefinitely; it appeared that beyond a redshift of 3.5 the number density of quasars actually declined. A number of recent investigations, using both photographic plates and CCDs and a variety of detection methods, indicate that the number density of luminous quasars peaked near redshift 3 (see figure 2).
- **The properties of intervening material.** One of the most important (if not the most important) areas of quasar research does not involve the properties of the quasars themselves but the ability to investigate a wide variety of types of non-luminous matter through absorption features in the quasar spectrum produced by material that lies along the line of sight. Since the quasar must obviously be at a greater distance than the material for absorption lines to be created, the higher the quasar redshift the further back in time we can investigate non-luminous material; we can now trace the properties of a number of types of features (e.g. the Lyman α forest, haloes of galaxies) throughout nearly the entire history of the universe.
- **Evolution of abundances of the elements.** Quasars possess emission lines of elements produced only in stellar nucleosynthesis (e.g. carbon, oxygen); one might expect that the metal abundances of quasars would

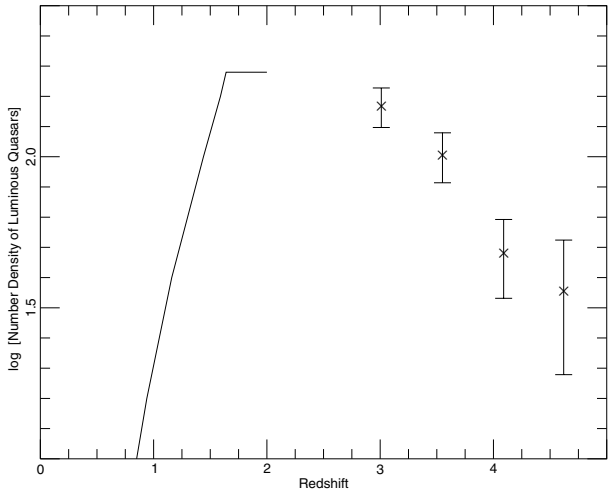

Figure 2. The number density of luminous quasars as a function of redshift based on low-redshift studies containing several hundred quasars (straight line, $z < 2$) and a $z > 2.7$ slitless survey with 90 quasars (points).

decrease with increasing redshift. An interesting aspect of quasar spectra is that, if one ignores the region shortward of the Lyman α emission line, where the high-redshift Lyman α forest removes a majority of the radiation, it is impossible to make any estimate of the quasar redshift if the spectrum is translated to the rest frame; in other words, there appears to be no evolution in the strengths of the emission lines. Quasar abundance determinations are notoriously difficult, but the best estimates suggest that even in the highest-redshift quasars the metal abundances are approximately ten times the solar value.

- **Detection of distant clusters of galaxies.** If high-redshift quasars mark the sites of substantial density perturbations, as seems plausible, it may be possible, with substantial efforts of observing time, to detect 'normal' galaxies that are physically associated with the quasar. Some preliminary studies have already yielded intriguing results.
- **Gravitational lenses.** The longer the path length to an object, the greater its chance of being gravitationally lensed; hence high-redshift quasars are attractive candidates for gravitational lenses. If a multiply imaged high-redshift quasar is found where the lens can be identified and characterized, one will have a test of General Relativity on the largest imaginable scale!

The first decade of $z > 4$ research has revealed much about the conditions of the universe in its first billion years. Nature has been able to assemble massive objects in that time, but we have clearly seen past the peak of quasar activity (at least in the rest frame optical and ultraviolet). At redshifts above 4 the absorption due to the Lyman α forest removes more than half of the incident radiation, and this opacity continues to increase at the limits of our measurements. These discoveries, and other results summarized in the bibliography, have been produced by a sample of a few dozen objects. The next ten years should witness a dramatic increase (more than a factor of ten!) in the number of known high-redshift quasars given the capabilities of planned optical surveys and the recent demonstration that both x-ray and radio observations can be effective methods for detecting $z > 4$ objects.

High-velocity Cloud (HVC)

An interstellar cloud of neutral hydrogen whose velocity exceeds, typically by 100–200 km s^{-1}, the rotational speed of the Galaxy (which is 220 km s^{-1}). Some HVCs are thought to have been produced by gravitational interactions—most notably the Magellanic Stream, a huge bridge of material between the Galaxy and the Magellanic Clouds, presumed to have been drawn out during a close passage in the past. Other HVCs may be clouds of intergalactic hydrogen falling into the Galaxy, or material expelled out of the galactic plane as supernova remnants and now falling back.

See: Magellanic Stream.

High-velocity Star

A star that is moving with very high velocity relative to the Sun, usually 65 km s^{-1} or more, faster than the average velocity of stars in the solar neighborhood. High-velocity stars are usually part of the galactic halo and move in very elliptical orbits which are highly inclined to the galactic plane. Hence they do not share the revolution of the Sun and other stars in the spiral arms of the Galaxy around the galactic center and are being left behind as the Sun races ahead of them. They may be remnants of a very early stage in the evolution of the Galaxy, so high-velocity stars are runaway stars.

Hind, John R (1823-1895)

English astronomer, discovered in 1852 a small nebula in Taurus which, in 1861, was found by HEINRICH D'ARREST to have disappeared. By the end of the year, D'Arrest and OTTO WILHELM STRUVE had recovered it. *Hind's variable nebula*, as it came to be called, demonstrated that at least some nebulae were small, as nothing larger than a light year in dimension can disappear in a year. The nebula is a reflection nebula which comes and goes as dark clouds intercept the light from its illuminating star. Hind discovered 11 asteroids, Nova Ophiuchus 1848, and became Superintendent of the Nautical Almanac Office.

Hinotori (Astro-A)

Japanese satellite, launched in February 1981 to observe the Sun during the peak of its 11-year cycle. Carried instruments to image x-rays from solar flares and detect x-ray emission lines from highly ionized iron in solar flares. Hinotori means 'firebird'. (See also ASTRO.)

Hipparchus

Hipparchus (2nd century BC) was the most highly regarded Greek astronomer in antiquity before Ptolemy. In a series of writings, only one of which has come down to us, he investigated a wide range of problems in observational and mathematical astronomy. In his most important works he studied the periodicities of the motions of the heavenly bodies and used observations to test and quantify geometrical models for those motions.

Biography and writings

Hipparchus was born at Nicaea in Bithynia (Iznik, Turkey) within the first half of the 2nd century BC. While living in Bithynia, he recorded observations of weather correlated with the solar year and the risings and settings of fixed stars. (Such weather calendars were produced by many Greek astronomers from the 5th century BC onwards.) The earliest dated observations that he appears to have made—there is some disagreement about whether they should be attributed to him—are determinations of the date of the autumnal equinox in 162–158. After this there is an 11 yr gap, and then about 25 observation reports spread through the years 147–127. These reports are known to us only because they are cited in Ptolemy's *Almagest* (see PTOLEMY). Ptolemy informs us that Hipparchus was on the island of Rhodes when he made observations in 141 and 128–127, and there are plausible arguments for supposing that he resided there through most of his working life. He was in contact with astronomers in Alexandria, and very likely also with those of Babylon (see BABYLONIAN ASTRONOMY). It is not known how long he lived after 127 BC.

Late in his career Hipparchus published an annotated list of his writings, which must therefore have been numerous; most, however, seem to have been comparatively short and dealt with specialized topics. In addition to the surviving *Commentary on the Phainomena of Aratus and Eudoxus* we know titles of about 14 books. Almost all the works that we know something about were connected with astronomy, although there exist tantalizing references to his investigations of falling bodies and combinatoric mathematics. A highly critical, even polemical, tone characterized certain of his writings (the *Commentary on the Phainomena*, the *Against the Geography of Eratosthenes* and the work on planetary models). Ptolemy, who among all the classical authors who praise Hipparchus was the most competent to judge him, singles out Hipparchus for his 'love of truth' and diligence.

Models and periodicities

In his studies of solar and lunar motion, Hipparchus assumed that each of these bodies has only one periodic anomaly and travels according to a simple kinematic model of either the epicyclic or eccentric variety (see PLANETARY THEORY FROM EUDOXUS TO COPERNICUS). In the epicyclic model, the body revolves uniformly about an epicycle, that is, a circle the center of which itself revolves uniformly on a larger deferent circle concentric with the Earth. In the eccentric model, the body revolves uniformly about an eccenter, that is, a circle surrounding the Earth but with its center at a fixed distance from the Earth's center; the direction from the Earth's center to the eccenter's center may be either fixed or uniformly rotating. The two kinds of model are, as Hipparchus knew, interchangeable. In various works Hipparchus attempted to determine the periodicities of the several circular motions presumed in these models and the relative sizes and orientations of the radii.

The approach that Hipparchus used to establish periodicities can be illustrated by his determination of the length of the mean synodic month and the Moon's period of anomaly. Hipparchus started out with a relation that was embedded in the Babylonian lunar theory known as System B:

$$251 \text{ synodic months} = 269 \text{ anomalistic periods.} \quad (1)$$

This relation can be read as saying that any interval of 251 synodic months bounded by a pair of conjunctions or oppositions has exactly the same length. Since the only direct way of observing the precise moment of a syzygy was at a lunar eclipse, Hipparchus found the smallest multiple of 251 synodic months that also brings the Moon roughly from one of its nodes back to one of its nodes, which is 4267 synodic months (or just short of 345 yr).

Conveniently, Hipparchus had access to records of observations of lunar eclipses made at Babylon this long before his time. To compare them with his own eclipse observations, however, would not have been easy. The Babylonian records would have been dated according to the regnal years of the Persian kings who ruled Mesopotamia, with dates in an observational lunar calendar and probably only the time of the beginning of obscuration noted. Hipparchus must have possessed a king list giving lengths of reigns, but he cannot have known the precise sequence of 29 and 30 day Babylonian lunar months over the several intervening centuries. He did, however, have a value for the length of the mean synodic month, again from the Babylonian system B theory:

$$1 \text{ mean synodic month} = 29;31,50,8,20 \text{ days} \quad (2)$$

(the numerals after the semicolon are to be read as sixtieths, sixtieths of sixtieths, etc). Hipparchus evidently had enough confidence in equation (2) to conclude that the resulting equation

$$4267 \text{ mean synodic months} = 126\,007 \text{ days} + 1 \text{ h} (+ \text{ less than } 4 \text{ min}) \quad (3)$$

was at least accurate to the nearest day, so that it would only be necessary to compare the times of observed eclipses 345 yr apart. To test for the constancy of the time interval, he found two pairs of observed eclipses such that in one pair the Moon was both times close to its maximum

apparent speed, and in the other pair close to its minimum apparent speed, so as to maximize any discrepancy. In comparing the times, Hipparchus had to estimate the duration of the eclipse observed in Babylon to find the mid-eclipse and take account of the geographical situations of Babylon and Rhodes to synchronize the times. He even introduced a correction for the small influence of solar anomaly. The result of this carefully thought out analysis was a confirmation of the accuracy of the Babylonian period relations (1) and (2). By a similar investigation of the magnitudes of widely separated eclipses, Hipparchus also confirmed a Babylonian value for the Moon's mean period of latitude.

To measure the length of the tropical year, Hipparchus attempted to determine the intervals separating three observations of the summer solstice, by Meton and Euctemon in 432 BC, by Aristarchus in 280 BC, and by himself in 135 BC. For the oldest of these observations, which was originally dated according to a lunar calendar, it is probable that Hipparchus had to determine the date in his own calendrical system by assuming a first approximation of the length of the year, and the date that he found looks as if it is a day too early. The interval that he found between Aristarchus' observation and his own was $52\,960\frac{3}{4}$ days, implying a tropical year of approximately 365;14,47,35 days, whereas between the Metonic observation and his own he appears to have counted 108 478 days, implying a tropical year of approximately 365;14,44,51 days. Remarkably, the latter value, which can only have arisen from comparison of observations at precisely the 297 year interval, is attested in a Babylonian tablet (which thus is strong evidence for Babylonian contacts with Hipparchus or someone who knew his work). On the other hand, Ptolemy cites several passages in writings of Hipparchus where he elects for the value 365;14,48 days. Ptolemy also reports that Hipparchus was led by his observations to suspect that the tropical year was subject to small short-term fluctuations.

Hipparchus' most famous accomplishment, the discovery of the PRECESSION of the EQUINOXES, was made in connection with these last measurements. During lunar eclipses, Hipparchus observed the elongation of the Moon from certain fixed stars close to the ecliptic, and from this he was able to deduce the elongation of the stars from the equinoctial points. As well as small inconsistencies, which he was ready to attribute to a wobble in the equinoctial points, he also found that the elongations were about 2° less in his own time than about 150 yr earlier, when Timocharis had performed similar observations. Hipparchus was uncertain of the nature of this displacement, hypothesizing among other things that the fixed stars close to the ecliptic might exhibit a very slow quasi-planetary motion of their own. Ptolemy was able to find passages in which Hipparchus seemed to maintain the model that Ptolemy himself adopted, that the fixed stars make a slow revolution about the poles of the ecliptic relative to the equinoctial points.

Hipparchus was the first known astronomer to deduce the eccentricity of a hypothetical orbit from selected observations. His method required three observations of the longitude of a heavenly body at known times; with approximate values for the periods of longitude and anomaly of the object in question, he could reduce the problem to the geometrical problem of finding the point from which the sides of a given triangle are seen as subtending given angles. A numerical solution further necessitated some sort of trigonometry, and Hipparchus is believed to have constructed a table of the lengths of chords of angles in a standard circle, perhaps the first such table.

In the case of the Sun, observations of the dates of two equinoxes and a solstice provided the required three positions, since, if the Sun travels on a great circle (the ecliptic), the longitudes of the tropical and equinoctial points must be separated by right angles. Taking the interval from vernal equinox to summer solstice as $94\frac{1}{2}$ days, and the interval from summer solstice to autumnal equinox as $92\frac{1}{2}$ days, Hipparchus calculated that the eccentricity of the Sun's hypothetical circular orbit was 1/24 of its radius, with the apogee $65\frac{1}{2}^\circ$ east of the vernal equinoctial point. This is the version of the solar model that Ptolemy later adopted. There is good reason to believe, however, that Hipparchus also performed the same calculations with at least one other pair of intervals ($94\frac{1}{4}$ days from vernal equinox to summer solstice, and $92\frac{3}{4}$ days to the autumnal equinox), hence obtaining a different eccentricity and apogee. What Hipparchus made of this is not known.

Similarly, Hipparchus measured the lunar anomaly twice, with conflicting results. In this instance, he used sets of three observed lunar eclipses, for which it was possible to estimate the Moon's longitude by calculating the diametrically opposite position of the Sun. Ptolemy later showed that the discrepancy arose from inaccuracies in Hipparchus' solar longitudes and time intervals. Again, we have no knowledge of how Hipparchus reconciled his results.

Ptolemy knew of no writings by Hipparchus on the planets comparable with his works on the solar and lunar models. He does, however, describe a book in which Hipparchus gave observational arguments for the inadequacy of the planetary models proposed in his time. According to Ptolemy, the critical defect Hipparchus exposed in these models was that they assumed a single periodic anomaly for each planet, so that, for example, their retrogradations were always of the same size and duration.

Other astronomical research

Hipparchus devised two methods of estimating the distance in Earth radii of the Moon from the Earth's center. The first method assumed that the distance of the Sun is effectively infinite, and finds the distance of the Moon by comparing observations of the magnitude of a solar eclipse seen in two localities on the same

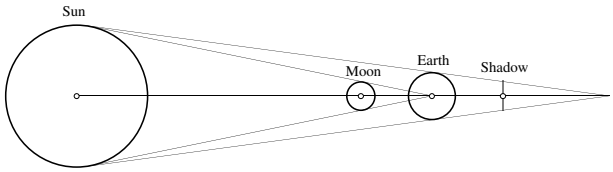

Figure 1. Hipparchus' eclipse diagram relating the Sun's and Moon's distance from the Earth.

meridian. The second method uses the eclipse diagram made familiar by Ptolemy to relate the distance of the Moon to a hypothesized solar distance. In this diagram (figure 1) it is assumed that the Sun and Moon subtend the same angle from the Earth's center and that the ratio of the diameter of the Moon to the diameter of the Earth's shadow at the Moon's distance is known. From these relations it is theoretically possible to derive the solar distance from the lunar distance and vice versa, although in practice small variations in the lunar distance correspond to extremely large variations in the solar distance. Assuming that the Sun is 490 Earth radii from the Earth's center (corresponding to a 'least perceptible' parallax of 7 arcmin), Hipparchus found the mean distance of the Moon as $67\frac{1}{3}$ Earth radii, while from the solar eclipse he found it to be 77 Earth radii.

With an approximate value for the distance of the Moon, Hipparchus was able to determine the magnitude of lunar parallax and correct observed positions accordingly. Regrettably little is known of the details of Hipparchus' handling of this topic. Of his work on the theory of eclipses, our most substantial information concerns his examination of the possible time intervals separating lunar and solar eclipses.

The most controversial part of Hipparchus' astronomical work is his star catalogue. His one surviving book, the *Commentary on the Phainomena of Aratus and Eudoxus*, is devoted to a detailed criticism of the detailed nonmathematical description of the constellations given by Eudoxus in the 4th century BC, and versified by Aratus a century later. The *Commentary* closes with a presentation of data concerning the risings, culminations, and settings of constellations, all of which presupposes numerous observations of stellar positions. Classical authors, particularly Pliny, make vague references to a Hipparchian star catalogue containing positions of the stars along with some indication of their brightnesses. Since Tycho, arguments have repeatedly been put forward, and repeatedly disputed, that the catalogue in Ptolemy's *Almagest* is an unacknowledged substantial reproduction of Hipparchus', with the longitudes adjusted to reflect the precessional motion between Hipparchus' time and Ptolemy's. At present the balance of evidence seems to preponderate in favor of the hypothesis that Ptolemy depended heavily on Hipparchus' catalogue.

Hipparcos

The Hipparcos space astronomy mission was dedicated to the very accurate measurement of star positions, and their distances and motions in space. The satellite was designed, built and operated under the responsibility of the EUROPEAN SPACE AGENCY (ESA), with the guidance of an international scientific advisory committee. Launched in August 1989 and operated until mid-1993, two resulting star catalogs were completed and published in 1997: the Hipparcos Catalog is a high-accuracy compilation of nearly 120 000 star positions, distances and space motions; the Tycho Catalog is a lower-accuracy catalog of slightly more than one million stars. Together they represent astronomers' best understanding of the space distribution, space motion, and corresponding physical properties of stars in the solar neighborhood. The experiment was carried out within a large collaboration of about 200 mainly European scientists.

Background

Catalogs of star positions have been compiled for more than two thousand years. The name of the ESA mission, as well as being an acronym for 'high precision parallax collecting satellite', reflects the contribution of the ancient Greek astronomer HIPPARCHUS who prepared a naked-eye catalog of about 1000 stars around the first century BC.

Over the past few hundred years, improved instruments and observational techniques have led to star catalogs of continuously improving accuracy and size. This astronomical discipline, technically referred to as ASTROMETRY, has led to a greatly improved picture and comprehension of our place in our Galaxy. Directly and indirectly the accurate measurement of star positions has provided profound insights into the content and structure of the universe as a whole.

Star position measurements in the 17th century were directed at compiling catalogs to assist sea navigation and the determination of longitude, but measurements were also aimed at furthering scientific understanding of the Earth's motion in space. During the 18th and 19th centuries positional improvements led to the detection of small changes in the relative positions of stars, attributed to the motions of the stars themselves through space. The realization that stars lie at finite, albeit very large, distances from our own solar system led to intensified efforts at measuring the effect of PARALLAX, which is the apparent displacement of nearby stars compared to more distant stars as the Earth moves in its orbit around the Sun. Because of their enormous distances, the resulting angular displacements are very small, and even the nearest stars have parallaxes of only about 1 arcsec ($1/3600^\circ$). For more distant stars the effect is much smaller. Consequently, to measure stellar distances even within our Galaxy, angular accuracies very much better than 1 arcsec are required.

Similar considerations apply to the measurements of PROPER MOTION, which are the changes in angular position on the sky with time resulting from the projection, on the plane of the sky, of the star's motion through space. While the largest proper motions reach about 10 arcsec per year, typical stellar motions within our Galaxy, of the order of several tens of km s^{-1}, combine with their considerable distances to result in typical angular positional motions of only a few hundredths of an arcsec per year. Ground-based proper motion measurements can often discern these tiny motions, in particular by extending the observational baseline over decades. Nevertheless, reaching very high proper motion accuracies, with minimal systematic errors, faces problems similar to those encountered for high-accuracy parallax work.

Because of the size of the effects involved, the measurement of stellar parallaxes from the ground has always been very difficult, and complicated primarily by the perturbing effects of the Earth's atmosphere. Measurements are made relative to an average parallax of more distant background stars, and an estimate of this background parallax is accounted for in the correction of the measured (relative) parallax to an absolute value.

In the 1960s an alternative approach for measuring parallaxes was developed, with particular emphasis on obtaining absolute rather than relative values. The basic idea was to combine the images from two areas of sky onto one detector, and to do this at different times of the year. The parallactic displacements for the two fields would then be uncorrelated, and relative measurements would therefore circumvent the parallax zero-point problem. It was soon realized that such technology could not be employed from the ground, as it required a stable and precisely known angle between the two viewing directions, which was affected by variable atmospheric refraction, along with gravitational and thermal effects. The first ideas for implementing this technique in a space mission were submitted by P Lacroute in France in 1966. The implementation appeared too complex at that time, in particular with respect to the construction of the mirror necessary to combine the two viewing directions, and in 1970 further studies for a space mission were suspended.

The basic idea, however, survived and with the input of several new ideas, the concept of a space astrometry mission became more realistic. A meeting on space astrometry in Frascati in 1974 marked the start of what was to develop into the Hipparcos project. Its official status as an ESA study was obtained in 1976, and growing recognition of the fundamental importance of being able to obtain greatly improved stellar distances and space motions led to the acceptance of the Hipparcos mission within ESA's scientific programme in 1980.

For the 120 000 stars observed and contained within the Hipparcos Catalog, mean errors in positions, parallaxes, and annual proper motions are around 0.001 arcsec, a value which yields distance accuracies of 10% for stars at a distance of 100 pc. These numbers can be compared with the relatively small number (about 8000 stars in the 1995 Yale Parallax Catalog) of pre-Hipparcos parallaxes accumulated through a century of astrometric work, and with the lower precision

(5–10 milliarcsec at best) of the classical photographic parallaxes. Modern ground-based electronic parallax observations (e.g. from the US Naval and Allegheny observatories) are comparable to Hipparcos both in precision and accuracy, but only a few hundred stars, mostly quite faint, have been observed to date. Hipparcos therefore provides the unique source of large numbers of high-quality parallaxes for bright stars; these are the data needed for most luminosity calibration and distance-scale problems.

As the first satellite devoted to star position measurements, the scientific interest in the Hipparcos results has led to plans for future space missions aiming at significantly higher angular accuracies, of a few millionths of a second of arc, and for a very much larger number of stars.

Operational principle

The Hipparcos satellite was built by a large European industrial consortium, led by Matra Marconi Space and Alenia Aerospazio, under contract to ESA. The satellite comprised a spacecraft platform, including the power, telecommunications, attitude and thermal control subsystems, and the payload containing the optical telescope and detector chains (table 1). The satellite was launched by an Ariane 4 rocket, flight V33, on 8 August 1989, and was operated from ESA's satellite operations center at ESOC (Darmstadt, Germany) through ground stations at Odenwald (Germany), Perth (Australia), Goldstone (USA), and Kourou (French Guyana).

Table 1. Instrument characteristics.

Optics	
Telescope configuration	All-reflective Schmidt
Field of view	$0.9^\circ \times 0.9^\circ$
Separation between fields	58°
Primary mirror diameter	0.29 m
Focal length	1.4 m
Scale at focal surface	6.8 μm arcsec^{-1}
Mirror surface accuracy	$\lambda/60$ rms at 550 nm
Primary detection system:	
Modulating grid	2688 slits
Slit period	1.208 arcsec (8.2 μm)
Detector	Image dissector tube
Photocathode	S20
Scale at photocathode	3.0 μm arcsec^{-1}
Sensitive field of view	38 arcsec diameter
Spectral range	375–750 nm
Sampling frequency	1200 Hz
Star mapper (Tycho) system:	
Modulating grid	4 slits at 90° to scan
	4 slits at $\pm 45^\circ$ to scan
Detectors	Photomultiplier tubes
Photocathode	Bi-alkali
Spectral range (B_T)	$\lambda_{\rm eff}/\Delta\lambda = 430/90$ nm
Spectral range (V_T)	$\lambda_{\rm eff}/\Delta\lambda = 530/100$ nm
Sampling frequency	600 Hz

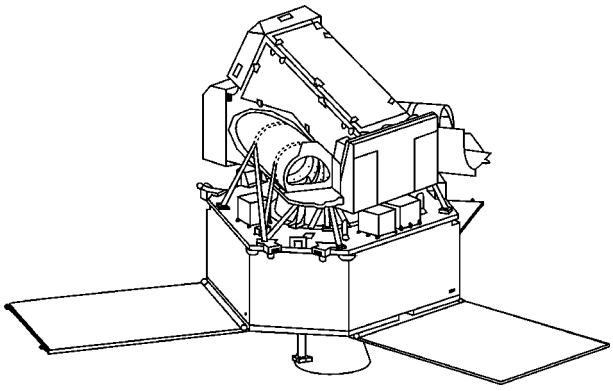

Figure 1. The Hipparcos satellite configuration with the three solar array panels deployed (seen at bottom). The hemispherical apertures define the two viewing directions. The satellite rotated about the vertical axis.

Originally intended to be stationed in a geostationary orbit, the apogee boost motor intended to circularize the orbit failed to function, and the mission was conducted from a highly elliptical transfer orbit. Apart from a considerable increase in operational complexity and a reduced fraction of useful observing time, the unplanned orbit had a relatively small effect on the data quality, and all of the mission's original goals were comfortably surpassed. Nevertheless, the high particle radiation levels in the operational orbit led to a progressive deterioration of certain satellite elements (gyroscopes, thermal control, telecommunications). Useful observations ceased in March 1993, and satellite operations were terminated on 15 August 1993. More than three years of useful data had been acquired, exceeding the 2.5 yr design goals.

The satellite comprised a small but highly accurate optical telescope, with a primary mirror diameter of about 0.3 m, and with two distinct viewing directions separated by about 58° (figure 1). A beam combiner mirror brought the light from the two viewing directions to a common focal surface. A highly accurate grid system in the focal surface modulated the star images, and the modulated light was sensed by a detector located behind the grid. The measurement principle was similar to that used in ground-based meridian instruments, the purpose of both types of instrument being the determination of accurate transit times. In the case of meridian telescopes the stellar images pass through a set of slits as a result of the Earth's rotation. In the case of Hipparcos, the passages were the results of the satellite rotation, which was maintained at a roughly constant spin rate of approximately 168 arcsec s^{-1} through the periodic firing of 20 mN gas jet thrusters. These were activated in order to maintain the required attitude, itself sensed by the passage of bright stars across the satellite's star mappers. The near simultaneity of measurements obtained in the two fields of view, together with the satellite scanning, made it possible to obtain a very accurate calibration of the angle between the two viewing directions, using closure conditions on the observed great

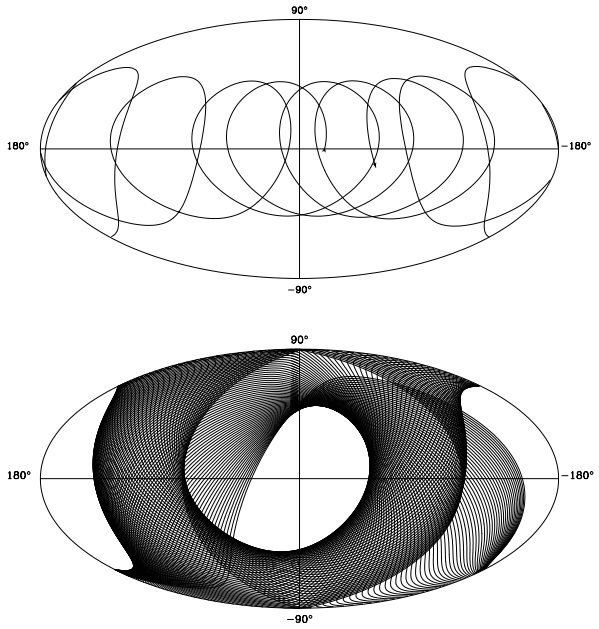

Figure 2. The scanning motion of the Hipparcos satellite on the celestial sphere, shown in ecliptic coordinates. Top: the path of the spin axis between 22 May 1990 and 23 September 1991. Bottom: the two viewing directions swept out great circles on the sky: one out of five of every great circle scan is shown for the interval 22 May 1990 to 14 July 1990 (courtesy F van Leeuwen).

circle. As a result, the very precise relative separations measured in the $0.9^\circ \times 0.9^\circ$ combined field of view could be transformed into very precise large angular separations on the sky.

Scanning the entire sky in a continuous and regular manner, whilst maintaining a constant inclination of the spin axis to the Sun direction for thermal control reasons, the observations were used to build up a network of one-dimensional angular measurements between the stars (figure 2). Scanned at different orientations and at many different epochs throughout an operational lifetime of about 3 yr, the on-ground processing then led to the reconstruction of the positions, distances, and proper motions of each star.

The two widely separated viewing directions led to the construction of a very rigid positional frame, and to the possibility of determining absolute parallaxes, in which the stellar distance determinations are independent of the assumed distance to other stars. The resulting network of star positions and proper motions was, however, not directly connected to other independent reference points, but was attached to a quasi-inertial system through the linking of the resulting star positions to those of extragalactic objects, especially extragalactic radio sources. As a result, the Hipparcos reference frame is the optical realization of the International Celestial Reference System (ICRS): the catalog positions are on the same reference system as VLBI radio measurements, and the proper motions are inertial.

Satellite observations were conducted on the basis of an 'input catalog', the compilation of target stars to be observed throughout the mission. Selected stars were chosen on the basis of their scientific importance (as perceived during the years before launch), taking into account operational and data reduction requirements of a reasonably uniform distribution of stars on the sky, with a surface density of about 3 stars per square degree. The magnitude distribution down to the observational limiting magnitude of about 12 mag also had to be consistent with the available observing time as a result of the regular scanning motion of the satellite.

Stellar images modulated by the grid in the focal surface were sampled by an image dissector tube's sensitive area, pointed sequentially to the star positions defined by the input catalog, and sampled at 1200 Hz. A data rate of 24 kb s^{-1} yielded a data stream distributed to and analysed by three European scientific consortia. The data analysis tasks were lengthy and complex, and proceeded from the raw satellite data, using the attitude determination on the basis of the satellite's sky mappers, to yield one-dimensional positions of the stars along a reference great circle at the epoch of observation.

Data analysis

The interconnection of all of the reference great circle data obtained throughout the mission, during which the sky was scanned at many different epochs, and at many different position angles, eventually yielded the two-dimensional positions of each star (in right ascension and declination), the time-dependent proper motion of each star due to its motion through space, and the additional annual elliptical component of motion due to the Earth's motion around the Sun, which provides the stellar distances. The radial component of the space velocity of each star (which can be obtained spectroscopically from the Doppler shift of the star's spectrum), needed to complete the full six-dimensional Cartesian coordinate location of each star (the three positional components and the three velocity components), was not measured by the Hipparcos satellite.

The entire data analysis chain, from the determination of one-dimensional great circle coordinates and their interconnection through the 'sphere reconstruction' step, was iterated a number of times to achieve full consistency and convergence. Results were verified through extensive cross-checks of the results of two parallel reduction efforts before publication. Median accuracies, around 1 milliarcsec (mas), depend primarily on the star magnitude (the Hipparcos measurements are in a broad-band system, referred to as Hp), and on its ecliptic latitude, due to the form of the scanning law (figure 3).

The more complex observational behavior of double and multiple stars and astrometric binaries were subjected to specific analysis procedures. In the case of resolved double or multiple systems, the results yielded accurate angular separations, position angles, and magnitude differences at the various epochs of observation, and these

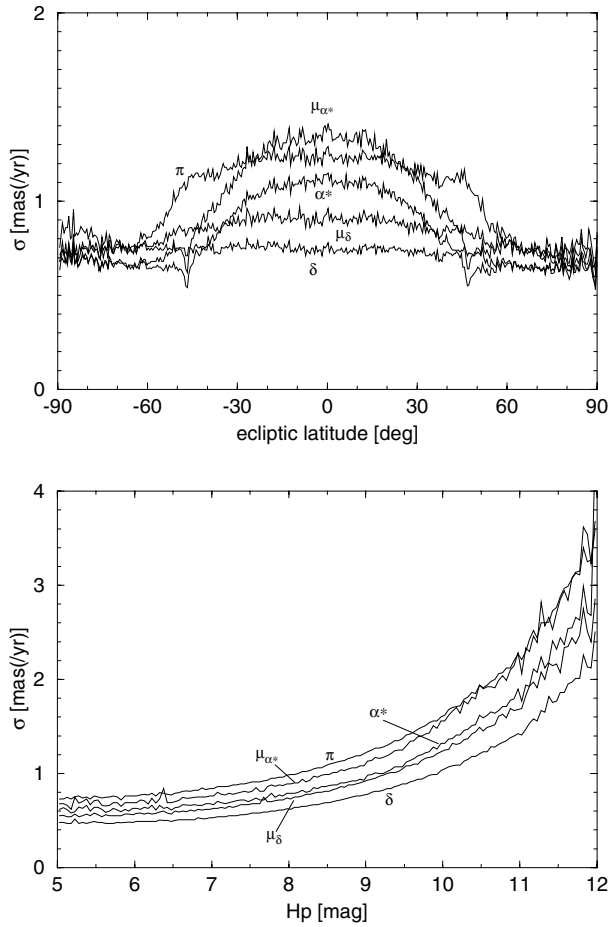

Figure 3. Hipparcos Catalog errors as a function of position and magnitude. Top: median standard errors of the five astrometric parameters as a function of Hp magnitude. The unit of the standard error is milliarcsec (mas) for the positional components (α, δ) and parallax (π), and mas yr^{-1} for the proper motion components ($\mu_{\alpha*} = \mu_\alpha \cos\delta$, μ_δ). Bottom: median standard errors of the astrometric parameters as a function of ecliptic latitude. The dependency on ecliptic latitude is a consequence of the ecliptic-based scanning law. The errors are given at the catalog epoch, J1991.25 (courtesy H Schrijver).

results were compiled into a specific annex of components of 12 195 double and multiple systems. A further 235 orbital systems, 2910 astrometric binaries (recognized through the nonlinear motion of their photocenters), and 8542 suspected non-single objects make up the total of 23 882 solved or suspected double or multiple systems classified in the Hipparcos Catalog.

Although the primary objective of the mission was the determination of accurate astrometric data, the positional results were obtained from a modulated stellar signal whose careful analysis and calibration yielded a substantial database of homogeneous photometric data which is contained in annexes to the main Hipparcos Catalog. Each star was observed an average of about 110 times throughout the 3 yr mission, yielding a median broad-band photometric precision of about 0.0015 mag for stars brighter than 9 mag. The results provide extensive data on stellar variability. As a result of the photometric analysis undertaken in advance of the catalog publication, 11 597 stars were classified as variable, of which 8237 were newly identified as such. Of these, 2712 stars were classified as periodic variables, with light curves provided in the catalog annexes, and 5542 non-periodic and unsolved variables were classified, of which 4145 were newly identified. These results have underlined the quality of photometric data which can be acquired above the Earth's atmosphere, and have led to greatly improved categorization of stellar luminosity and variability as a function of position in the HERTZSPRUNG–RUSSELL DIAGRAM.

The Tycho Catalog of more than one million stars, of lower astrometric accuracy than that of the main catalog, was constructed from the data derived from the satellite's sky mappers. It provides a positional reference catalog with about 25 stars per square degree, with a limiting magnitude of about $V = 11.5$ mag, completeness at about $V = 10.5$ mag, and a median precision at the catalog reference epoch of about 25 milliarcsec. The median astrometric precision is about 7 milliarcsec for stars brighter than 9 mag, and systematic errors are expected to be below about 1 milliarcsec.

Although the majority of objects contained within the Hipparcos Catalog are stars within our Galaxy, about 45 are bright stars in the Magellanic Clouds. In addition, a particular effort was devoted to obtaining observations of all solar system objects which could be observed by the satellite, taking into account the observing constraints of magnitude, angular size, and proximity to nearby bright objects (planets). In total, 48 minor planets and three planetary satellites (J II Europa, S VI Titan, S VIII Iapetus) were observed by the main experiment. Observations of solar system objects were complicated by their non-point-like nature, which affects the phase estimates (due to the varying solar aspect angle) and their resulting relation to stellar positions. Additionally, their rapid motion on the sky called for specific treatment of the data during their crossing of the instrument's focal plane.

Following the scientific analysis phase, the European Space Agency published the results of the project on behalf of the scientific collaborators in June 1997: the Hipparcos Catalog is a 17-volume publication containing the positions, distances, proper motions, and photometric, variability, and multiplicity properties of the more than one hundred thousand stars brighter than about 12 mag observed by the satellite (see HIPPARCOS AND TYCHO CATALOGUES). Volume 1 is an introduction and guide to the catalog data, including sky distributions illustrating statistical properties of the data. Volumes 2–4 document the satellite measurement and operational principles, and the construction of the Hipparcos and Tycho Catalogs respectively. Volumes 5–9 contain the main Hipparcos Catalog, with annexes of double and multiple star data

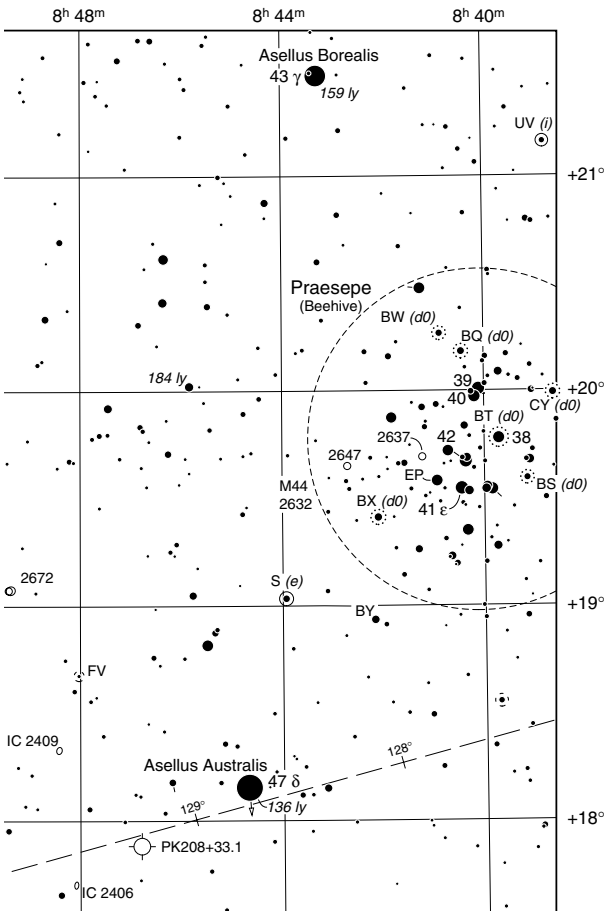

Figure 4. The Hipparcos and Tycho Catalogs are the basis for Sky Publishing Corporation's three-volume *Millennium Star Atlas*, published in 1997. Each square represents an area of 1 square degree. Graphical representation of magnitudes and variability, and of nearby and high-proper motion stars, is included in the Atlas. This example is from Chart 712, and includes the Praesepe star cluster (courtesy Sky Publishing Corporation and ESA).

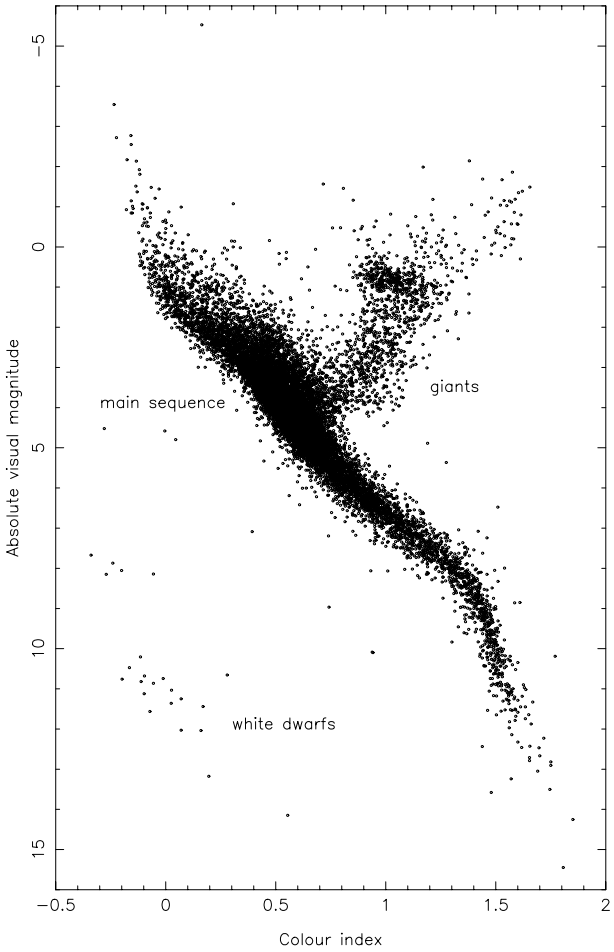

Figure 5. The Hertzsprung–Russell diagram (absolute visual magnitude, M_V, versus color index $B - V$) for about 14 000 single stars within a sphere of radius 100 pc centered on the Sun, taken from the Hipparcos Catalog. The few objects lying between the main sequence and the white dwarf sequence mostly arise from color index errors in the catalog.

(Volume 10), variability data and light curves (Volumes 11–12), and identification charts (Volume 13). Volumes 14–16 are sky charts of the Hipparcos and Tycho Catalog, comprising the Millenium Star Atlas, and indicating the most significant motions, distances, duplicity and variability properties (figure 4). All results from the mission, including intermediate astrometric data and individual photometric measurements, are included in the 6 CD-ROMs of Volume 17. The Hipparcos results can also be accessed via the WWW.

The scientific effort involved in the preparation of the Hipparcos mission and in its data analysis was substantial: some 200 scientists were involved in various aspects of the mission, in many cases for the 18 yr project's duration, from acceptance by ESA (or before) to the catalog publication.

Catalog details

The basic astrometric data in the Hipparcos and Tycho Catalogs include directions (positions), specified by celestial coordinates, their rate of change (proper motions), and trigonometric parallaxes. They are the first observational catalogs to contain parallaxes in addition to positions and proper motions for all stars in the observing programme. Positions and proper motions are given within the International Celestial Reference System (ICRS), which is consistent with the conventional equatorial system for the mean equinox and equator of J2000, previously realized by the FK5 Catalog. Timing of events is consistently based on terrestrial time (TT).

The standard astrometric model for a single star assumes uniform rectilinear space motion relative to the solar system barycenter. At some reference epoch, T_0, the motion of a star is described by the following six

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

parameters: barycentric coordinate direction, specified as right ascension, α, and declination, δ; annual parallax, π, from which the coordinate distance is $(\sin\pi)^{-1}$ astronomical units (to sufficient approximation, the distance in parsec is given by $1000/\pi$, where π is expressed in milliarcsec); the rate of change of the barycentric coordinate direction expressed as proper motion components $\mu_\alpha \cos\delta$ and μ_δ, in angular measure per unit time; radial (i.e. line of sight) velocity, V_R, in linear measure per unit time. The radial velocity is normally obtained from spectroscopic observations. The remaining five parameters are determined from analysis of the Hipparcos observations and are given for almost all stars in the catalog.

The standard astrometric model was adequate for the majority of stars, including the components of most resolved double and multiple stars. For several thousand apparently single stars, however, the standard model did not give an acceptable fit to the observations. These are probably binary stars, in which the center of light describes a curved path on the sky due to the orbital motions of the components around their common center of mass. For such 'astrometric binaries' additional parameters were introduced to describe the motion in accordance with the observations. In most cases a good empirical fit was obtained by including one or two additional terms in the Taylor expansion of the variation of the barycentric coordinate direction with time. In a few hundred cases even this was not sufficient, and Keplerian elements (sometimes partially based on existing ground-based data) were introduced to describe the orbital motion of the photocenter.

The catalog reference epoch is T_0 = J1991.25(TT), close to the central epoch of observations (the distinction between the epoch which specifies the equinox and equator of a coordinate system, typically B1950 or J2000, and the epoch at which the star passed through the given position, should be noted). The International Celestial Reference System (ICRS), as represented by the Hipparcos and Tycho Catalogs, replaces the FK5 system as the practical definition of celestial coordinates in the optical region. The construction of the ICRS ensures that no discontinuity larger than the uncertainty of the FK5 system occurs in the transition from FK5 (mean equinox and equator J2000) to ICRS. Thus, from the viewpoint of optical astrometry, the Hipparcos and Tycho Catalogs can be regarded as an extension and improvement of the J2000(FK5) system, retaining approximately the global orientation of that system but without its regional errors. However, the Hipparcos and Tycho Catalogs have not simply been tied to the FK5 system, but to the ICRS through the extragalactic radio frame. Providing positions within the ICRS means that they are consistent with present knowledge of the (extragalactic) radio reference system. Providing proper motions within the ICRS means that they are consistent with the best present realizations of a quasi-inertial reference system (i.e. non-rotating with respect to distant galaxies).

Since parallax is explicitly derived in the data reduction, the directions represented by the right ascension and declination at epoch T_0 are strictly barycentric. In previous astrometric catalogs, the unknown displacement due to parallax for each observation perturbed the final catalog positions.

At the accuracy achieved by Hipparcos, general relativity effects cannot be ignored. In the relativistic framework, the observed directions are 'proper directions' referred to the Lorentzian frame moving with the observer. In order to relate the observed directions at different epochs and of different objects to a simple geometrical model of the stars and their motions, the 'local' effects of the moving observer (stellar aberration) and space curvature (gravitational light deflection by the Sun) are removed by transforming the proper directions to 'coordinate directions' corresponding to the coordinate differences between the object and observer, expressed in the (solar system) barycentric coordinate system.

Stellar aberration was computed from the barycentric motion of the satellite, using the full relativistic formula and combining the geocentric satellite velocities accurate to about 0.2 m s^{-1}, determined by the ground stations, with the appropriate ephemeris for the barycentric motion of the Earth. Gravitational light deflection was computed in the heliocentric metric, assuming spherical symmetry. The treatment of aberration is consistent with the IAU (1984) recommendation that the total barycentric velocity of the Earth should be used; prior to that date the elliptic component of velocity, which changes very slowly with time, was conventionally ignored.

For the propagation of the astrometric parameters and their covariances to arbitrary epochs, normally only the changes in α and δ, due to the proper motion, are appreciable. In rigorous treatment the time dependence of all six parameters must however be explicitly considered, as described in the published catalog.

The proper motions are instantaneous rates of change of the barycentric coordinates at the epoch T_0. For stars with large parallax, large proper motion, and large radial velocity, the apparent acceleration of coordinates due to perspective effects may be significant. These can be calculated on the assumption of uniform space motion relative to the barycenter, and were accounted for, in the case of the few most significantly affected stars, in reducing the individual observations to T_0.

Scientific applications

The resulting stellar distances and motions impact on all areas of astronomy and astrophysics, but most particularly on the understanding of stellar structure and evolution, and the structure and dynamics of our own Galaxy. More than twenty thousand stars out to distances of about 100 pc now have their distances known to better than 10%, and another thirty thousand are known to better than 20%. Table 2 lists the 20 stars closest to the Sun, as deduced from the Hipparcos parallaxes, and supplemented by Yale

Parallax Catalog data for nearby stars too faint to be observed by Hipparcos.

Stars differ from each other in many important respects: in their mass, chemical composition, size, rotation rate, age, and in many other details. Understanding their composition and structure, how and where they were born, how they are evolving, and how they will eventually die, means determining their individual properties, and comparing them with detailed models of their initial conditions and subsequent evolution, involving a very comprehensive understanding of many areas of physics. Specifically, knowing the luminosity of a star requires knowledge of the star's distance, in order to convert its apparent magnitude into an absolute luminosity. The Hertzsprung–Russell diagram is the distribution of absolute magnitude versus color index. In its observational form (figure 5) it reveals one of the most important correlations of stellar properties known. The Hipparcos results have made significant contributions to the understanding of stellar properties, through the improved definition of their luminosities.

Comparing theoretical models with measurements of the brightnesses, temperatures, masses, and ages of the stars provides direct information on whether present understanding of the star formation process and subsequent evolution are correct. Ultimately, it leads to an understanding of the internal structure and other 'hidden' properties of the stars, since only when the correct physical ingredients and processes are included will the models agree with ever-improving observations. In the context of the relatively new discipline of asteroseismology, in which stars other than our Sun are scrutinized for observational signatures of solar-like oscillations, accurate distance measurements yield precise stellar luminosities, and thus provide a direct check on models of internal stellar structure.

The collective positional and kinematical distribution of the one hundred billion stars comprising our own Galaxy are linked through their gravitational environment, and via the history of star formation throughout the Galaxy. The initial properties are subsequently modified, often substantially, by small- and large-scale dynamical processes. Thus present-day star positions and motions encode the details of the initial formation and subsequent evolution of our Galaxy.

The Hipparcos Catalog results have led to important progress in understanding the space and velocity distribution of nearby stars. This knowledge is used to define the distribution of stellar luminosities, the distribution of stellar masses, and the kinematical behavior of stars in the solar neighborhood. Additionally, by observing the distances and motions of stars perpendicular to the plane of our Galaxy, the results have also been used to probe the distribution of 'dark matter' in the Universe, which is inferred to exist from cosmological and other arguments. This is possible because stars act as kinematic tracers, probing the gravitational signature of material irrespective of its physical manifestation. The results support a growing consensus concerning the main structural parameters of the galactic disk populations of stars, and on the possible distribution of dark matter in our Galaxy.

The Hyades is the nearest moderately rich open CLUSTER, whose distance has been the subject of intense interest and investigation over a very long period, due to its central role in defining the entire distance scale used in astronomy. More generally, clusters are important because they represent a gravitationally bound collection of typically a few hundred stars, born at the same time, and with a given chemical composition. The development of such a coeval system, both dynamically and with respect to the individual stellar properties such as temperature and luminosity, therefore provides an ideal laboratory for testing models of stellar evolution. Open star clusters are also subject to 'evaporation' and eventual disruption over timescales of tens or hundreds of millions of years due to gravitational encounters between stars within the cluster, or between the cluster and the galactic disk or giant molecular clouds. Hipparcos has provided a reliable direct distance measurement to about 200 stars in the Hyades cluster, allowing its internal structure, internal motion, mass segregation, and disintegration processes to be observed.

Distance estimates for clusters out to several hundred parsec have also been measured directly with Hipparcos. These are being used to extend the distance scale calibrations, and to verify models of stellar evolution according to age and chemical composition.

The problem of deriving accurate distances to objects throughout our Galaxy, beyond distances which are directly accessible by means of trigonometric parallax determinations, is one of the central themes in present day astronomy. On the largest scales, distances to other galaxies affect our knowledge of the HUBBLE CONSTANT. While most astronomers do not question the fact that the universe is expanding, the actual expansion rate is still vigorously debated. The precise value, as given by the Hubble constant, is of more than quantitative interest, since theories seeking to explain the formation and subsequent evolution of the early universe now predict properties of the present day universe which are becoming ever more stringently constrained by observations. Cepheid variables have played a very crucial role in these discussions, due to their regular pulsations with a period considered to depend primarily only on their luminosity. The Hipparcos results on these and other objects is leading to more secure distance scales within and beyond our Galaxy.

Hipparcos results are facilitating efforts to determine stellar ages and, in particular, to date the oldest stellar populations in our Galaxy, the GLOBULAR CLUSTERS. These ages therefore provide a lower limit on the age of the universe. Pre-Hipparcos estimates had put some globular cluster ages as high as 18 Gyr, older than current cosmological age estimates of the universe itself. Revised ages, derived from the new distance measurements, of perhaps 12–14 Gyr may have alleviated this age paradox.

Future developments

A number of proposed space missions are set to exploit the possibilities of measuring significantly more accurate stellar positions from space. The SPACE INTERFEROMETRY MISSION (SIM) is a US mission which will employ a medium-sized pointed interferometer to establish measurements of several tens of thousands of stars with microarcsec precision. GAIA is a mission under consideration by the European Space Agency which will combine the basic principles of Hipparcos with numerous innovative features, and which will result in microarcsec positional accuracy for approximately one billion stars. In addition to the satellite's two main astrometric lines of sight, a third viewing direction is devoted to the acquisition of radial velocities of the brighter 10^8 or so stars, down to about 17 mag. Sampling roughly 1% of the stellar population of our Galaxy, GAIA is designed to provide a six-dimensional spatial and velocity mapping extending throughout the Galaxy. The motivation is to rectify the shortcoming of classical two-dimensional star measurements by providing the third space component of the star's velocity vector, important for understanding and interpreting stellar kinematics and dynamics.

GAIA will be positioned and operated at the Sun–Earth LAGRANGE POINT L2, roughly 1.5×10^6 km from Earth, which provides a rather benign thermal environment, and an absence of eclipses and occultations. It will demand data transmission rates of about 1 Mb s^{-1} throughout the planned 5 yr lifetime. The payload will employ larger optics, CCD detectors giving higher efficiency and parallel observation of many more stars, and innovative approaches to the problem of structural and thermal stability, yielding positions nearly a thousand times better than Hipparcos. GAIA will circumvent the complexities of an 'input' or pre-defined observing catalog, and select its targets autonomously on-board. The goal is to observe essentially every star down to 20 mag, thereby largely eliminating the problems of 'selection effects' which plague the interpretation of catalogs relying on the pre-selection of objects. At an average of around 25 000 stars per square degree GAIA will dwarf the Hipparcos Catalog's 3 stars per square degree, or even the Tycho Catalog's 25.

Hipparcos and Tycho Catalogues

The decision of the International Astronomical Union to adopt the new celestial reference system ICRS (see EXTRAGALACTIC REFERENCE FRAMES), and its realization in the radio domain (ICRF, see SPACE AND TIME REFERENCES: CONCEPTS), was contingent upon the completion of a secondary catalog of star positions and proper motions in optical wavelengths. The only suitable catalog was the one obtained from the data of the Hipparcos space astrometry mission (see HIPPARCOS).

Reference frame of the Hipparcos Catalogue

Hipparcos measured the angles between the objects in its observing list. From these and their variations with time, positions, proper motions and parallaxes were calculated in a single coordinate system. However, because the angles are invariant with respect to a rigid rotation of the coordinates, the axes of this preliminary Hipparcos Catalogue were arbitrarily placed and had an arbitrary linearly time-dependent rotation. The necessary link to ICRS could then be expressed as a rotation vector R that would bring the coordinates and proper motions into the ICRS:

$$R = \epsilon + \omega(T - T_0).$$

where ϵ is the rotation vector to be applied at a reference time T_0 and ω is the yearly spin vector. The components of ϵ and ω were obtained by comparing the positions and/or proper motions of stars in the preliminary Hipparcos Catalogue with those observed with respect to extragalactic radio sources of the ICRF or more generally to galaxies which were assumed to be remote enough in order to be considered as fixed. Ten different programs were organized to provide the necessary relations to determine R. They included observation of radio stars with respect to ICRF objects by VLBI or connected radio interferometers, special large-scale photographs including Hipparcos stars and galaxies taken at two largely separated epochs, the use of large proper motion surveys made with respect to galaxies and the comparison of Earth rotation parameters obtained by VLBI and optical astrometry using Hipparcos positions. The synthesis of all these results provided the components of ϵ for 1991.25 with an uncertainty of 0.6 mas (milliseconds of arc) and of ω with an uncertainty of 0.25 mas yr^{-1}.

Contents of the Hipparcos Catalogue

The catalog contains astrometric data for 117 955 stars. It includes a basic list of 52 000 bright stars, a survey to a limiting visual magnitude V that is a function of the star's spectral type and galactic latitude b: for spectral types earlier than or equal to G5,

$$V \leq 7.9 + 1.1 \sin |b|$$

for spectral types later than G5,

$$V \leq 7.3 + 1.1 \sin |b|.$$

In addition, there are 66 000 stars of magnitudes up to $V = 12.4$ selected for their astrophysical or astronomical interest, or chosen in order to fill up empty regions of the sky. The mean astrometric characteristics of the catalog for stars of magnitude $V \leq 9$ are the following:

> Median uncertainty of positions: 0.77/0.64 mas (RA/dec)
> Median uncertainty of proper motions: 0.88/0.74 mas yr^{-1} (RA/dec)
> Median uncertainty in parallaxes: 0.97 mas
> Ten per cent of these parameters have uncertainties less than 0.47/0.66 mas (RA/dec)

In addition, complete or partial information on 14 340 double or multiple systems is provided, while 8542 other stars are marked as suspected double stars.

Hipparcos was also a wide-band photometer. Results for 118 204 stars are given, in the mean, from 110 observations of each object. The median photometric precision for bright stars (Hipparcos magnitude up to 9) is 0.0015 mag. Within the whole material, there are 11 597 variable stars, 70% of which have been first identified as variables by Hipparcos.

Contents of the Tycho Catalogue

The Tycho Catalogue was constructed from the data collected by the star-mapper of the Hipparcos mission (see also TYCHO STAR CATALOGS). In contrast with the main mission in which stars are observed roughly during 4 s per transit, all stars in the field of view of the star-mapper gave a signal, but during only a quarter of a second. This explains why many more stars have been observed and are present in the Tycho Catalogue, but that the uncertainties are much larger. Actually for most stars only positions at the mean epoch are really useful. The total number of entries is 1 058 332. This includes practically all stars up to V magnitude 10.5 and many others up to $V = 11.5$. The mean median uncertainty in position for all stars is 25 mas. It is 7 mas for stars with $V < 9$.

During the construction of the catalog, the coordinate axes were identical to those of the preliminary Hipparcos Catalogue. Then, the catalog was turned by the same rotations as the Hipparcos Catalogue so that the reference system of the final Tycho Catalogue is also the ICRS. This means that, although the Hipparcos Catalogue is the best optical reference frame realizing the ICRS, the Tycho Catalogue is also a realization of the same system.

Tycho measured magnitudes in two colors close to the V and B magnitudes of the Johnson system. The mean uncertainties for all stars are 0.07 and 0.06 mag respectively for the Tycho B and V magnitudes. For stars with $V < 9$, these numbers should be divided by 5.

Hirayama Family

Any of several groups of asteroids each of whose members share similar orbital elements, in particular a closely similar semi-major axis and orbital inclination. These similarities are surmised to indicate that the members of a particular Hirayama family share a common origin in the collisional break-up of a large parent body. The existence of such groups were first pointed out by Kiyotsugu Hirayama in 1918. Several dozen Hirayama families have been identified with a fair degree of certainty. Spectral similarities within some families support the idea of a common origin. This is true of the most populous families. The Themis family, for example, orbits at 3.13 AU with an inclination of 1°. It has several main members, including the 228 km diameter (24) Themis, and many minor members, which are all low-albedo C-type (carbonaceous chondrite) objects. However, there are families which contain a variety of types: the Alexandra family, for example, orbits at between 2.6 and 2.7 AU with inclinations of 11° to 12°, but has C-, G- and T-type members—difficult to reconcile with an origin as a single object.

Hiten (Muses-A)

First Japanese Moon mission. Launched January 1990. Named Hiten after a Buddhist angel who plays music in heaven. Used to verify the swingby technique by utilizing lunar gravity. Returned engineering data, detected cosmic dust, and released a 12 kg orbiter called Haroromo.

Hoba Meteorite

The largest known single meteorite mass, weighing an estimated 60 tonnes; it is sometimes called the Hoba West meteorite. It still lies where it was discovered in 1920, at Hoba Farm, near Grootfontein in Namibia. It produced no impact crater, but sits partially embedded in a hollow in the ground. The Hoba meteorite is an ataxite, a variety of iron meteorite, and measures about 2.7 m in its longest dimension. It is considerably weathered, and the surrounding surface is covered by a rusty deposit, the amount of which suggests that when the meteorite landed it may have weighed 75 tonnes.

Hoffman, Jeffrey A (1944–)

X-ray astronomer and astronaut, born in Brooklyn, New York, educated as an astrophysicist. Researched cosmic gamma ray and x-ray astronomy, flying a balloon-borne, low-energy, gamma ray telescope as a PhD project, worked at Leicester University on the x-ray astronomy rocket payload, and was project scientist for the medium-energy x-ray experiment on the EXOSAT satellite. At MIT worked on HEAO-1. Became an astronaut in 1979 and made five flights, during the fourth of which in 1993, on the shuttle Endeavor, he serviced and restored to full capacity the Hubble Space Telescope.

Hoffmeister, Cuno (1892–1968)

German astronomer, founder of the Sonnenberg Observatory. Discovered thousands of variable stars through repeated photography of the sky and his technique of 'fly-spanking', comparing the size of the stellar images to identify changes.

Hogg [Sawyer Hogg, Hogg-Priestley, Sawyer-Hogg-Priestley], Helen, née Battles (1905-93)

Astronomer, born in Lowell, MA, and planned a career as a chemist. However, a total eclipse of the Sun in 1925, as she said, 'tied me to astronomy for life'. After meeting ANNIE CANNON of the Harvard College Observatory, she worked at Harvard with HARLOW SHAPLEY on star clusters. She moved to Victoria, British Columbia, and started an observing program with the 72 in telescope to study variable stars in globular clusters, chaperoned by her astronomer husband and accompanied to the dome at night by her new-born baby girl in her basket. The work continued in Toronto's David Dunlap Observatory, where she became professor at the University of Toronto. She took over 2000 photographs during her research on variable stars in globular clusters, discovering hundreds of them, and compiling her work and others into the *Catalogs of Variable Stars in Globular Clusters*.

Hogg, Arthur Robert (1903–66)

Australian atmospheric physicist, turned astronomer, born at Creswick, Victoria. Hogg joined the Mount Stromlo Observatory and became an astronomer after the Second World War, carrying out photoelectric photometry on eclipsing variables. The most important system that he observed was zeta Phoenicis, one of the 13 for which 'first-order' masses and radii can be determined. He determined standard magnitudes, and measured the integrated magnitudes and colors of the Magellanic Clouds, finding that the Small Cloud was appreciably bluer in its bright nuclear regions than in its outskirts. He worked on galactic clusters (he measured color–magnitude diagrams for five galactic clusters, and published a photographic atlas of southern galactic clusters). He played a leading part in the setting up and testing of the new 74 in telescope. Directed by BART BOK, he surveyed outback Australia for alternative astronomical sites when the sky quality at Mount Stromlo was compromised by the growth of Canberra, as result of which Siding Spring Mountain near Coonabarabran was chosen, becoming the site for the Anglo-Australian 150 in telescope.

Holmberg, Erik [Eric] Bertil (1908–)

Swedish astronomer who investigated the photometric properties of galaxies. He identified a characteristic size for a galaxy in terms of its brightness (the *Holmberg radius*) and by comparing elliptical galaxies tilted at different angles to the line of sight found that galaxies do not differ significantly in brightness, concluding that they were relatively free of dust obscuration.

Home Observatories

Sooner or later—generally sooner, rather than later—the average amateur astronomer is going to feel the need for a telescope. Binoculars are of immense use (see BINOCULAR ASTRONOMY), but their low magnification means that they are bound to be limited. Most amateur societies either have observatories or include members with telescopes of their own (see AMATEUR ASTRONOMICAL SOCIETIES) but it is much more satisfying to be able to go straight outdoors and make ready for observing without the need to go on a journey.

Small telescopes are portable, and this is almost essential for the would-be observer who lives in a town; light pollution will probably make the seeing conditions intolerable, and the only solution is to have a telescope which can be put into the boot of a car and moved around. There are also many observers who keep their telescopes indoors and take them out when needed, but this too has its disadvantages; moving a telescope (particularly a Newtonian REFLECTOR) may well disturb the alignment of the optics, and in any case it is only a matter of time before something is dropped, with disastrous results. All in all, a permanent observatory is very much to be recommended.

The first essential is to select a site, and this is never easy, particularly if the choice is restricted. Let it be said at once that setting up an observatory on the roof of a dwelling house is unwise. Heated air rising from below will swirl around and destroy the SEEING. It is necessary to build the observatory well away from the house—within reason, the further away the better. Also, with a permanent building, planning permission has to be watched, at least in the UK. If you are faced with an awkward Council, the way round this problem is to put down a concrete base and then place the observatory on top, without actually fastening it. It then comes under the heading of a portable structure, and the Council will be powerless unless the building interferes with a neighbor's view.

Houses and trees are always inclined to cut off part of the view of the sky, and it is axiomatic that if a tall tree can be in the most awkward possible position, it is. Remember, too, that heated air will always rise from a dwelling house, so if possible site the observatory so that there is an unobstructed view of the horizon—or, more precisely, that part of the horizon in which you are particularly interested. Lunar and planetary observers will need the southern sky, while the variable-star enthusiast or the nova hunter may well prefer the north, and those who search for comets will try to ensure that there is nothing to obstruct the western sky after sunset or the eastern sky before dawn. Nearly always, of course, it is a matter of compromise. Street lights can be an unmitigated nuisance, particularly if they remain on all night (as many of them now do), but there is no real solution here. The airgun remedy is, unfortunately, illegal.

The very simplest form of observatory, suitable for any kind of telescope, is the run-off shed. This is simply an ordinary shed mounted on rails; when the telescope is to be used, the shed is simply rolled back by its wheels. It is wise to make the shed in two sections which join in the middle, rather than having a single shed with a door. Any door has to be fixed at one end of the shed and must be either hinged or removable. If hinged, it flaps; if removable, there may be problems in replacing it during a dark, possibly windy night, because it will tend to act as a powerful sail.

Anyone who is reasonably good with their hands can make a run-off shed, and there is very little to go wrong, but it does mean that the observer is in the open when actually observing, so that the telescope may be affected by wind-shake and the observer may feel decidedly chilly. Certainly it is much more comfortable to carry out one's observational program from inside a structure.

Another simple pattern is the run-off roof. Here there are permanent walls, and the roof—or even the entire top part of the structure—is rolled back on rails, which means of course that the rails have to protrude and must be supported on an adequate mounting. Again there is not much to go wrong, and the observer is shielded from the wind as well as being screened, at least to some extent, from obtrusive lights. The run-off roof is better suited to refractors, because a Newtonian reflector must be mounted lower down and will have a more restricted view of the sky, but there are in general no insurmountable difficulties, and again an observatory of this kind is comparatively easy to build.

The material for the observatory may be wood, metal, plastic, brick or fiberglass; metal has the disadvantage of shutting in the daytime heat, so that it is essential to open the observatory and stabilize the temperature some time before observing is due to begin. One point is worth noting (it should be obvious, but can sometimes be overlooked): make sure that the roof is not perfectly level. If it is, the first shower of rain will convert it into a pond.

The popular picture of an observatory is that of a graceful dome, with a slit which can be opened; the dome must be rotatable, so that full access can be given to any part of the sky. The main problem here is that making a dome is by no means easy, and it is also essential that the ring upon which it revolves is absolutely true; otherwise the dome will stick. In some cases the entire observatory rotates, and this does solve some of the difficulties, but a complete dome is heavy to push around, and it too is apt to stick unless all the components have been made with real precision.

Fiberglass domes can now be bought commercially, and many amateurs are now making use of them; purchasing a dome and then building the supporting structure is much cheaper than paying for a complete observatory. A 'skeleton' dome, with roofing felt, can also be used, although it is less durable and cannot be expected to last for very long without major repairs.

One variant which is quite popular is what can be referred to as the 'wedding-cake' pattern. Here there is a basic structure, with a ring upon which the upper section rotates, but the shape is not that of a dome; there are vertical sides and a roof made in sections, of which one

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

can be swung back to provide access to the sky. In this case the design should not be perfectly symmetrical; if it were, the telescope would never be able to point to the zenith—and although one seldom wants to look 'straight upward', it can be necessary occasionally, to observe a comet or perhaps an interesting variable star.

Probably the first decision to be made is a straightforward one: buy an observatory complete, buy parts, such as the dome, and make the rest or construct the entire observatory oneself? A run-off shed, or even a run-off roof pattern, is within the scope of most people, but it is true that making a dome, or even a wedding-cake, is more of a problem.

Some observatories are designed for special needs. The solar observer will work by day and may not be much concerned with anything but the Sun; he or she may well need an observatory with a coelostat which catches the Sun's rays and sends them in a fixed direction, so that there is no need for a rotating dome or roof, and even the observatory itself can remain fixed. One leading British solar observer, Commander Henry Hatfield, has taken matters to the limit—he designed his spectrohelioscope, and then literally had his house built round it. It works excellently, but not many people, however enthusiastic, will be able to follow his example. Amateur radio astronomers will have different requirements, and will be concerned largely with avoiding electronic 'noise' rather than light pollution.

Various other points are worth noting here. First, any driven telescope will need a power supply. Falling weights are convenient and self-sufficient, but in most cases the drive will be electrical, and connecting the observatory to a mains power supply can be awkward. Secondly, there is the question of security. If the observatory is to be set up in the owner's garden this should not be a problem, at least in most areas, but if it is to be built on a site well away from the house there must be adequate protection; there have been many cases of observatories being vandalized. It is also wise to have proper insurance cover. Moreover, there is always a potential threat from the forces of nature. A local tornado, for example, can have devastating results.

Finally, always make sure that your observatory is large enough for your needs. For much of the time it will be used in the dark, and it is only too easy to damage oneself by blundering into a telescope or some other piece of equipment.

Not every amateur astronomer can own an observatory, and there is certainly no point in erecting any permanent structure in a small garden which is surrounded by trees or houses and is flooded with artificial lights nearby. However, there is no doubt that there is tremendous satisfaction in being able to walk through one's door into an observatory which can be opened and made ready for use in a matter of minutes.

Hooke, Robert (1635–1703)

Scientist, born in Freshwater, Isle of Wight, England, educated at Christ Church College, Oxford where he met Boyle and was employed by him to construct his air pump, became professor of geometry at Gresham College, London. Discovered *Hooke's law of elasticity*. Worked on optics, simple harmonic motion and elasticity in strings. Published a monograph called *Micrographia*, containing beautiful pictures of objects Hooke had studied through a microscope he had made himself. He coined the use of the word 'cell' (meaning a tiny bare room) for the structures in cork and other living organisms. Hooke invented the conical pendulum and is credited with HADLEY as the first to build a reflecting telescope to GREGORY's design. He made important astronomical observations including the fact that Jupiter revolves on its axis. He determined this from the Great Red Spot, which he was first to observe. His drawings of Mars were later used to determine its period of rotation, since they recognizably showed Syrtis Major, and were the earliest drawings to fix the phase of Mars. He wrote a book on comets which was read by NEWTON. In 1672 Hooke attempted to show that the Earth moves in an elliptical orbit and in 1678 that an inverse square law of gravitation explained planetary motions, but seemed unable to give a rigorous proof. He communicated these ideas to Newton, and, in a bad tempered dispute continued to this day by his descendants, claimed priority in the discovery of the inverse square law. Newton, as a consequence of the dispute, expunged all references to Hooke from the *Principia*.

Horizontal-branch Stars

This article deals with the subject of the horizontal branch and horizontal-branch stars, those stars which are found on the horizontal part of the Hertzsprung–Russell diagram of a globular cluster. Figure 1 shows the location of this type of star. After an introduction there are sections on studies of globular clusters and the horizontal branch, the second parameter problem and field horizontal-branch stars.

In the 19th century, astronomers thought that stars of different spectral types were composed of different elements. In the 1920s a major step forward in stellar analysis was made by Cecilia Payne Gaposchkin who determined that stars were essentially the same, i.e., they are made up mostly of hydrogen with a lesser amount of helium and very small amounts of all the other elements in the periodic table. Later on in the 20th century, with an increasing precision in the ability to measure stellar abundances, a major advance in stellar analysis was to show how stars are different. Stars have been divided into many groups depending on their detailed spectroscopic abundances. This article will discuss one important group of old stars, the horizontal-branch (HB) stars. HB stars are most easily detected in GLOBULAR CLUSTERS and open clusters, but have also been detected in the general field of the Galaxy.

Astronomers have an impressive tool to use in the study of stellar evolution, the HERTZSPRUNG–RUSSELL DIAGRAM (HRD), in which the absolute magnitudes of stars are plotted versus their colors (or spectral type or temperature). For a group of stars at the same distance, the apparent magnitude can be used (i.e., for a globular or open cluster) in place of the absolute magnitude. In the original HRDs the majority of stars fell in an inclined band, named the main sequence, running from the upper left to the lower right (from high temperature and luminosity to low temperature and luminosity). These were the normal Population I (Pop I) stars like the Sun, with spectral types running from O (very hot) to M (cool). In the upper right side of the diagram there are the red giants, which are cool, more luminous stars that have evolved from the main sequence and have become stars of a much larger radius.

Globular clusters are important objects for the study of stellar evolution. They are presumed to be among the first objects formed in our galaxy and thus give us information about the galaxy's very early history. The stars in a cluster are all at the same distance from the Sun and they (in almost all cases) are formed coevally out of interstellar material with the same chemical composition. Thus, they are experimental 'test beds' to be used by astronomers in their studies of STELLAR EVOLUTION.

HARLOW SHAPLEY investigated the magnitudes of stars in globular clusters, starting about 1915 at MOUNT WILSON OBSERVATORY. He found that the HRDs for globular clusters differed from the diagrams for the stars near the Sun in that the red stars (red giants) were brighter than the blue stars in the cluster. In the diagrams of stars near the Sun, the blue stars were the brightest stars in the diagram. The significance of this different distribution of stars in the HRD was not understood until the work of Walter Baade. He took pictures of the Andromeda galaxy (M31) in which, for the first time, individual stars in the central regions of the galaxy were resolved. These pictures were taken at Mt Wilson on the 100 inch telescope during WWII blackouts under good seeing conditions. The stars in the center of M31 had an HRD similar to that of globular clusters; the stars in the outer regions had an HRD similar to the distribution of stars in Russell's diagram for the nearby stars. This was the start of the idea of STELLAR POPULATIONS; that there are young stars with relatively larger abundances of elements other than hydrogen and helium, distributed mainly in the spiral arms of our galaxy, and that there are old stars with very small abundances of elements other than hydrogen and helium, distributed in a spherical halo around the galaxy. In time this simple picture of two populations was modified with the addition of other population types.

In 1952 at a Symposium on Stellar Populations held at the Vatican Observatory, Jan Oort presented a table in his summary in which stars were divided into five different populations. At one extreme were the Halo Pop II stars, then Intermediate Pop II, Disk Population, Intermediate Pop I and at the other extreme were the Extreme Pop I stars. We know now that Pop II stars are old, metal poor and have high velocities while the Pop I stars are young, have a higher metal abundance and have small velocities. Globular clusters were members of the Halo Pop II and it is in these clusters that we find a distribution of stars known as HB stars. In figure 1, at the top, a color–magnitude diagram (CMD) is presented for the globular cluster M92 (by Peter Stetson, Dominion Astrophysical Observatory). It is the result of CCD (charge coupled device) photometry of more than 50 000 stars. Below, a CMD is shown for the globular cluster M3 by Roberto Buonanno and his collaborators (University of Bologna) with the various areas of the diagram labeled.

In the lower middle of each diagram, a band of points can be seen, extending up to the left. These points represent the main sequence of the cluster, which is made up of stars burning hydrogen in their cores. In the early 1900s stellar energy was thought to be produced by stellar contraction. However, contraction models did not provide a long time scale for stellar evolution. In the late 1930s Bethe and von Weizäcker showed that nuclear fusion takes place in the solar core and this understanding provided the means to calculate stellar models showing how stars evolve over time. Stellar evolutionary theories are tested mainly by comparing theoretical models with observations made of stars in clusters. For stars like the Sun, protons are transformed into helium nuclei in the stellar core, liberating vast amounts of energy. This is a long-lived stage in a star's life, and during it the star remains at almost constant temperature and luminosity, on the main sequence. The more massive stars form on the upper left of the main sequence and evolve rapidly;

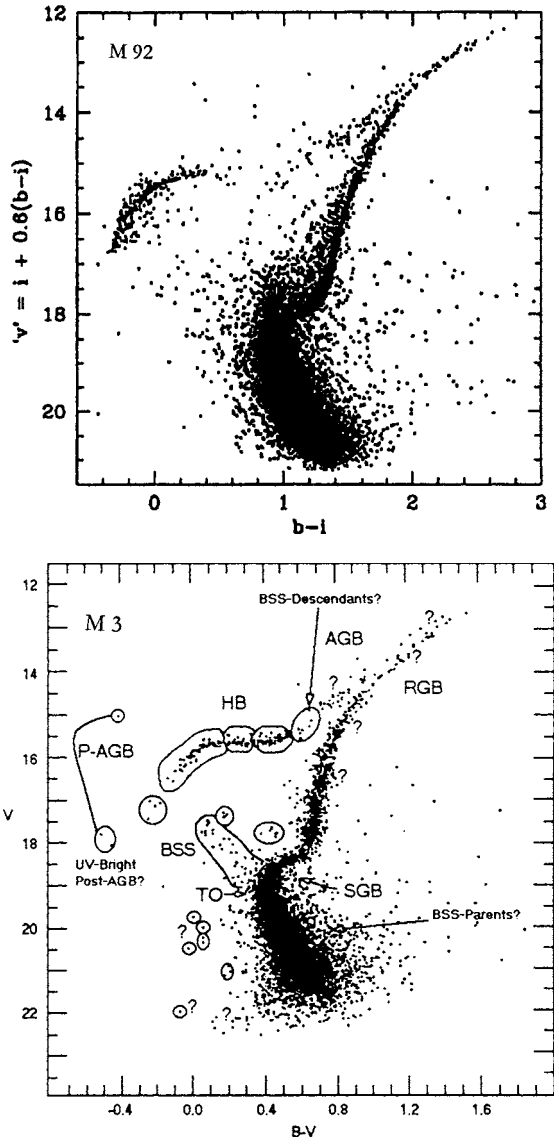

Figure 1. Top: a CMD for the globular cluster M92, showing the distribution of more than 50 000 stars (Peter Stetson). Bottom: a CMD for M3 with the various regions labeled (Roberto Buonanno).

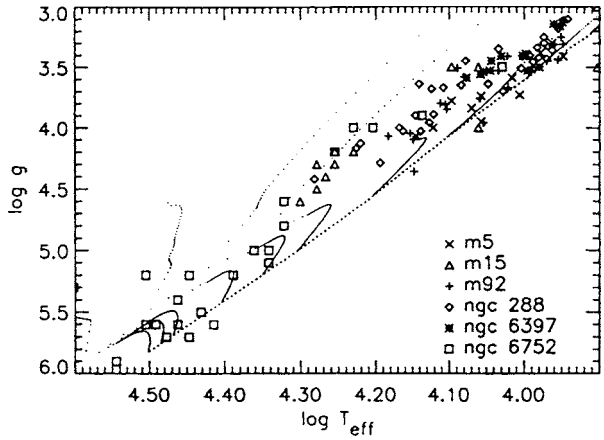

Figure 2. Sweigart models of the horizontal branch. Data points from observations in globular clusters are also shown.

the smaller mass stars sit on the lower right of the main sequence and evolve very slowly. Eventually all the hydrogen is converted to helium in the center of the star. However, the helium is at too low a temperature to burn and the core contracts, raising the temperature in the central regions of the star. Hydrogen burns in a shell outside the core, and the star leaves the main sequence and starts moving up and to the right in the diagram, mapping out the red giant branch (RGB). As the star becomes more extended on its way up the giant branch, it becomes more difficult for it to retain the gas on its surface and there is envelope mass loss. It is thought that perhaps 0.2 solar masses are lost before the star reaches the horizontal branch (HB). At the tip of the RGB, the helium in the core of the star ignites, in the so-called helium flash. The star then moves rapidly to the HB, the group of stars on the far left in the range $v = 15$–17 in the M92 diagram. If the mass of the star is small, it lands on the left extension of the HB; if the mass of the star is larger, it will fall further to the right on the HB. The locus of points that is defined by stars arriving on the HB, as a function of mass, is called the zero-age horizontal branch (ZAHB). During this stage of its life the star is burning helium in the core and hydrogen in a shell surrounding the core.

According to HB stellar models calculated by Allen Sweigart (NASA/GSVC), the evolutionary path of a classical HB star starts by brightening a bit and then moves to the blue (left), paralleling the zero-age horizontal branch (ZAHB). Then the star brightens some more and turns back toward the red (right), climbing up the asymptotic giant branch (AGB), which is the locus of the points scattered in a band just above the giant branch in the CMD (figure 2). These evolutionary tracks depend on the specific parameters of the HB star under investigation. On the AGB a star has two burning shells: hydrogen and helium.

It is interesting to note that in the 1960s, some textbooks had diagrams showing that stars evolved down the asymptotic giant branch and finally reached the HB. In modern theories of stellar evolution, the stars evolve to the ZAHB and then evolve to the red, up the asymptotic giant branch in the opposite direction.

In studies of certain variable stars (called RR LYRAE STARS) on the HB of globular clusters, Oosterhoff found in 1939 that there were two groups determined by their average period. One group had average periods of 0.55 days, the other had average periods of 0.65 days. The long-period group was found to be more metal poor than the short-period group. Work by ALLAN SANDAGE (Carnegie Observatory) and others showed that there was a difference in their periods, in that for stars at constant effective temperature the more metal-poor stars

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

had longer periods than the stars of higher metallicity. This is an illustration that the parameters concerning stars in globular clusters are more complex than originally thought.

Studies of globular clusters and the horizontal branch

In 1919 Shapley noted that the LUMINOSITY FUNCTIONS OF GALAXIES for M3 and M13 were different. M3 had many cluster-type variables but was poor in the number of blue stars, and M13 had few variables but had many blue stars. He commented that there might be significance in this difference. This was one of the first statements concerning differences between globular clusters.

In the following decades observational evidence, combined with theoretical studies, showed that globular clusters were old. Shapley had already placed the center of the globular cluster distribution at the center of the Milky Way. It was assumed that each globular cluster is formed of stars created out of the same interstellar material, at the same time and at the same distance from the solar system. Thus, if the chemical compositions, ages and kinematics could be determined for clusters as a function of galactocentric distance, one could learn much about the early chemical and dynamical history of the Galaxy.

In 1955 Halton Arp (now at the Max Planck Institute) published the results of an investigation of seven globular clusters (M2, M3, M5, M10, M13, M15 and M92). The CMDs of these seven clusters were quite similar. The [Fe/H] values (the so-called metal-abundance parameter which is the logarithm of the iron abundance divided by the hydrogen abundance, all relative to the Sun) varied from [Fe/H] $= -2.02$ for M15 to [Fe/H] $= -1.34$ for M5. It is now known that for the most metal-rich clusters [Fe/H] reaches values of -0.3, close to the solar value of zero, but in Arp's original sample there were no clusters this metal-rich. The clusters in the list all had CMDs with strong, blue HBs and there was not much variation from one cluster to the next. Even in the days of photographic photometry, the narrow sequences found in the CMDs implied that the stars in a globular cluster were chemically homogeneous. Changes in the chemical abundances, and other parameters, affect the position of the star in the HRD and thus, if the sequence is narrow, imply that the stars are very similar. Modern CCD diagrams have sequences which are much more sharply defined, reinforcing this conclusion.

The CMDs provide several methods of determining ages of globular clusters. One of the first methods was to measure the magnitude difference between the bluest point on the turnoff (TO in figure 1, bottom diagram) and the magnitude of the HB at the same color. The TO magnitude gets fainter by about 0.01 mag for each 1% increase in the age. Cluster model builders, like Don VandenBerg (University of Victoria) create isochrones which predict how a CMD of a cluster should appear, given a set of parameters (such as helium abundance, [Fe/H], [CNO/Fe], age). These isochrones can then be fitted to observed CMDs to obtain estimates of cluster ages.

In 1976 Philip, Cullen and White published a compendium of all the galactic globular clusters then available, all drawn to the same scale and with [Fe/H] and reddening values listed for each. This presentation made it easier to intercompare clusters. The first CMDs were made photographically by taking pictures through V (visual) and B (blue filters). When the magnitudes were reduced to the UBV SYSTEM then one could plot V versus $(B–V)$ and so arrive at a CMD. The accuracy of the magnitude determination for a single star was of the order of $\sim$0.03 mag for the brightest stars in a globular cluster and decreased in precision as one went to fainter magnitudes. Photoelectric photometry was much more accurate but in the 1970s stars were measured with a single-channel photometer, one at a time, and so it was difficult to measure a large number of stars in any given cluster. In the 1980s the CCD was introduced and soon became the instrument of choice at observatory telescopes to take images, measure magnitudes and record spectra. For the first time, stars in the central areas of globular clusters could be measured, and as can be seen in figure 1, tens of thousands of stars could be recorded with a single exposure. The CCD allows one to measure stars much fainter than could be measured with photography and the precision of the measurements is much higher. One per cent photometry is now possible for faint stars and this allows the various regions of the HRD (or a CMD) to be much more precisely defined. Some recent technological advances have made stellar photometry even more effective. The HUBBLE SPACE TELESCOPE has allowed extremely faint objects to be measured in very crowded areas with high accuracy. On the ground ADAPTIVE OPTICS allows a telescope to be kept in the best possible focus during observations and thus increases the accuracy of the measurements. CCDs also allow high resolution spectra with signal/noise ratios of 150 to be obtained for stars even in globular clusters and equivalent widths of lines can be measured with errors as small as $\sim$2 mÅ. This means that better tests can be made of the predictions of stellar evolution theories.

Studies of HB and other stars in clusters have been greatly aided by the increased photometric accuracy possible due to the new software which has been created to measure images on CCD frames. The most important part of this process is the fitting of the point spread function (PSF), which is a three-dimensional model of the shape of the intensity distribution of each image. This method replaces the older aperture photometry, which just measured the total luminosity of the image. At the Dominion Astrophysical Observatory Peter Stetson has written DAOPHOT, at MIT Paul Schecter has written DoPhot and in Italy Roberto Buonanno and collaborators have written ROMAFOT. These programs allow one to create a mean PSF (by measuring the profiles of isolated stars well spaced over the frame) which is then fitted to all the images to find the magnitude of each star. If

Dirac House, Temple Back, Bristol, BS1 6BE, UK

the PSF varies across the frame (which happens as the frames become larger) the programs can apply a variable PSF as a function of position on the frame. Without the development of modern computer technology these kinds of reduction programs for magnitude determination would not be possible.

As more globular clusters were studied, it was found that not all clusters had the same type of HB. Some had long, extended blue tails; others had only red HB stars, to the right of the RR Lyrae gap. The main factor that seemed to determine the morphology of the HB was metallicity, [Fe/H], but investigators found some clusters with the same metallicity which had very different distributions of stars along the HB, suggesting the influence of a 'second parameter'.

In the early 1970s Robert Rood (University of Virginia) constructed synthetic HB models and he studied what parameters would produce the observed HBs. He confirmed the need for a mass loss of $0.2M_{\odot}$ between the main sequence and the HB and for a 10% dispersion in the amount of mass loss for stars on the HB to reproduce the observed distribution of stars. He produced a list of second parameter candidates and showed how it was possible to produce any desired HB morphology.

Gaps have been found in the distribution of stars along the HB, in field HB stars and for HB stars in globular clusters. One of the first people to discuss the gaps was Barry Newell (Canberra, Australia) while he was at Yale in the late 1970s. He found two gaps at effective temperatures $\log T_{\rm eff} = 4.11$ and 4.33 in the distribution of galactic halo blue stars and suggested that these gaps were an HB phenomenon. In the CMD these gaps occur at $(U-B), (B-V) = -0.4, -0.14$ and $-0.9, -0.24$. Another possibility, discussed by others later to explain stars on the blue end of the HB, is that some stars of a different type end up in positions near the HB.

The second parameter problem

The changes found in the morphology of the CMD of the HB were first attributed to a change in the metal abundance. As the metal abundance of the cluster increases, the giant branch in the CMD shifts to the red. For high metal abundance the blue HB stars do not appear and the red part of the HB becomes a short red stub. The most metal-poor clusters showed strong, blue HBs, and more modern observations which reach stars of fainter magnitudes show long, drooping blue tails for blue HBs of metal-poor clusters. In figure 3 two pairs of CMDs are shown. The first pair is NGC 1904 and NGC 6637 which show the change in HB morphology from a [Fe/H] of -1.5 to -0.2 in a $V, (B-V)$ diagram. The HB changes from one with a very strong, blue component to a cluster with only a short red stub of a HB. The second pair, on the right, shows a $V, (U-V)$ diagram for M3 and M13 and is a clear example of the influence of a second parameter acting. At the bottom are three CMD, reported on by Jim Hesser, quoting photographic observations by Roberto Buonanno of the clusters M15, M92 and NGC 5466, each of which have [Fe/H] near -2.1. Again there is a dramatic change in the morphology of the HB. This is in spite of the fact that these three clusters have the same metal abundance.

As more clusters were investigated it was found that there were some clusters with HBs too blue or too red for their metallicity. Astronomers studying CMDs searched for another parameter that could cause such an effect. The effect was found to be stronger for globular clusters furthest from the galactic center and is very weak for clusters in the central regions of the Milky Way. One of the first papers on the second parameter problem was by Sidney van den Bergh (Dominion Astrophysical Observatory) in 1967, in which he stated: 'It is shown that at least two parameters (one of which is metal abundance) are required to describe globular clusters. ... a second parameter which might be either age or the helium to metals ratio'. Also in 1967 Allan Sandage and Robert Wildey discussed the globular cluster NGC 7006 and pointed out that, although its metal abundance was low, it had a distribution of stars similar to the HB of a cluster of much higher metallicity.

Some additional examples of globular clusters with 'second parameter' problems are M3 and M13; M15, M92 and NGC 5466; Arp 2 and Ruprecht 106. M3 and M13 (top right in figure 3) have [Fe/H] values of about -1.6, but M3 has a redder HB while M13 has a very strong blue HB. (Note that this diagram is a $V, (U-V)$ diagram and not the usual $V, (B-V)$ diagram). Their helium abundances seem to be the same and the differences in magnitude between the main-sequence turnoff and the HB (a measurement of the cluster age) in a $V, (B-V)$ diagram are similar, implying that the two clusters have the same age.

Many parameters have been suggested as the prime second parameter. One of the first suggested was the helium abundance, but later evidence showed that the helium abundance does not vary very much from globular cluster to globular cluster. The abundances of the elements carbon, nitrogen and oxygen (CNO) have been proposed as parameters affecting HB morphology. The density of the stellar environment in which the cluster was formed may have an effect. The core mass and the rate of rotation have an influence on the morphology of the HB. A strong parameter is the age of the cluster. Young-Wook Lee, in his 1989 thesis at Yale University, has presented the results of many models of the HB. Some of these are shown in figure 4. These diagrams help to explain the effects of various parameters on the shape of the HB. The five sets of diagrams are explained in the caption.

A ratio involving the numbers of stars on various parts of the HB has been constructed by Zinn (Yale University) and Lee. It is $c = (B-R)/(B+V+R)$ where B is the number of stars bluer than the RR Lyrae gap, V is the number of variables and R is the number of stars redder than the RR Lyrae gap. It is a good way of assigning a number to the HB distribution, but it does not work well for globular clusters without blue HB stars or without red HB stars.

There are some groups of astronomers (notably the Yale group) who argue that age is the second parameter.

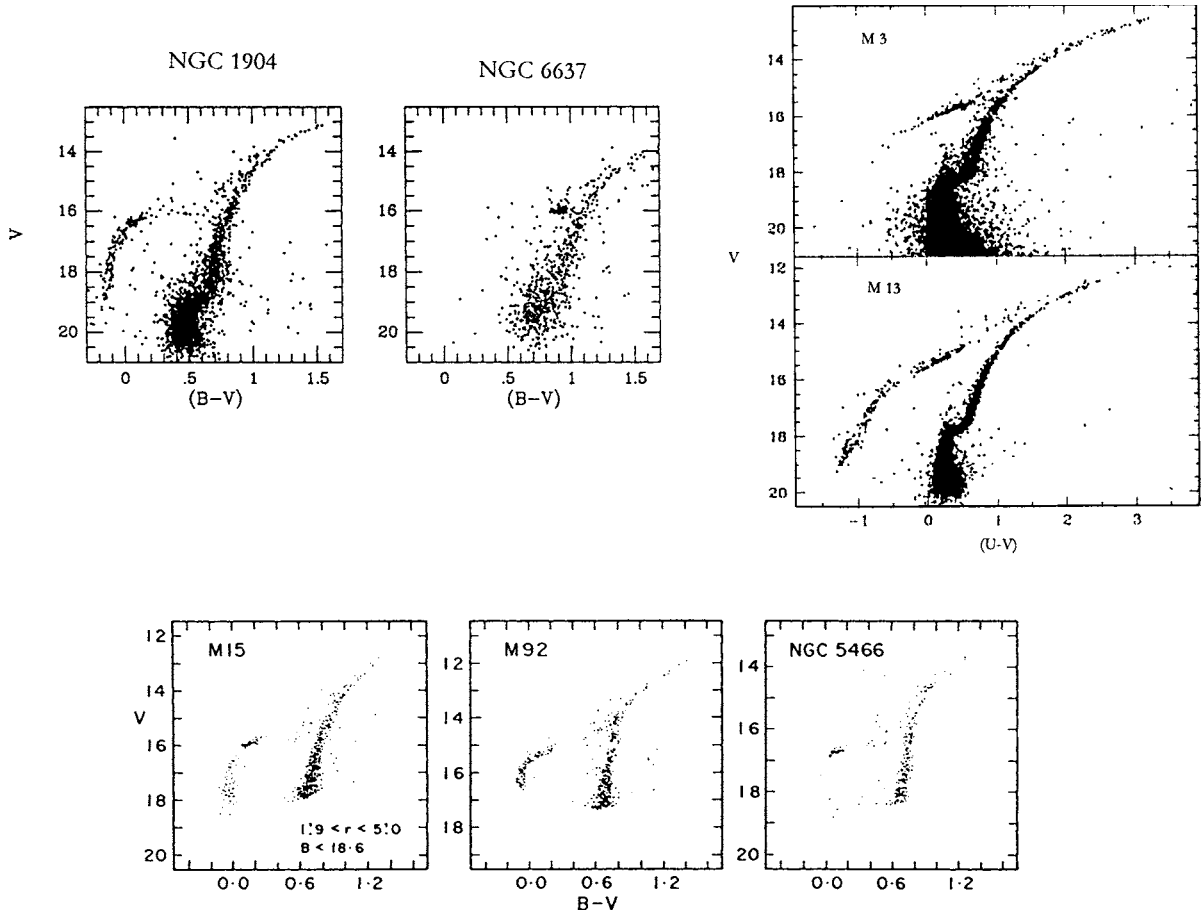

Figure 3. On the upper left is a pair of CMD of two globular clusters showing the normal differences in HB morphology for clusters with different metal abundances. On the upper right are two CMD (V versus $U-V$) of two clusters with [Fe/H] $= -1.6$ but with very different HB morphology. On the bottom are three CMD of clusters with [Fe/H] $= -2.2$, again showing very different HB morphology.

Age variations of several 10^9 years could explain the CMD differences found for globular clusters with the same [Fe/H] but different morphology. However, as we saw in figure 4, there are other possibilities. The Italian group (Flavio Fusi-Pecci, Roberto Buonanno and collaborators) contend that, although age sometimes is a second parameter, the morphology of the HB is the result of the global combination of age and other parameters. The problem has become more complex with the stream of increasingly accurate new data based on the CCD observations being made all over the world. As more spectral observations are made of HB stars in second parameter clusters with the new, very large telescopes already working and those still in construction, there will be many further discussions on the second parameter problem.

Field horizontal-branch stars

In 1933 Albitzky obtained a spectrum of HD 161817 and noted that it had a high radial velocity (-363 km s^{-1}). In 1952 Arne Slettebak noted that the hydrogen lines in HD 161817 were slightly weaker than normal for a star of its type. In 1966 Bev Oke, Jesse Greenstein and James Gunn proposed that four stars (HD 2857, 86986, 109995 and 161817) were field horizontal-branch (FHB) stars on the basis of photoelectric spectrum scans. These are stars which are supposed to be identical to the blue horizontal-branch stars in globular clusters, but which are found in the field and not associated with any cluster. They have the characteristics of low surface gravities, low metal abundance and a high velocity dispersion, all of which place them as members of Pop II.

Further observations of faint blue stars were made by Barry Newell, using his special filter system, and he identified three additional field HB candidates (HD 60778, 74721 and 130095). In 1964 the First Conference on Faint Blue Stars was held in Strasbourg, where reports were made on numerous surveys for faint blue stars and follow-up observations of selected stars. The proceedings contain a bibliography of the important papers in the field and a set of finding charts for the Humason–Zwicky (HZ) stars (a search for faint blue stars that was published in 1947).

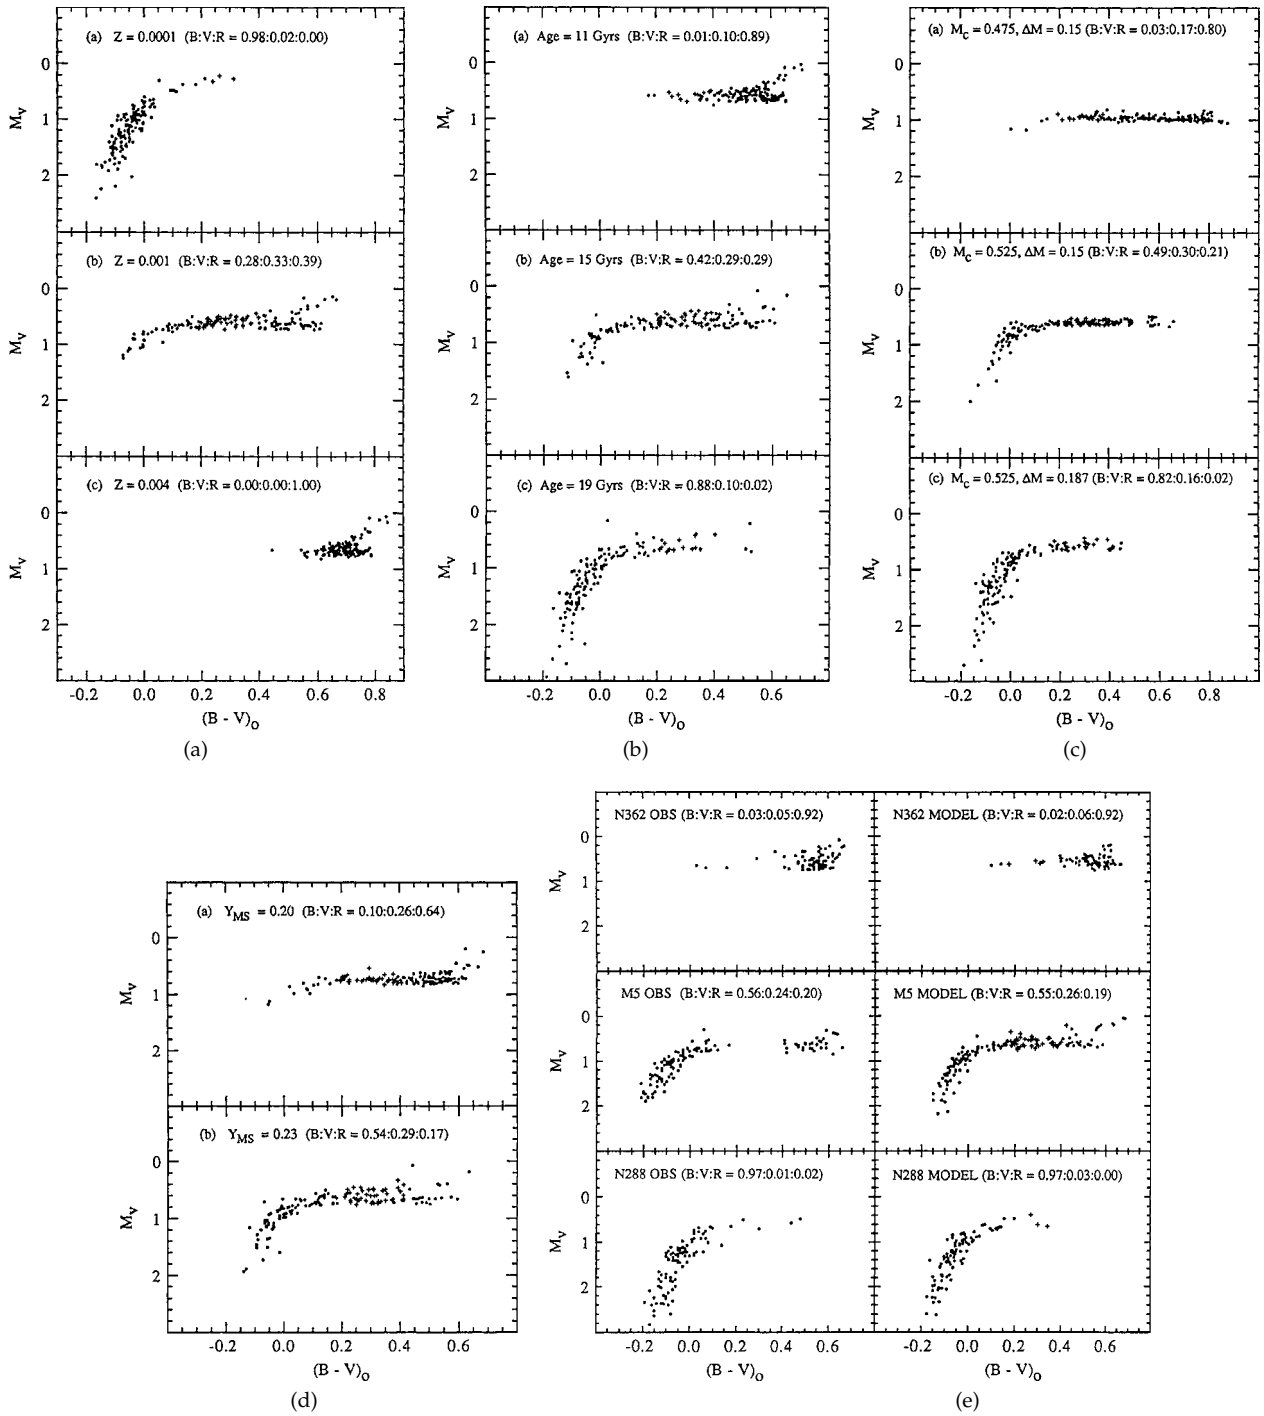

Figure 4. Models published in Y-W Lee's thesis (1989) from Yale University. The upper set of diagrams on the left show the effect of changing [Fe/H]. As the metal abundance approaches the solar value the blue HB does not appear and there is only a short red HB. The middle diagram shows the effect of changing the age of the cluster. Younger clusters have red HBs and the older clusters have blue HBs. The upper right diagram shows the effect of stellar rotation, which affects the core mass. As the rotation increases the CMD becomes bluer. On the lower left the effect of changing the surface helium abundance is shown. HBs become bluer as the helium abundance increases. On the lower right three sets of diagrams compare observational data for the globular clusters NGC 362, M5 and NGC 288 with models. The agreement is quite good.

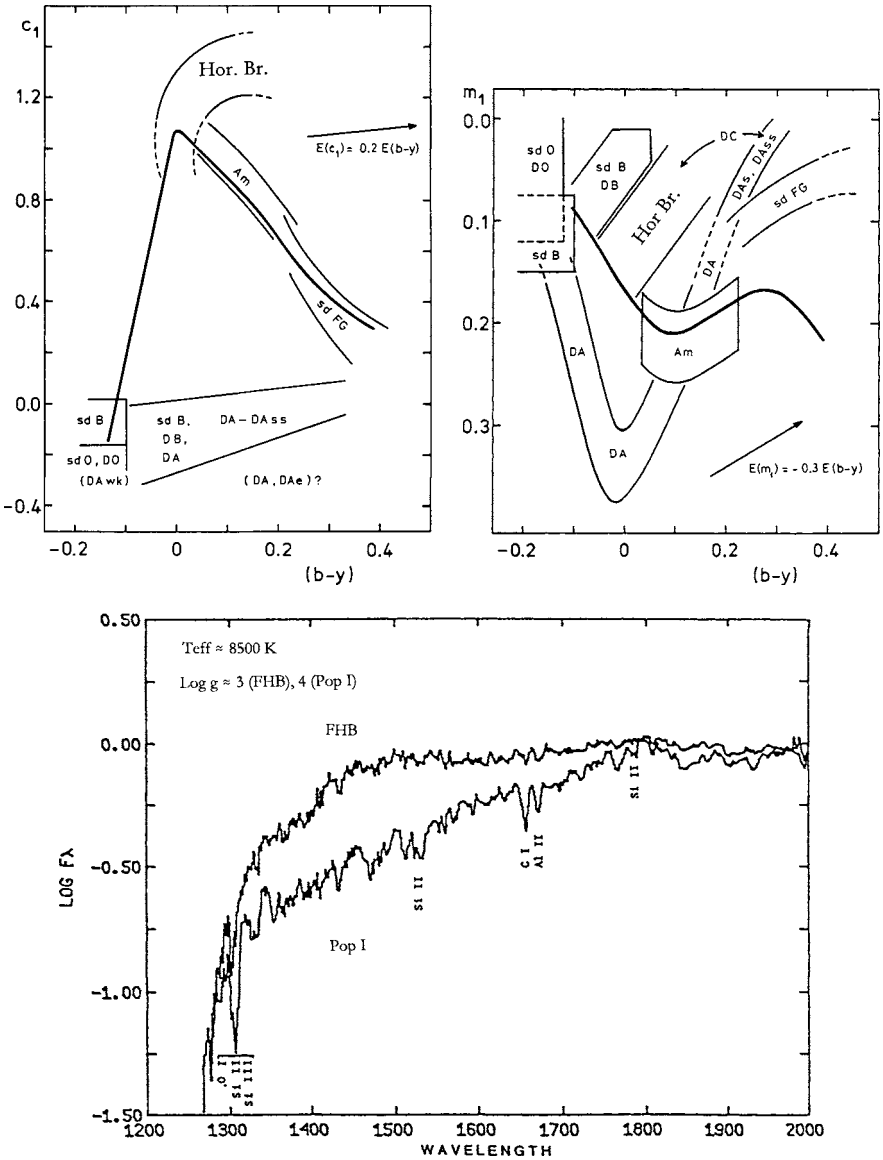

Figure 5. Ways of classifying early-type stars as field HB stars. The two diagrams at the top are from Kilkenny and Hill, showing the location of field HB stars in the Strömgren four-color system. The diagram at the bottom shows mean ultraviolet spectra of an average Pop I A-type star compared to an average Pop II A-type star. The field HB spectrum has a higher luminosity in the region around 1500 Å and does not show the absorption line features seen in the Pop I spectrum.

In the mid 1960s Tom Kinman (KPNO) made a survey for RR Lyrae stars in a field at the North Galactic Pole and a field towards the Galactic center.

In the 1960s Bengt Strömgren set up a new system of photometry, the four-color system (uvby). David Crawford was one of the people who helped calibrate the new system and Davis Philip started using it in the 1970s. John Graham (Carnegie Institution) and Katy Doremus (University of Colorado) made the first four-color observations of blue HB stars in a globular cluster, in NGC 6397. David Kilkenny (SAAO) and Graham Hill (University of St Andrews) published two plots in 1975 showing how the system could be used to classify early-type stars. They are reproduced at the top of figure 5. The leftmost plot shows the c_1 (Balmer Jump index) versus $(b-y)$ and the right plot shows m_1 (the metal index) versus $(b-y)$. The Strömgren four-color system does very well in identifying field HB stars because of the high c_1 index and lower than normal m_1 indices found for these stars. Using this system to measure early-type stars in the High Latitude Field (HLF) survey project lists of field HB stars were published and then summarized by Philip in *Finding Charts for FHB Stars* for 71 stars. As shown at the bottom of figure 5, ultraviolet spectroscopy is a good way to separate

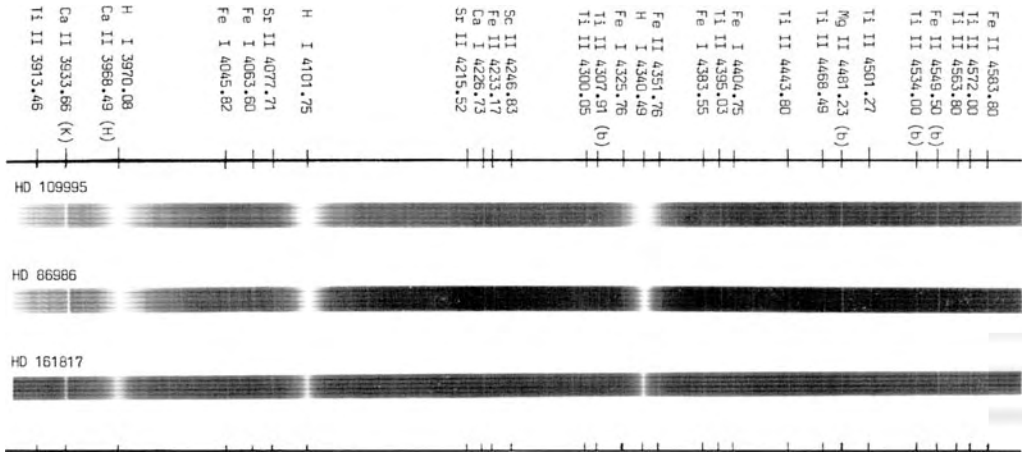

Figure 6. 6 m spectra, at 9 Å mm^{-1}, of three of the prototype FHB stars obtained by Philip and Samus in 1980.

field HB stars from normal Pop I A-type stars.

George Preston, Stephen Shectman (both Carnegie Observatory) and Timothy Beers (Michigan State University) have made a Schmidt objective-prism survey using narrow interference filters centered on the Ca II H and K lines. This HK survey identifies low-metallicity stars and a good proportion of these stars turn out to be field HB stars. They are following up with photometry and spectroscopy and there is now a catalog of thousands of field HB candidates. The new Sloan Survey is now underway and it is also turning up large numbers of faint, metal-poor early-type stars. Another survey, the Hamburg/ESO survey, has identified tens of thousands of field HB candidates. Follow-up spectral studies of these stars are being made with the CTIO/KPNO 4 m telescopes. These investigations will reach stars out to 25 kpc. Future studies of these stars will enable the galactic halo to be studied out to many tens of kiloparsecs.

Figure 6 shows the spectra of three of the original field HB stars obtained with the 6 m telescope in Russia by Philip and Samus. Spectroscopic work of Chris Corbally (Vatican Observatory) and Richard Gray (Appalacian State University), who measured stars from the Philip catalog of field HB stars, found that only two of the stars had the characteristic sharp-line features expected. The rest of the stars had broader hydrogen lines than expected.

The field HB stars are like the blue HB stars in globular clusters in that they have similar four-color indices, metallicities, photoelectric scans, velocities and stellar rotation. However, there are some differences. The field star metallicities reach much lower values of [Fe/H] (to −3.8) than do the cluster stars. Robert Kraft, in a review article, has pointed out that some field stars have lower nitrogen abundance than the cluster stars. The field HB stars could be stars that escaped from globular clusters or stars left in the halo after a globular cluster is broken up or stars captured in the halo from incoming fragments. Now that there are large databases of field HB stars and field HB candidates available, combined with the substantial number of large telescopes online and coming online, much progress in the spectroscopy of these stars should be made.

Jesper Sommer-Larsen (Copenhagen, Denmark) and his collaborators have been analysing the kinematics of the HB stars in the galactic halo and they have found that the radial component of the stellar halo's velocity dispersion decreases fairly rapidly beyond the solar circle. At the same time the tangential velocity dispersion increases with increasing radius. They conclude that the Galaxy may have formed from the merging of smaller subsystems, a formation theory favored by many theorists. For example, Leonard Searle (Carnegie Observatory) and Robert Zinn (Yale University) have proposed such a model from studies of globular clusters.

Ronald Wilhelm (University of Texas) and his collaborators have been making photometric and spectroscopic observations of the A-type stars in the galactic halo. They obtain effective temperatures, surface gravities, [Fe/H] values and radial velocities for approximately 1000 stars. They find that 40% of the stars in the sample were FHB stars, 37% were main-sequence A-type stars, 12% were Am or Ap stars and 11% were unclassifiable.

The masses of field HB stars have been investigated by Klaas de Boer (Bonn University) using Hipparcos data and he finds masses from 0.32 to $0.48 M_{\odot}$ for five field HB stars. Their absolute magnitudes follow the theoretical HB calculated by Ben Dorman (NASA/GSFC). Plans are underway to use the Space Interferometry Mission (SIM) to measure the parallaxes of the 100 or so brightest field HB stars, which will then give us better data to determine their masses and absolute magnitudes.

The HB is a remarkable feature and it is fortunate that nature has produced a situation where the HB covers such a wide range of the CMD. Different initial conditions (such as a higher average [Fe/H], could have given us only short, red HBs and we would not have the opportunity to study the effects of variations of the parameters mentioned above. At present, as more data arrive in the database,

things are getting ever more complex. The possibilities of gaining a better understanding of the HB will improve with time and new, accurate observations. With this improvement, we will arrive at a better understanding of globular clusters and their formation.

Horologium

(the clock; abbrev. Hor, gen. Horologii; area 249 sq. deg.) A southern constellation which lies between Eridanus and Reticulum, and culminates at midnight in early November. It was introduced by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2.

A small, inconspicuous constellation, the brightest star in Horologium is α Horologii, magnitude 3.9. There are no other stars brighter than fourth magnitude. Interesting objects include R Horologii, a Mira-type variable star (range 4.7–14.3, period about 408 days), and NGC 1261, an eighth-magnitude globular cluster.

Horrocks, Jeremiah (1619–41)

Schoolmaster (?) and astronomer, born in Toxteth, near Liverpool, educated at Cambridge, lived for a mere 22 years. His colleague WILLIAM CRABTREE lived near Manchester, and the group that formed around them constituted Britain's first Keplarians, *nos Keplari* as they called themselves. When he found that Ptolemaic predictions of the positions of the planets were incorrect, Horrocks developed a celestial dynamics, related to Kepler's but not identical to it, which employed concepts from terrestrial dynamics. Horrocks predicted a transit of Venus, and with Crabtree observed it by a telescopic projection method. From the observation, Horrocks calculated the solar parallax, finding a much greater distance of the Sun than anyone before him. The Keplari were the first people to realize the solar system's size and their figure was incredible to some of their contemporaries. When in 1662 the Dutch astronomer Helvetius published some material by Horrocks (*Venus in Sole Visa*), he scaled down Horrock's estimate of the size of the solar system. With his theory of celestial mechanics, Horrocks calculated the motion of the Moon, which FLAMSTEED admired as '... questionless the finest of his monuments'. NEWTON's theory of the motion of the Moon, according to one historian, was 'Newton's interpretation of HALLEY's variation of Flamsteed's version of Crabtree's account of Horrock's lunar theory'. Apparently Horrocks made his own telescope, and developed projection techniques to view the Sun.

Horsehead Nebula (B33)

A dark nebula in the constellation Orion, position RA 05^{h} 41.0^{m}, dec. $-02^{\circ}\,24'$. Though small ($6'$ by $4'$), it has the distinctive shape of a chess knight, and is one of the best known of all astronomical images, projected in silhouette against the emission nebula IC 434.

Hot Dark Matter

Dark matter made of light neutrinos, with masses of a few electron-volts (eV) or less, is called 'hot dark matter' (HDM) by cosmologists. Light neutrinos would have been 'hot', moving at nearly the speed of light, in the early universe. For a few years in the late 1970s and early 1980s, hot dark matter looked like the best dark-matter candidate. However, HDM models of cosmological structure formation led to a 'top-down' formation scenario, in which superclusters of galaxies are the first objects to form after the big bang, with galaxies and clusters forming through a subsequent process of fragmentation. Such models were abandoned by the mid-1980s after cosmologists realized that if galaxies had formed early enough to agree with observations, their distribution would be much more inhomogeneous than is the case.

Since 1984, the most successful structure-formation models have been those in which most of the mass in the universe comes in the form of cold dark matter (CDM)—particles that were moving sluggishly in the early universe. For a while in the mid-1990s it appeared that a mixture of mostly CDM with 20–30% HDM gave a better fit to the observations than either one or the other. This 'cold plus hot dark matter' (CHDM) theory fitted data on nearby galaxies and clusters only if the average density of matter in the universe were at or close to the critical density ($\Omega_m = 1$). However, like all such critical-density models, CHDM required that galaxies and clusters must have formed fairly recently. It is now clear that this disagrees with observations. The evidence now increasingly favors ΛCDM models, in which CDM and a little ordinary matter make up about a third of the critical density, with a cosmological constant or some other form of 'dark energy' contributing the remainder. This model also helped resolve a crisis regarding the age of the universe. The HDM question has now become how much room is left for neutrinos in such a universe.

To understand the possible role of neutrinos as dark matter, consider how structures such as galaxies formed as the universe expanded. The expansion itself is described by our modern theory of gravity and spacetime, Einstein's theory of general relativity. In order for structure to form, there must have been some small fluctuations in the initial density of matter. The only alternative is that some mechanism generated such fluctuations after the big bang, but the only such mechanisms that have been investigated are 'cosmic defects' such as cosmic strings, and the pattern of fluctuations produced by such defects is inconsistent with the temperature fluctuations observed in the cosmic microwave background (CMB) radiation. However, 'adiabatic' fluctuations—in which all components of matter and energy fluctuate together—occur naturally in the simplest cosmic inflation models and are in excellent agreement with the latest CMB results. The evolution of adiabatic fluctuations into galaxies and clusters is easy to understand: the rich always become richer and the poor become poorer. A 'rich' region of the universe is one that has more matter than average. Although the average density of the universe steadily decreases owing to its expansion, those regions that start out with a little higher density than average expand a little slower than average and become relatively more dense, while those with lower density expand a little faster and become relatively less dense. When any region has attained a density about twice the average, it stops expanding and begins to collapse—typically first in one direction, forming a pancake-shaped structure, and then in the other two directions.

The first HDM boom occurred about two decades ago. By about 1980, improving upper limits on CMB anisotropies were ruling out the previously favored cosmological model, which included only ordinary matter. There was also evidence from a Moscow experiment suggesting an electron neutrino mass of about 20 eV, which would have corresponded to a nearly-critical-density universe in which neutrinos would have constituted most of the matter. In such a cosmology, the primordial fluctuations on galaxy scales are erased by 'free streaming' of the relativistic neutrinos in the early universe. About 1 yr after the big bang, a region about 1 ly across contained the amount of matter in a large galaxy like our own Milky Way. However, the temperature was then about 100 million kelvins (10^4 eV), so each particle had a thermal energy far higher than the rest energy of light neutrinos. As they would therefore have been moving at nearly the speed of light, these neutrinos would have rapidly spread out, and any fluctuations in density on the scale of galaxies would soon have been smoothed back to the average density. The first scales to collapse in such a HDM scenario would therefore correspond to the mass inside the cosmic horizon when the temperature dropped to a few eV and the neutrinos inside it became non-relativistic. This mass turns out to be about 10 000 times the mass of our galaxy, including its dark halo. Evidence was just then becoming available from the first large-scale galaxy surveys that the largest cosmic structures—superclusters—have masses of approximately this size, which at first glance appeared to be a success for the HDM scenario. Superclusters of roughly pancake shape were observed to surround roughly spherical voids (regions where few galaxies are found), in agreement with the first cosmological computer simulations, which were run for the HDM model. In this picture superclusters should have formed first, since any smaller-scale fluctuations in the dominant HDM would have been erased by free streaming. Galaxies then had to form by fragmentation of the superclusters. However, it was already becoming clear from observations that galaxies

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

are much older than superclusters, contrary to what the HDM scenario implies. Also, the apparent detection of electron neutrino mass by the Moscow experiment was soon contradicted by results from other laboratories. Hot dark matter fell into decline.

The CDM model originated in 1982–1984, just as the problems with the HDM model were becoming clear. Proto-galaxies form first in a CDM cosmology, and galaxies and larger-scale objects form by aggregation of these smaller lumps—although the cross-talk between smaller and larger scales in the CDM theory naturally leads to galaxies forming earlier in clusters than in lower-density regions. In this and other respects, CDM models appeared to fit observations much better than HDM. The first great triumph of CDM was that it successfully predicted (to within a normalization uncertainty factor of about 2) the magnitude of the CMB temperature fluctuations, which were discovered in 1992 using the COBE satellite. However, the simplest CDM model, standard CDM (SCDM) with the matter density equal to the critical value ($\Omega_m = 1$), had already begun to run into trouble.

Cosmological theories predict statistical properties of the universe—for example, the size of density fluctuations on various scales, described mathematically by a power spectrum. Sound or other fluctuation phenomena can be described in the same way—for example, low frequencies might be loud, corresponding to relatively high power at long wavelengths. With a given amount of fluctuation power on the large scales probed by COBE (billions of light-years), SCDM has a little too much power on small scales relevant to galaxies and clusters (millions of light-years and less). However, the fact that the SCDM theory could work fairly well across such a wide range of size scales suggested that it had a kernel of truth. Cosmologists began to examine whether some variant of SCDM might work better. For example, in the late 1980s, my former student Jon Holtzman calculated detailed expectations for 96 variants of CDM. When we compared these predictions with the data available in early 1992, it was clear that the best bets were CHDM and ΛCDM, each of which could fit the data on small scales better than SCDM. Both of these variants had been proposed in 1984, when CDM was still a new idea, but their detailed consequences were not worked out until the problems with SCDM began to surface.

Even if most of the dark matter is cold, a little HDM can still have dramatic effects on the small scales relevant to the formation and distribution of galaxies. In the early universe, the free streaming of fast-moving neutrinos would have washed out any spatial inhomogeneities in the neutrino component on the scales that later became galaxies, just as in the HDM scenario. Consequently, fluctuations in the CDM component grew more slowly on these scales, and at the relatively late times when galaxies formed there was less fluctuation power on small scales in CHDM models. Adding a little HDM appeared to be just what was needed to solve the SCDM problem that the galaxy-scale inhomogeneities are too big. Also, there was even a hint from an accelerator experiment that neutrino mass might lie in the relevant range. This was the Liquid Scintillator Neutrino Detector (LSND) experiment at Los Alamos National Laboratory, which recorded a number of events that appear to be $\nu_\mu \rightarrow \nu_e$ neutrino oscillations. Comparison of the LSND data with results from other neutrino experiments allows two discrete values of $| m^2(\nu_\mu) - m^2(\nu_3) |$, around 10.5 and 5.5 eV^2, or a range of values between 0.2 and 2 eV^2. If true, this means that at least one neutrino has a mass greater than 0.5 eV, which would imply that the contribution of HDM to the cosmological density is much greater than that of all the visible stars. Such an important conclusion requires independent confirmation. The Karlsruhe Rutherford Medium Energy Neutrino (KARMEN) experiment results exclude a significant portion (but not all) of the LSND parameter space, and the numbers quoted above take into account the current KARMEN limits. The Booster Neutrino Experiment (BooNE) at Fermilab should attain greater sensitivity and help to resolve this issue.

By 1995 simulation techniques and supercomputer technology had advanced to the point where it was possible to do reasonably high-resolution cosmological-scale simulations including the random velocities of an HDM component. The results at first appeared very favorable to CHDM. Indeed, as late as 1998 a CHDM model with Hubble parameter $h = 0.5$, mass density $\Omega_m = 1$ and neutrino density $\Omega_\nu = 0.2$ was found to be the best fit of any cosmological model to the galaxy distribution in the nearby universe. However, cosmological data were steadily improving, and even by 1998 it had become clear that $h = 0.5$ and $\Omega_m = 1$ were increasingly inconsistent with observations, and that $h \sim 0.7$ and $\Omega_m \sim 1/3$ worked much better. For example, CHDM predicts that galaxies and clusters formed relatively recently, but around 1998 increasing numbers of galaxies were discovered to have formed in the first few billion years after the big bang. Also, the fraction of baryons found in clusters, together with the reasonable assumption that this fraction is representative of the universe as a whole, again gives $\Omega_m \sim 1/3$. That there is a large cosmological constant (or some other form of dark energy) yielding $\Omega\Lambda \sim 2/3$ then follows from any two of the following three results: (1) $\Omega_m \sim 0/3$, (2) CMB anisotropy data implying that $\Omega_m + \Omega\Lambda = 1$, and (3) high-redshift supernova data implying that $\Omega\Lambda - \Omega_m \sim 0.4$. The abundance of galaxies and clusters in the early universe agrees well with the predictions of the ΛCDM model. However, the highest-resolution simulations of this model that were possible in the mid-1990s gave a dark matter spectrum that had more power on scales of a few million light-years than did the observed galaxy power

spectrum, although the simulations and data agreed on larger scales. This result was inconsistent with the expectations that galaxies would be more clustered than the dark matter on small scales, not less. When it became possible to do even higher-resolution simulations that allowed the identification of the dark matter halos of individual galaxies, however, their power spectrum turned out to be in excellent agreement with that of galaxies. The galaxies were less clustered than dark matter because galaxies had merged or were destroyed in very dense regions owing to interactions with each other and with cluster centers. This explanation turned a troubling discrepancy into a triumph for ΛCDM.

Thus ΛCDM is the favorite theory today. However, we know from the Super-Kamiokande evidence for atmospheric neutrino oscillations that there is enough neutrino mass to correspond to some HDM, at least $\Omega_\nu \approx 10^{-3}$, about one-fourth as much as the visible stars. How much room remains for a little HDM in ΛCDM cosmologies? The reason there is any upper limit at all from cosmology is because the free streaming of neutrinos in the early universe must have slowed the growth of the remaining CDM fluctuations on small scales. Thus, to have the galaxy structures we see today, there must be much more cold than hot dark matter. From the shape of the galaxy power spectrum observed by the 2dF galaxy redshift survey, the limit on the sum of the neutrino masses is $m(\nu) < 2.2$ eV, corresponding to $\Omega_\nu < 0.05$. This limit on $m(\mu)$ is much stronger than the best current laboratory limit. Astronomical observations that may soon lead to stronger upper limits on neutrino mass—or perhaps a detection—include more precise measurements of the power spectrum from galaxy redshift surveys, data on the distribution of low-density clouds of hydrogen (the 'Lyman-alpha forest') at high redshifts, large-scale weak gravitational lensing data and improved measurements of the cosmic background radiation temperature fluctuations on small angular scales. These types of data can be used to probe for the effects of any free streaming of neutrinos in the early universe, which can lead to less power on small scales depending on the values of the neutrino masses.

Hot Stellar Populations in Elliptical Galaxies

The term 'hot stellar populations in elliptical galaxies' refers to the presence of a population component that produces a thermal far-ultraviolet continuum in spectra taken of the centers of elliptical galaxies. This phenomenon, called the 'UV rising branch', 'UV upturn' or 'UVX'[1] is also found in the spectra of S0 galaxy nuclei, and in those of the bulges of spiral galaxies (see GALAXIES: CLASSIFICATION).

The UVX was first discovered by the OAO-2 (see ORBITING ASTRONOMICAL OBSERVATORY). Since then, it has been found to some measure in all of the above systems observed to date. Additional data have been collected with the IUE (see INTERNATIONAL ULTRAVIOLET EXPLORER), the Astro Shuttle missions (Hopkins Ultraviolet Telescope and Ultraviolet Imaging Telescope) and with the HST (see HUBBLE SPACE TELESCOPE).

The most striking characteristic of the UVX phenomenon is its high variability among galaxies, ranging by a factor of 10 in intensity as measured by the color $(15 - V)$, the ratio of a broadband magnitude centered at 1500 Å to the optical light (see figure 1). Arguably the single most important observation, which has dominated work on the far-ultraviolet radiation from galaxies, is the apparent correlation with galaxy abundances first noted by Faber (1983). The variability and apparent relation to galactic abundances, as well as evidence for relationship to dynamic properties, have made the UV upturn an important issue for the study of the origin and formation of galaxies. It represents a discriminant among objects that is not available from the optical record.

The thermal nature of the radiation—corresponding to a blackbody spectrum with $T_{\rm eff} \sim 20\,000$ K—pointed to an origin in starlight, rather than one in galactic nuclear activity, for this ultraviolet flux component. It was also noted that the old stellar populations expected to constitute the ellipticals were likely to contain post-asymptotic giant branch stars (see STELLAR EVOLUTION, RED GIANT STARS, PLANETARY NEBULAE), which become very hot during their evolution from the red giant branch (RGB) to become white dwarfs. The other obvious candidate for the origin of the flux was a population of normal early B stars, products of recent star formation.

It was later realized that hot (blue) horizontal branch (HB) stars (see HORIZONTAL BRANCH STARS) were a copious source of ultraviolet radiation. HB stars are differentiated according to the size of their hydrogen-rich envelope that remains after the RGB phase, where mass loss takes place. Blue horizontal branch stars (with $8000 < T_{\rm eff} < 20\,000$ K) are abundant in the Galactic globular clusters (see GLOBULAR CLUSTERS) of low metal abundance. The hottest HB stars have extremely thin hydrogen envelopes, less than 0.05 solar masses, and during central helium burning evolution have surface temperatures up to 36 000 K. Their thin envelope cannot support a return to the giant branch after the central helium is exhausted, and thus they continue to emit copiously in the far-ultraviolet until their evolution to the white dwarf phase. These are termed extreme horizontal branch (EHB) stars.

However, the appearance of hot HB stars in metal-rich stellar populations was thought to be rare since, until about 1995, they had never been observed in globular clusters with metal abundances approaching that of the Sun. Indeed, until the last few years, the existence of EHB stars was thought to be rare even among the metal-poor globulars, whereas the elliptical galaxies have spectra implying a dominant population of stars exceeding the solar abundance (see ELLIPTICAL GALAXIES).

On the other hand, as was known from studies in the early 1970s, the field population of our own galaxy contains many hot subdwarf (sdB and sdO) stars. Their location on the Hertzsprung–Russell diagram coincides with the EHB stars and their post-HB progeny. However, the possible connection between the UVX phenomenon and the field hot subdwarf population was not realized until much later.

In the last few years, great strides have been made in observing hot populations in ellipticals, and these have all but ruled out an explanation in terms of radiation from young, massive stars, as is detailed in the next section. The widely accepted model is now of a hot, evolved stellar population of EHB stars whose numbers and spatial distribution may reflect both galactic enrichment history and dynamical properties. The study of the UVX has therefore concentrated on determining not only the origin of the flux but its relation to other known properties of galaxies, both of population and of structure.

Summary of data

A number of different observations have provided constraints on the originating population of the UV upturn. To summarize, the main points are as follows.

- It is observed in all elliptical, S0, and spiral bulges that have signs of neither nuclear activity nor recent star formation.
- Its amplitude, measured by the color $(15 - V)$, varies by 2.5 magnitudes and attains $15 - V \sim 2$ in the brightest example, NGC1399 (Burstein *et al* 1988) (figure 2).

[1] It is also sometimes confusingly referred to as the 'UV excess', which has a separate meaning in stellar photometry.

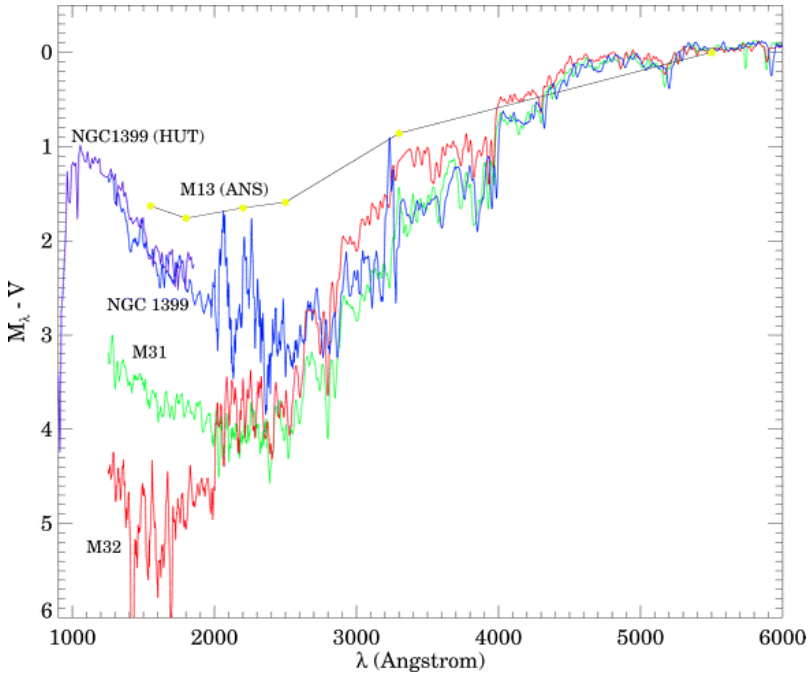

Figure 1. The UVX phenomenon as seen with IUE and HUT data. The spectra are of NGC1399 (uppermost), M31 (middle) and M32 (lowermost). For comparison is shown also the flux distribution of the Galactic globular cluster M13 taken with the Astronomical Netherlands Satellite (ANS); its ultraviolet radiation is thought to emanate from similar stars (see text). The galaxy spectrum is, however, harder (emanating from hotter stars) and has a much steeper descent from the optical to the mid-ultraviolet wavelengths, which is a consequence of the higher abundance of the background population.

- It is positively correlated with the optical magnesium index Mg_2 (Burstein *et al* 1988)[2], which in turn correlates with the galaxy central velocity dispersion σ_0 (a measure of the galaxy mass). It is also correlated with other light element indices. The UVX is not, however, correlated with indicators of iron-peak element abundance. Burstein *et al*, noting both relationships, suggested that the abundance correlation was tighter than that in σ_0 and therefore more likely to be the causal factor. Additionally, there is not yet a theory linking variations in the stellar content (such as the production of hot stars) with galactic dynamical properties, whereas the effect of abundance on stellar populations can be studied using stellar evolution theory.
- Hopkins Ultraviolet Telescope (HUT) spectral data, reaching wavelengths beyond the Lyman break at 912 Å, give an effective temperature of 20 000–25 000 K for the far-UV flux in a sample of galaxies (Ferguson and Davidsen 1993). The narrow range of characteristic temperatures argues against an interpretation in terms of young massive stars, as did the lack of strong metal absorption lines characteristic of the spectra of such objects. The characteristic temperature also disfavors an explanation purely in terms of post-AGB stars, which radiate much of their energy while at higher temperatures.

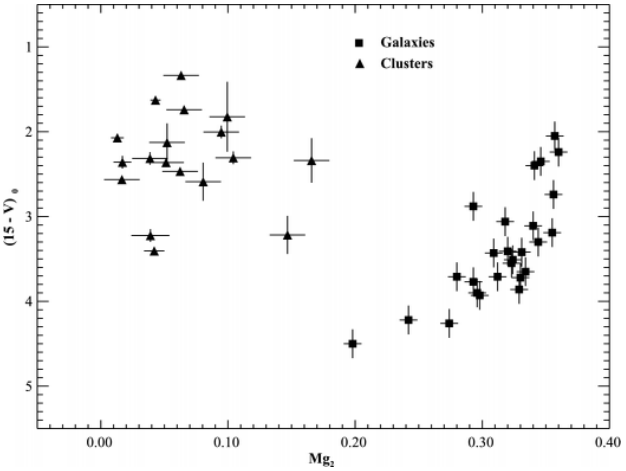

Figure 2. The 15 – *V* versus Mg_2 (UV upturn versus abundance) diagram. To the right are the galaxies, with strong absorption lines. For comparison plotted to the left are the Galactic globular clusters whose UV bright populations are resolved and studied in detail. They are weaker-lined (low-abundance) systems.

[2] Mg_2 is an abundance indicator that is strongly correlated with iron-peak abundances in (metal-poor) Galactic globular clusters, and is widely used as an abundance indicator in galaxies.

- HUT data also demonstrate qualitative differences in the spectral slopes between two systems, M31 in Andromeda and NGC1399 in Fornax (Ferguson and Davidsen 1993), implying that the UVX might emanate from a blend of sources with different properties.
- The spatially resolved data show the UV flux to be distributed in a fashion that is morphologically similar to that of old stellar populations, i.e. smooth and centrally concentrated (see figure 3). This is in contrast to the appearance of young star associations, which are clumped and dispersed from the center (O'Connell *et al* 1992). The data also show the 15 – *V* measure of UVX intensity to possess a radial gradient that is usually steeper than that of any optical index (O'Connell *et al* 1992).
- Ultraviolet photometry of Local Group galaxies, in which individual sources can be resolved and measured, confirms the presence of hot, old stellar populations in those systems, and a lack of evidence for massive stars (O'Connell *et al* 1992, Brown *et al* 2000).
- Radial gradients in the 15 – *V* color do not strongly correlate with radial gradients in the Mg_2 index (Ohl *et al* 1998). Thus, abundance cannot be the sole factor causing the strength of the UV upturn.
- The UVX has been observed with Hubble Space Telescope in galaxy clusters at redshifts $z = 0.375$ and 0.55, corresponding to lookback times of 4 and 6 Gyr. These two datasets give the first evidence that the phenomenon evolves with time, and may in future give evidence that constrains the age of galaxy formation.

Fuller reviews of the data and their implications are given in Burstein *et al* (1988), Greggio and Renzini (1990), Dorman *et al* (1995) and O'Connell (1999).

Hot evolved stellar populations

The extensive theoretical review of Greggio and Renzini (1990) named as possibilities evolved helium burning objects and their descendants, post-RGB remnants (stars losing so much mass on the red giant branch that they proceed directly to the white dwarf cooling phase), and various interacting binary star scenarios. However, the subdwarf population of our Galaxy dominates the detections of blue sources in field surveys looking for hot objects. Objects of this type, even while many of them have companions, have luminosities that imply a single- rather than multiple-star origin. This suggests that a population of hot horizontal stars may be a normal constituent of evolved stellar populations. Perhaps this also provides the strongest plausibility argument for the prevailing hypothesis that hot, helium burning stars are indeed responsible for the UVX phenomenon, rather than any of the other more exotic candidates that have yet to be fully investigated.

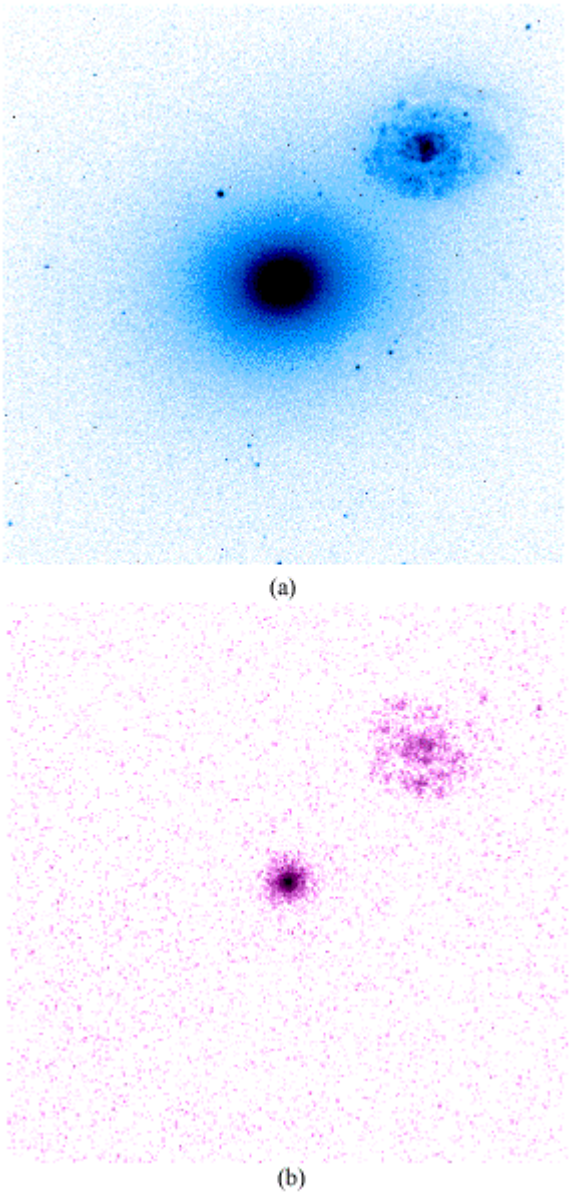

Figure 3. Elliptical and spiral galaxy optical–far-ultraviolet comparison. (*a*) B-band exposure of the same field obtained at Palomar Observatory. (*b*) Far-ultraviolet image of the elliptical M60 (NGC 4649) and Sc spiral galaxy NGC 4647, taken from the Ultraviolet Imaging Telescope. Note the contrast in the distribution of ultraviolet radiation between the elliptical and the spiral galaxy. From Ohl R G 2000 *PhD Thesis* John Hopkins University.

Much is known about hot evolved stars from the Galactic globular cluster system in which large HB populations can be resolved and studied in detail. The properties of stars in the field hot subdwarf population smoothly mesh with the hottest stars in these clusters. Additionally, the field population of hot subdwarfs is identified kinematically with the old disk population of our Galaxy which is thought to have an abundance distribution similar to that of the galaxies. Hence, our

understanding of the potential source of the UVX is augmented by analogy with both old Galactic hot stellar populations.

From the fuel consumption theorem (see next section), sources of far-UV radiation in old stellar populations that are most significant are those which are powered by stable nuclear reactions. The evolved hot stellar population components comprise stars in the post-asymptotic giant phase, hot and extreme horizontal branch stars, and the post-horizontal branch phases of extreme HB stars (see figure 4 for a schematic). Detailed evolutionary sequences and discussion can be found in Dorman *et al* (1993) and references therein.

Post-asymptotic giant stars are the central stars of planetary nebulae. When the hydrogen envelope of an asymptotic giant branch star is largely consumed, the star evolves rapidly towards higher temperatures. During this evolution, ending on the white dwarf cooling curve (see WHITE DWARFS) they span a temperature range of about 3000 to in excess of 100 000 K at a fixed luminosity that exceeds $2500L_{\odot}$. The lifetime in this phase, however, is short (since the fuel is rapidly consumed), generally a few times 10^4 yr to only a few thousand years. It decreases strongly with increasing luminosity, and the total energy radiated decreases with it. The spectrum integrated over this phase has a high characteristic temperature.

Horizontal branch stars are formed after a star reaches the tip of the red giant core, undergoes an off-center helium flash and subsequently develops a stable helium fusion source. The HB lifetime is substantial, about 100–150 Myr, at a luminosity of $(10–50)L_{\odot}$, so that stars that are sufficiently hot are important UV emitters. The key parameter determining ultraviolet radiation from HB stars is the size of the hydrogen-rich envelope, denoted $M_{\rm env}$, at the onset of stable central helium burning. Because the helium flash takes place at a fixed temperature in red giant interiors, the size of the helium core inside new HB stars varies relatively little with envelope mass (or, for that matter, abundance and age), being about $0.5M_{\odot}$. The temperature of an HB star increases with decreasing $M_{\rm env}$, which also corresponds to decreasing hydrogen shell luminosity. The most extreme HB stars (see below) are, initially, almost identical to pure helium burning stars.

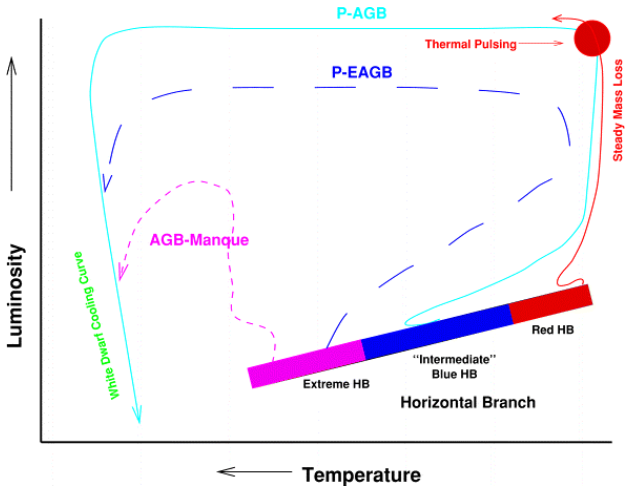

Figure 4. Schematic of the various types of hot, evolved star shown in the theoretical plane. From Dorman *et al* (1993).

Observations of Galactic globular clusters demonstrate that in real stellar populations $M_{\rm env}$ for the HB stars is often scattered, for reasons not properly understood. The distribution arises because stars in the population lose varying amounts of mass in the preceding red giant branch stage of evolution. The observational record shows that, with a few notable exceptions, stars in clusters that have relatively high heavy element abundance are usually cool ($T_{\rm eff} \sim 4000–5000$ K) and are therefore dark in the UV. In contrast, HB stars in clusters with low abundance are found to span a large range in temperature, $T_{\rm eff} \sim 6000–30\,000$ K.

Numerical models of HB stars show that stars sufficiently hot to radiate in the ultraviolet can be formed for almost any chosen abundance. However, the amount of mass that must be lost to make HB stars that are strong UV emitters is dependent on their heavy element abundance Z and also their helium abundance Y. For stars with high abundance, nearly the entire mass of the envelope must be stripped in order to produce a hot star. At low Z, models with substantial hydrogen-rich envelopes can be hot enough to radiate strongly in the far-UV.

After the core helium is exhausted, helium shell-burning is initiated. If the remaining envelope at this stage is sufficiently large (greater than $0.05M_{\odot}$) the hot HB stars return to the AGB (i.e. they develop a deep, cool convective exterior) as do their more massive red HB counterparts. They evolve through the thermally pulsing stage, finally becoming P-AGB stars and white dwarfs.

The designation ‘EHB star’ is used to refer to stars that do not reach the P-AGB stage of evolution. These stars have envelope masses $\geq 0.05M_{\odot}$, have weak or insignificant hydrogen shell burning during helium core burning and effective temperatures that range from about 20 000 to 37 000 K depending on both envelope mass and abundance. After core exhaustion they become brighter and develop significant hydrogen shell energy sources and are called ‘post-early AGB’ stars or ‘AGB manqué’ (‘failed AGB’) stars depending on whether or not they reach the early part of the AGB evolutionary sequence.

The later evolutionary stages of the EHB stars do not have enough hydrogen to develop a cool outer convection zone after the central helium source is exhausted. These stars remain hot in the post-HB phase and emit similar amounts of UV radiation over their post-

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

HB lifetime to those during core helium burning. These are the AGB manqué stars. They have lifetimes typically 20–40 Myr (similar to the AGB itself), with $L \sim (100–500)L_{\odot}$. They reach effective temperatures of 80–10 000 K before settling on the white dwarf cooling sequence. The continuum of possible evolutionary paths includes also a transitional type, the 'post-early AGB' stars, that reach the earlier but not the later stages of evolution on the asymptotic giant branch. These stars resemble the behavior of AGB stars, but are slightly less luminous and somewhat longer lived.

Observations indicate that there is a strong 'stellar populations' component to the mass loss during the RGB phase. That is, the mass loss phenomenon varies among populations, so that systems that are apparently similar in the gross properties that govern stellar evolution do not produce the same HB stellar distribution ('HB morphology')[3]. This complicates the explanation of HB populations in general, and the UVX in particular.

For example, one simple reason why HB morphology might be different between two populations is age. As a population ages, the mass of the stars at the tip of the red giant branch decreases. All things being equal—in particular, the abundance of the stars and distribution of total mass lost among stars of that abundance—one would expect the distribution of $M_{\rm env}$ on the HB to be smaller for older stars and thus the probability of forming more hot stars increases. However, the observational record only supports this explanation for HB morphology differences in a limited way on a subset of the Galactic globular cluster system, and thus the observations of a particular $15 - V$ color cannot be used to give a definitive age to a stellar population.

Nevertheless, for a sufficiently 'young' evolved population, one does not expect to see far-UV radiation. For example at age 5 Gyr, the mass of red giants in metal-abundant galaxies is about $(1.4–1.5)M_{\odot}$. The amount of mass loss required to produce hot stars, about $1M_{\odot}$, is much greater than in populations of age 14 Gyr, whose giants have mass $\sim(0.8–0.9)M_{\odot}$. If mass loss processes act in similar fashion in both cases, the number of hot stars in the younger population will be smaller. Thus it is predicted that the UVX arises later in galaxy evolution, or that the restframe UV radiation should fade with increasing redshifts of distant galaxy clusters. The observations of galaxies at moderate redshift are consistent with this prediction.

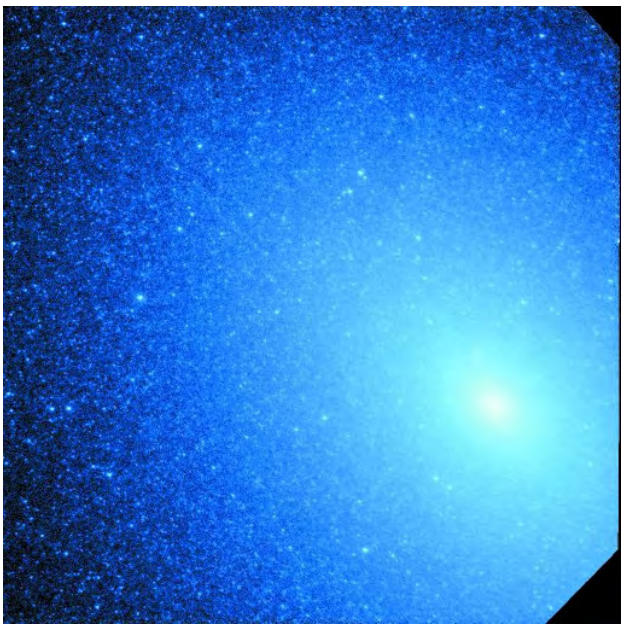

Figure 5. The local group galaxy M32, imaged in the UV (1450–3500 Å) with the Space Telescope Imaging Spectrograph of the Hubble Space Telescope. The individual stars in the picture have magnitudes consistent with being hot HB or post-HB stars. From Brown *et al* 2000, © *The Astrophysical Journal*, reproduced with permission.

The fuel consumption theorem and synthetic populations

The UVX phenomenon can be studied using the methods of evolutionary population synthesis (see SYNTHETIC STELLAR POPULATIONS). Briefly, such methods build a population model from the constituents of the population under study using results from stellar evolution calculations. Then, integrated spectra are computed using either synthetic stellar fluxes computed from model atmospheres and synthetic stellar flux calculations, or a library of empirical fluxes derived from observations. Finally, colors such as the $15 - V$ measure can be derived as a function of any input population model by integrating a synthetic spectrum over desired filter bandpasses.

To compute the synthetic $15 - V$ color of a stellar population, it is necessary to select the following ingredients for the model:

(a) The population responsible for the far-UV radiation.
(b) The constituents of the 'background' population. For elliptical galaxies the bulk of the population is unambiguously composed of older stars ($T_{\rm eff} < 7000$ K) on the main sequence and red giant branch, none of which emits significant far-UV radiation (see figure 5). This part will consist of a set of one or more isochrones representing populations of a set of ages and abundances and the assumption of a mass function.

[3] This problem is known as the Second Parameter Effect, the 'first parameter' being metal abundance: see GLOBULAR CLUSTERS.

(c) A measure of the input rate of stars into the late evolutionary stages. This can found empirically through relative number counts or theoretically by differentiation performed on stellar isochrone sequences (see Dorman *et al* 1995).

The fuel consumption theorem (see e.g. Renzini and Buzzoni 1986) states that the total bolometric flux produced in an advanced phase of stellar evolution is proportional to the fuel consumed during that phase. It is instructive to sketch the derivation of this result and to show how it may be extended to synthesize stellar population properties.

The energy radiated by a star during any evolutionary phase is

$$E = \int_{\text{phase}} L \, \mathrm{d}t.$$

This energy is, to a good approximation, produced by nuclear burning and therefore proportional to the fuel consumption.

In a large stellar system, the number of stars evolving off the RGB to the HB is a Poisson process, with the input rate to the HB having a finite mean. Since this mean varies on a timescale larger than the length of any subsequent phase, the numbers of stars in that phase will approach a steady state.

If we denote this mean input rate by $\dot{N}$, and divide the evolutionary path from the beginning of the HB phase to its end by a set of time intervals $\{t\}_i$, then the number of stars in the jth time interval $\Delta t_j = t_j - t_{j-1}$ is

$$\Delta N_j = \dot{N} \, \Delta t_j.$$

The total luminosity of all the stars along the track is then

$$L = \dot{N} \sum_j L_j \, \Delta t_j.$$

In the limit where the population is large,

$$\dot{N} \, \Delta t_j \gg 1$$

(i.e. there are expected to be many stars in each interval j), this equation becomes an integral, with

$$L = \dot{N} E.$$

This is the fuel consumption result. Derived in this form, one may also see that the luminosity of a stellar population in a given passband denoted by λ is proportional to the total energy radiated in that band given by their integrated luminosity at λ over their lifetime multiplied by their rate of formation, i.e.

$$L_\lambda = \dot{N} \int_{\text{birth}}^{\text{death}} L_\lambda \, \mathrm{d}t = \dot{N} E_\lambda.$$

The terms in these equations can be estimated from fits to stellar evolutionary sequences (Renzini and Buzzoni 1986), or computed directly from the stellar evolution calculations (Dorman *et al* 1995) if the bolometric correction at λ, $\alpha_\lambda = L_\lambda/L$, is also known. Bolometric corrections are derived from the stellar flux library adopted for the analysis.

Colors can then be computed for the synthetic stellar population and compared with observations. For example, to compute the $15 - V$ color one needs to calculate both L_{1500}, which arises purely from the hot population, and L_v, the visual brightness, which consists of

$$L_v = L_{\text{evolved}} + L_{\text{RGB}} + L_{\text{MS}}$$

since all of the evolved, red giant branch and main sequence stars radiate at optical wavelengths. The contribution from the two earlier stages is evaluated at fixed age and abundance by assuming a stellar isochrone[4] and a mass function describing the number of stars forming of a given mass.

The synthetic color of the model is then given by

$$15 - V = -2.5 \log(L_{1500}/L_v) + \text{constant}$$

where the constant is a normalization chosen by convention (-21.1 on the monochromatic scale), and similarly for other colors.

Quantitative analyses of the UVX

The object of quantitative analysis is to understand how the variation of UVX strengths in galaxies might arise, how that might account for the apparent variation of the amplitude with abundance, and what range of model parameters are consistent with the behavior of spectra such as are illustrated in figure 1.

Of particular utility is a measure of the lifetime-integrated ultraviolet energy, e.g. E_{1500}, the energy radiated in a bandpass centered at 1500 Å. One may evaluate this function for models of various potential contributors to the UV upturn and thus quantitatively estimate under which circumstances each will dominate the observed radiation.

For horizontal branch models, E_{1500} is a function of M_{env}, Z, Y and age. By varying the assumed mass distribution of HB stars the effect of various hypotheses concerning its behavior can be studied. In a population

[4] An isochrone is a curve constructed from stellar evolution calculations defining the locus on the theoretical Hertzsprung–Russell diagram joining stars at a chosen age.

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

model, for any given abundance E_{1500} (M_{env}) must be integrated over a mass distribution $P(M_{env})$, with unit integral over the range of the available horizontal branch masses. That is,

$$E_{\lambda}^{HB} = \int_{blue}^{red} P(M') E_{\lambda}(M') \, dM'.$$

A detailed study of the stellar models gives the following conclusions.

- The peak contribution from extreme HB stars is 20–30 times greater than for post-AGB stars, so that if the former exist in significant numbers they will dominate the UVX.
- The maximum possible post-AGB flux in a population cannot produce the strongest UV upturns that have been observed.
- E_{1500} itself is insensitive to age: it is the 'population' function $P(M)$ that gives rise to any age variation.
- E_{1500} is also relatively insensitive to the abundances of stellar populations, varying by some tens of percentage points rather than by orders of magnitude. This suggests that the variations in the UVX we see are due to variations in the number of sources that are present.
- If all of the red giants in an old stellar population turned into EHB stars, the resulting UV flux would be about 6 times stronger than in the strongest UVX galaxy. Thus, in the most extreme UVX object, NGC 1399, about 16% of the HB stars are hot.
- The range of masses for which E_{1500} is significant at high Z is somewhat smaller than at low abundance, and thus abundance alone cannot drive the UVX: one needs to invoke a variation in mass loss too.
- Surprisingly, the range of masses for which E_{1500} is significant increases with increasing Y, so that it is easier to make EHB stars in helium-enriched populations.

Figure 6, showing samples of galaxy and globular cluster data, supports the hypothesis that variability in the UVX is caused by a variation in numbers of sources. In figure 6(*a*), the globular clusters, which have known variation in the HB morphology (and therefore in numbers of UV emitting sources) and low abundance, are compared with the UVX data for galaxies, which have a spread in UVX strength and high abundance. The sequences of different types of objects separate into almost parallel lines. Figure 6(*b*) shows that the reason for the separation is the relative weakness of the galaxies in the mid-ultraviolet, at 2500 Å. This is the direct result of the steeper slope of the galaxy spectra compared with the cluster spectrum seen in figure 1.

Stellar population models constructed using the methods briefly described in the previous section can indeed reproduce the location of the data on these two diagrams. Hence, despite the uncertain relationship between the (far-ultraviolet) UVX and galaxy abundance, the mid-UV shows some promise as a population abundance indicator (but see SYNTHETIC STELLAR POPULATIONS for other issues arising from population indicators). Although the mid-UV fluxes of galaxies are strongly affected by the presence of a strong UV upturn component, the relative invariance of its temperature yields simple methods for subtracting this effect if it has been quantified by far-UV observations.

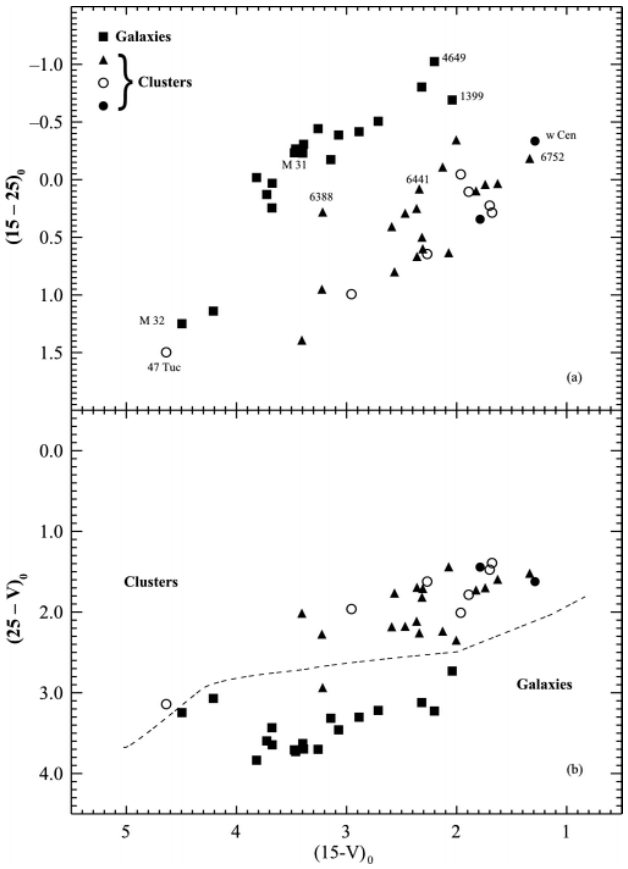

Figure 6. The UV characteristics of galaxy and globular cluster data compared (from Dorman *et al* 1995). The globular clusters (triangles and circles), with known variation in numbers of HB stars and low abundance, form sequences parallel to the galaxies (squares) with varying UVX strength and high abundance in mid-UV color–magnitude and color–color diagrams.

Various lines of argument have led researchers to adopt three distinct explanations for the galaxy population from which the UVX stars are drawn. All of these assume that the elliptical galaxies have an abundance spread which is similar to that found in our own Galaxy, and all appeal to different abundance ranges to explain the phenomenon.

(a) The UVX arises from the metal-poor tail of the galactic abundance distribution, from stars similar to

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

those found in the Galactic globular clusters. By extension of the age effect on HB morphology, the high temperature of the UVX relative to most globular clusters implies that the phenomenon implies an age for the galaxies greater than the globular clusters.

(b) Assuming that the helium content of high-Z stars continues to increase for $Z > Z_{\odot}$ as is found for $Z < Z_{\odot}$, (i.e. $\Delta Y/\Delta Z > 2.5$, so that for $Z = 3Z_{\odot}$, $Y \sim 0.4$) the UVX phenomenon will arise naturally from the high end of the galactic abundance distribution, also at great age.

(c) No inference can be drawn concerning the abundances of the UVX stars since the intrinsic properties of the HB vary only weakly with abundance parameters compared with the (undetermined) nature of mass loss. The most plausible assumption is that the UVX stars are most likely to be drawn from the peak of the abundance distribution since it is by definition the most numerous background population. According to this scenario, the UVX is not directly related to abundance but indicates something yet to be understood about the history of stellar populations in galaxies.

Of these hypotheses, the first two both interpret the UVX phenomenon as an age effect based on the argument given earlier for HB morphology as largely an age effect. The 'low-abundance' hypothesis (a) appears however, to be inconsistent with the observations, at least for the strongest UVX galaxies. Since these require about 15% of all HB stars to be of EHB type, a low-Z subcomponent of this size would radiate more strongly in the mid-UV than the observations allow. The 'high-Z' abundance argument depends on an uncertain extrapolation of the helium enrichment function for these stars. Since it appears both that the galaxy abundances are in fact more strongly enhanced in lighter elements and that the UVX is not correlated with Z, helium content in stars increases with elements such as magnesium. Finally, the third, most conservative, hypothesis leaves the direct interpretation of the UVX inconclusive.

While it is common in astronomy to appeal to the need for more observational data, this is particularly true in the ultraviolet. Observations require space-based astronomy and the number of observing platforms that have been able to collect sufficiently high-quality data of distant galaxies has been small.

A final point is that the UVX is observed to be correlated with the light element index Mg_2 and not with indices measuring the iron-peak elements (E_{1500} should be relatively insensitive to light element variations, since it is sensitive to the deep structure of the star which is unaffected by light element abundance). Further, resolved observations of the UVX indicate that it does not vary radially the same way that abundance measurements do. Hence, despite the initial optimism for understanding the UVX in terms of a variation in population abundance, later evidence implies that the relationship is far from straightforward.

There are a couple of lines of evidence tentatively linking the UVX to dynamical properties of galaxies rather than abundance, a link for which there is currently no explanation. The data suggest a relationship between the shape of galactic isophotes (curves of constant brightness) such that galaxies with 'boxy' isophotes associated with possible merger products are also galaxies with stronger UV upturns. Also, there is the possibility that the UVX–Mg_2 correlation actually consists of several distinct groups rather than a continuous relationship. In this view the brightest UVX galaxies, which correspond to giant ellipticals with the largest central velocity dispersions, form a group with distinct ultraviolet properties. The UV upturn may thus be an as yet inscrutable indicator of a relationship between galaxy dynamics and stellar populations.

Hour Angle

The angle between an observer's meridian and a celestial body measured westwards (i.e. clockwise) from the meridian in a direction parallel to the celestial equator. Hour angle is usually expressed in terms of time units (hours, minutes, and seconds, where 1 h is equivalent to 15°) since the value of hour angle increases due to the apparent daily rotation of the celestial sphere. Thus the hour angle of a star is zero when it crosses the meridian (at upper transit); 6 h later, the celestial sphere has rotated through 90°, and the value of hour angle is 6 h. Thus, the hour angle is equal to the time which has elapsed since the last occasion on which the star crossed the meridian. After 24 h, the star returns to the meridian once more.

Hourglass Nebula (MyCn 18)

A planetary nebula in the constellation Musca, position RA $13^{\mathrm{h}}\ 40^{\mathrm{m}}$, dec. $-67^{\circ}\ 23'$. It is only $4''$ in size, and was first imaged well by the Hubble Space Telescope. The twin lobes of ejected matter from the central star form a distinctive hourglass shape, while recently expelled gas at the center strongly resembles a human eye.

Hoyle, Sir Fred (1915–)

Astrophysicist, controversialist and science fiction writer, born in Bingley, West Yorkshire, England, became professor of astronomy at Cambridge where he founded the Institute of Theoretical Astronomy (IOTA), later merged with the Cambridge Observatory as the Institute of Astronomy. Motivated by anti-religious sentiments, and wishing to avoid the issue of cause of the start of the universe, Hoyle joined HERMANN BONDI and THOMAS GOLD in developing steady state cosmology, providing the general relativistic formulation of the theory. He became the most visible proponent of the new theory, and it was he who coined the term 'Big Bang' for the explosive event at the start of the universe, intending it to be derisive about evolutionary theories of cosmology. Since space was expanding but wanting to maintain the overall density of the universe in steady state, it was necessary to hypothesize the phenomenon of continuous creation of matter in space. Finding that this, contrary to intention, was regarded as evidence of a creator in action, Hoyle published the polemical *Nature of the Universe* about the steady state theory. The steady state theory is generally regarded as disproved (by the existence of the cosmic microwave background), although it survives in a version in which a large steady state universe in which there is a continuous sequence of randomly occurring Big Bangs. It is undisputable, however, that the development of the steady state theory led to an epoch-making discovery. It had been thought that the Big Bang created all the chemical elements (the alpha-beta-gamma theory), and if there was no Big Bang, then the elements must have been made elsewhere and at other times. This led Hoyle to work on the origin of chemical elements in stars. He collaborated through visits to the California Institute of Technology and the Mount Wilson and Palomar Observatories with MARGARET BURBIDGE, Geoffrey Burbidge and WILLIAM FOWLER, working on the synthesis of the elements, and became an author of the landmark paper on this topic, known from its authors' initials as B^2FH. Hoyle has also been, with N Wickramasinghe, a modern proponent of ARRHENIUS's panspermia hypothesis, that life on Earth comes from space, in particular in the form of viruses delivered by comets. Hoyle has published fourteen novels, a play, and numerous works for the popularization of science.

Hubble Classification

A classification scheme for galaxies, devised in its original form in 1925 by Edwin P Hubble (1889–1953), and still widely used today. The Hubble classification recognizes four principal types of galaxy—elliptical, spiral, barred spiral and irregular—and arranges these in a sequence that is called the tuning-fork diagram.

Elliptical galaxies are denoted by the letter 'E' followed by a number from 0 to 7 to indicate the degree of flattening of the observed elliptical shape. For an *En* galaxy, the number, n, is obtained from $n = 10[(a - b)/a]$ where a is the maximum diameter and b the minimum. Thus E0 galaxies appear spherical ($n = 0$ because $a = b$) while E7 galaxies are markedly flattened with a maximum diameter more than three times greater than the minimum diameter.

Spiral galaxies, denoted by the letter 'S', have a central bulge surrounded by a flattened disk within which stars, nebulae and clouds of gas and dust are concentrated into a pattern of spiral arms. Spirals are subdivided into three categories, Sa, Sb and Sc, an Sa galaxy having a large central bulge surrounded by tightly wound arms, an Sb galaxy having a somewhat smaller bulge and less tight arms, and an Sc galaxy having a relatively small bulge and loose, open arms. In barred spiral galaxies, denoted by 'SB', the arms emerge from the ends of what looks like a rigid bar, or elongated ellipsoid of stars and luminous material that straddles the central nucleus. Barred spirals are subdivided into types SBa, SBb and SBc according to similar criteria to ordinary spirals. Intermediate categories are labelled appropriately; for example, a galaxy mid-way in appearance between categories Sa and Sb would be labelled Sab. Other peculiarities are identified by additional letters such as 'p' (for 'peculiar') or 'r' (to denote the presence of a ring around the nucleus). The Milky Way Galaxy, of which the Sun is a member, used to be classified as an ordinary spiral of type Sbc, but because recent observations indicate that its central bulge is elongated, it may be more appropriate to regard it as an SBbc barred spiral.

Intermediate between the ellipticals and spirals are the lenticular (lens shaped) galaxies, denoted by 'S0' or 'SB0'. Although a lenticular possesses a central bulge surrounded by a disk, it displays no sign of a spiral structure.

Irregular galaxies, which have no obvious nucleus or ordered structure, are denoted by 'Irr' and are broadly subdivided into 'Irr I' and 'Irr II'. Irr I galaxies display evidence of ongoing star formation (for example bunches, or 'associations', of hot young stars and bright HII regions). Irr II galaxies have a disturbed appearance, their shapes seeming to have been distorted by violent internal activity or as a result of collisions or close encounters with other galaxies.

Ellipticals contain little, if any, gas and are dominated by the light of old red giant stars. Spirals and barred spirals contain significant quantities of gas and dust (about 5–15% of the galaxy's mass), Sc and SBc galaxies, on average, containing more than Sa and Sba galaxies. Some, but not all, irregulars contain higher proportions of gas and dust (up to 20–30% by mass).

Hubble constant

The constant of proportionality, denoted by H, that relates the velocities at which galaxies are receding to their distances. According to the Hubble law, velocity of recession (V) is directly proportional to distance (D), a relationship which may be expressed as follows: $V = H_0 D$, where H_0 is the value of the Hubble constant at the present epoch in the history of the universe.

The Hubble constant, or Hubble parameter, is a measure of the rate of expansion of the universe and is, in effect, a measure of the fractional increase in the scale of the universe in unit time. Its value is usually expressed in units of velocity, expressed in kilometers per second, divided by distance, expressed in megaparsecs (i.e. km s^{-1} Mpc^{-1}), but it may also be expressed in units of s^{-1}. There is still a significant degree of uncertainty about the precise value of H_0, although there is wide general agreement that it lies between 50 km s^{-1} Mpc^{-1} and 100 km s^{-1} Mpc^{-1}. The uncertainty arises primarily because it is hard to obtain reliable measurements of the distances of galaxies. Many recent research programs using the apparent brightnesses of Cepheid variables or Type Ia supernovae as distance indicators have yielded values in the range 57–80 km s^{-1} Mpc^{-1}, with a concentration of values in the range 60–70 km s^{-1} Mpc^{-1}. A value of 65 km s^{-1} Mpc^{-1}, for example, would imply, in principle, that a galaxy at a distance of 1 megaparsec should be receding at a speed of 65 km s^{-1}, a galaxy at a distance of 1000 megaparsecs at 65 000 km s^{-1}, and so on.

The Hubble time is the time that it would take for the universe to double its size (i.e. for each galaxy to recede to twice its present distance) at a constant rate of expansion equal to the present rate. Equivalently, it is the time that the universe would have taken to expand to its present size (i.e. for each galaxy to recede to its present distance) at a constant rate of expansion. The Hubble time is equal to the reciprocal of the Hubble constant (i.e. $1/H_0$). The uncertainty in the value of the Hubble constant is reflected in a similar uncertainty in the value of the Hubble time, and hence in estimates of the age of the universe. If H_0 lies in the range 50–100 km s^{-1} Mpc^{-1}, values of the Hubble time lie between 20 and 10 billion years, respectively. If, for example, $H_0 = 65$ km s^{-1} Mpc^{-1}, then the value of the Hubble time is 15 billion years. The Hubble time is related to the age of the universe through a model of its expansion. In the standard model, the age of the universe is two-thirds the Hubble time.

Hubble Deep Fields

The Hubble Deep Fields are two small areas of the sky that were carefully selected for deep observations by the HUBBLE SPACE TELESCOPE (HST). They represent the deepest optical observations to date and reveal galaxies as faint as $V = 30$, 4 billion times fainter than can be seen with the unaided eye.

Ten-day observing campaigns were carried out by HST in December 1995 on a field in the northern hemisphere (HDF-N) and in October 1998 on a field in the southern hemisphere (HDF-S). The fields were chosen to avoid bright stars, dust or nearby galaxies interrupting the view of more distant galaxies. To make the most efficient use of HST, the fields were also required to be in the 'continuous viewing zone', at about $\pm 60^\circ$ declination. Other than that, the fields are essentially random 'core samples' of the universe. The observations were released to the public within weeks of being obtained and have been the subject of extensive research and followup observations with other telescopes. The Hubble Deep Fields represent the deepest observations not only of HST but also of some the largest ground-based telescopes and other space observatories.

Observational details

The coordinates of HDF-N are $12^{\rm h}36^{\rm m}49.4^{\rm s}$ + $62^\circ 12' 58''$ (J2000). The HDF-N has been observed at optical wavelengths by the Wide Field Planetary Camera-2 (WFPC-2) (see also ASTROMETRY WITH HUBBLE SPACE TELESCOPE), which has a field of view roughly 3 arcmin on a side, and in the infrared with the NICMOS camera. The coordinates of the HDF-S field are $22^{\rm h}32^{\rm m}56.2^{\rm s} - 60^\circ 33' 03''$. During the HDF-S campaign, observations were carried out in parallel on adjacent fields with NICMOS and STIS. The STIS field was centered on QSO J2233-606. The WFPC-2 camera observed both fields through four broadband filters, centered at 300, 450, 606, and 814 nm. The STIS observations of the southern field included UV spectroscopy of the QSO and optical and UV observations of the field around the QSO. The NICMOS observations of both the southern and northern fields were taken through broadband filters centered at 1.1 μm and 1.6 μm.

Census of the HDF-N

The WFPC-2 image of HDF-N covers an area of 5 arcmin^2. Within this area it contains approximately

3000	galaxies brighter than magnitude $V = 29$,
130	galaxies with measured spectroscopic redshifts,
20	galaxies with spectroscopic redshifts greater than $z = 2.5$,
17	sources brighter than 65 μJy at at 6.7 μm or 200 μJy at 15 μm detected by the Infrared Space Observatory,
10	stars along the line of sight through the Milky Way,
9	radio sources brighter than 9 μJy at 8.5 GHz or 40 μJy at 1.4 GHz,
4	sources brighter than 2 m Jy at 850 μm detected by the SCUBA bolometer array at the James Clerk Maxwell Telescope,
0	stars redder than $V - I = 1.8$ and
3	sources redder than $V - K = 7$.

The numbers are approximate because it is difficult to differentiate true sources from noise at the limits of the observations and because among the brighter galaxies it is sometimes difficult to decide whether to count neighboring objects separately or as part of a larger galaxy. The HDF-S has a similar number of galaxies but roughly five times as many stars owing to the different line of sight through the Milky Way.

Galactic dark matter

The lack of faint red stars in the HDF-N was used to rule out faint hydrogen-burning stars as the source of Galactic DARK MATTER. The HDF constraint is most concisely expressed as a limit on the I band absolute magnitude of the constituents of the Galactic dark halo:

$$M_I > 15.9 + \frac{5}{3}\log\left(f\frac{0.5M_\odot}{M}\right) \qquad (1)$$

where M is the mass of the objects and f is their density as a fraction of the local halo density. Faint RED DWARFS account for less than 1% of the Galactic dark halo for $M_I < 14$ and less than 6% for $M_I < 15$. The limits are even more stringent on the contribution from extremely metal-poor dwarfs.

Galaxy counts

Figure 1 shows the number of galaxies as a function of brightness in HDF-N and HDF-S, together with results from shallower ground-based surveys. The counts are compared with a simple model that includes the effect of cosmological curvature but does not include galaxy evolution. A variety of evolutionary models have been shown to match the counts, but work is still underway to determine which if any of the models match the full distribution of colors, sizes and morphologies of the HDF galaxies.

Spectroscopic and photometric redshifts

The spectroscopic survey of the HDF with the W M Keck telescope is among the deepest ever attempted. The survey is nearly complete to a magnitude $R = 23.5$ and extends more than a magnitude fainter for selected objects. Although this spectroscopy at this depth is limited to the brightest 5% of the HDF galaxies, it has served to confirm the existence of a population of galaxies at redshifts $z > 2.5$ and has validated the use of broadband photometric data as a means for estimating redshifts. These 'photometric redshifts' are determined either by fitting template spectra to the photometry of galaxies through different filters or by using the spectroscopic sample as an empirical 'training set' to determine the relation between colors and redshift.

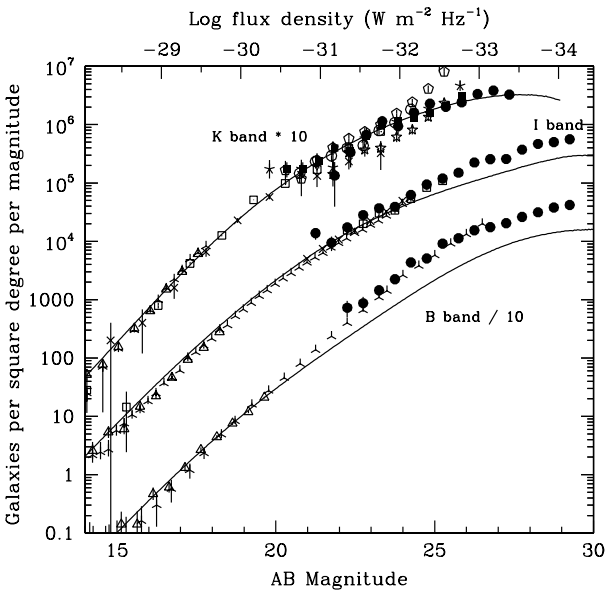

Figure 1. Counts of galaxies in the B, I and K bands (centered roughly at 0.4, 0.8 and 2.2 μm, respectively). The full symbols show the counts from the HDF observations. The HDF counts in the K band are from observations at 1.6 μm, corrected by 0.4 mag in mean color to match the brighter K band observations. The other symbols show measurements from various ground-based surveys. The lines show a no-evolution model with the following cosmological parameters: $H_0 = 65$ km s^{-1} Mpc^{-1}, $\Omega_{\rm tot} = 1$, $\Omega_{\rm matter} = 0.3$ and $\Omega_\Lambda = 0.7$. Galaxies in this model are distributed with the brightnesses and colors typical of present-day galaxies, and these are held constant with lookback time. The deviation of the counts from this model (a factor of ∼3 at faint magnitudes in the B band) indicates the extent to which galaxy evolution contributes to the modeling problem.

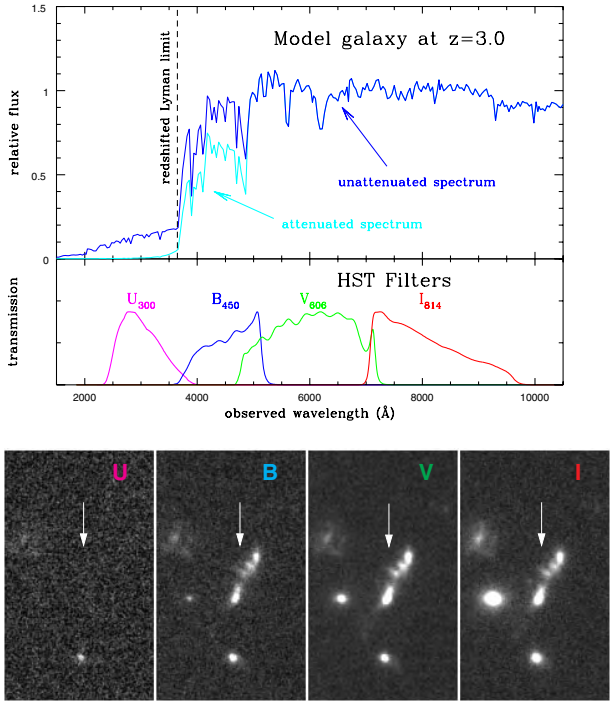

Figure 2. Illustration of the Lyman-break technique for identifying high-redshift galaxies. The top figure shows the theoretical spectrum of a star-forming galaxy at a redshift $z = 3$, with and without attenuation from intergalactic hydrogen along the line of sight. The curves below the theoretical spectra show the bandpasses of the HST filters used for the HDF observations. The signature of a high-redshift galaxy is that it 'drops out' of the ultraviolet F300W band (being either undetected or much fainter than at the next-longer wavelength). The image below shows the brightest of the Lyman-break galaxies identified in the HDF-N. **This figure is reproduced as Color Plate 11.**

Lyman-break galaxies

The most robust feature in the spectra of star-forming galaxies is the Lyman break. This opacity edge is produced when hydrogen atoms in the ground state are ionized by photons of energy greater than 13.6 eV (corresponding to wavelengths shorter than 912 Å). Photons with wavelengths slightly shorter than this are absorbed by hydrogen in stellar atmospheres, the interstellar medium of a galaxy and the intergalactic medium. In addition, as the light travels through the intergalactic medium it is partially absorbed by the Lyman-series lines of hydrogen at rest-frame wavelengths between 912 and 1216 Å. The combined effect produces a discontinuity in the spectra of high-redshift galaxies that is easy to detect. Figure 2 shows an example.

The four filters of the HDF offered the first opportunity with HST to search for Lyman-break galaxies. While the exact number of galaxies found depends on the color selection criteria, roughly 100 candidate objects were found with redshifts likely to be in the range $2.5 < z < 3.5$ and roughly 15 with redshifts likely to be in the range $3.5 < z < 4.5$. The brightest of these objects were confirmed spectroscopically. In addition, several objects were noted with colors consistent with redshifts higher than $z = 4.5$. Spectroscopy at the Keck telescope confirmed one of these candidates to be at redshift $z = 5.34$.

The Lyman-break galaxies are generally compact, with half-light radii 1 kpc $< r <$ 7 kpc. Those that are well resolved generally appear morphologically peculiar. There are several prominent examples in the HDF of Lyman-break galaxies made up of multiple components spaced irregularly within a region of less than 2 arcsecs, suggesting that we are witnessing the merging of several smaller components into a larger galaxy.

See HIGH-REDSHIFT GALAXIES for more detail.

Cosmic star-formation history

The photometric redshift estimates (including in particular those from the Lyman break) can be used to estimate the ultraviolet luminosity density of the universe as a function of redshift. This is a particularly useful quantity as it is closely tied to the history of heavy-element formation: the massive stars that emit most of the UV radiation detected in the HDF (redshifted to optical wavelengths) also produce most of the elements of atomic number $Z > 6$.

In the approximation of instantaneous recycling, the metal ejection rate can be written as

$$\dot{\rho}_z = \psi \int m p_{zm} \phi(m)\, \mathrm{d}m \qquad (2)$$

where ψ is the star formation rate per unit co-moving volume, $\phi(m)$ is the stellar initial mass function (IMF) and p_{zm} is the stellar yield, i.e., the fraction of a star of mass m that is converted to metals and ejected. At short wavelengths, the luminosity density radiated per unit frequency during the main-sequence phase of stellar evolution is related to the star-formation rate ψ by

$$\rho_n u = 0.007 c^2 \psi \int m f_{\mathrm{He}}(m)\, f_\nu(m) \phi(m)\, \mathrm{d}m \qquad (3)$$

where $f_{\mathrm{He}}(m)$ is the mass fraction of hydrogen burned into helium and $f_\nu(m)$ is the normalized spectrum of stars of mass m on the main sequence. Evolutionary synthesis models give the following approximate relation between luminosity density at a rest-frame wavelength of 1500 Å and star-formation rate ψ in solar masses per year:

$$\rho_{1500} = 8.0 \times 10^{27} \psi \ \mathrm{erg\ s^{-1}\ Hz^{-1}\ Mpc^{-3}}. \qquad (4)$$

Figure 3 shows the star-formation or metal-formation rate as a function of redshift as derived from the HDF (north and south) and various ground-based surveys. Two major uncertainties affect these estimates: the effects of dust and the amount of light coming from galaxies too faint to be detected individually. Dust in star-forming galaxies absorbs ultraviolet light and reradiates it at longer wavelengths. The attempt to quantify the amount of dust-enshrouded starlight motivated studies of the HDF with the Infrared Space Observatory and with the SCUBA submillimeter bolometer array on the James Clerk Maxwell Telescope. These observations, together with measurements of the spectral-energy distributions and optical emission-line strengths for Lyman-break galaxies, suggest that the star-formation rates derived purely from the UV luminosities should be corrected upwards by a factor of 3–10.

Background measurements

To derive the luminosity density, the counts of galaxies in a particular redshift interval are extrapolated to magnitudes below the detection limit of the images. This extrapolation can be tested by measuring the background light between the detected galaxies. Measuring the extragalactic component of this background light is difficult because it is only small percentage of the zodiacal background. Estimates of the fraction of the total extragalactic background accounted for by the detected galaxies range from 30% to 90%. An analysis of the autocorrelation of the residual fluctuations in the HDF image suggests that the total extragalactic background at $\lambda = 8100$ Å lies in the range 7.8×10^{-6} erg s^{-1} cm^{-2} sr^{-1} $\leq \nu I_\nu < 1.2 \times 10^{-5}$ erg s^{-1} cm^{-2} sr^{-1}, while the analysis of the total flux left after subtracting galaxies and zodiacal light gives somewhat higher values. See also EXTRAGALACTIC BACKGROUND LIGHT.

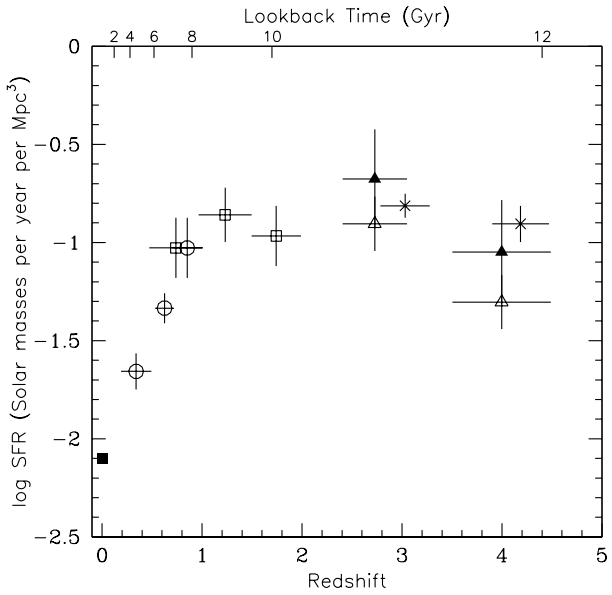

Figure 3. The star-formation rate per unit volume versus redshift (bottom axis) or lookback time (top axis). The assumed cosmology has $H_0 = 50$ km s^{-1} Mpc^{-1} and $\Omega_M = 1$. The points are derived from the total integrated UV fluxes of galaxies measured in various surveys, including the HDF-N (open triangles) and the HDF-S (solid triangles). A simple correction for dust extinction has been applied to the data, but there are large uncertainties in this correction.

Galaxy clustering

The combination of deep photometry and photometric redshifts makes the HDF images a useful tool for studying the evolution of clustering in the universe (see GALAXY CLUSTERS). However, these studies are limited by the small field size, which subtends no more than about 2 Mpc at any redshift. Nevertheless, the analyses of galaxies in different redshift bins suggests that the amplitude A_w of the angular correlation function decreases with redshift out to $z = 1$ and then rises again to higher redshift. A plausible explanation is that the galaxies at higher redshift trace higher peaks in the underlying density field and are hence biased relative to the underlying mass distribution. Another possible contribution to the stronger clustering at high redshift is the tendency for high-redshift galaxies to have multiple components, suggesting that in many cases the structures are part of the same underlying galaxy.

Hubble Diagram

Initially introduced as a way to demonstrate the expansion of the universe, and subsequently to determine the expansion rate (the HUBBLE CONSTANT H_0), the Hubble diagram is one of the classical cosmological tests. It is a plot of apparent fluxes (usually expressed as magnitudes) of some types of objects at cosmological distances, against their REDSHIFTS. It is used as a tool to measure the global geometry of the universe, and as a probe of galactic evolution.

As in most other cosmological tests, the observables used in this diagram are really proxies for the expansion factor of the universe (measured as the cosmological redshift) and some independently determined proper distance to the objects used in the test. The observed trend of distance-related quantities (e.g. apparent fluxes, angular diameters, etc) against the redshift can thus, at least in principle, be mapped to the expansion history of the universe, which in turn uniquely determines the COSMOLOGICAL MODEL. The *slope* of the trend at low redshifts determines the present normalized expansion rate, i.e. the Hubble constant. The *shape* of the trend at large redshifts determines the global geometry of the universe.

In the case of the Hubble diagram, a relativistic version of the inverse square law is used to determine the relative distances to the light sources used. Simply put, the more distant objects of a fixed intrinsic brightness should be fainter, by a factor determined exactly by the geometry of space. Redshifts are measured spectroscopically, and do not depend on the complicating factors which may affect the distance measurements, such as the evolution of sources used, sample selection effects, etc. The distances are much more difficult to determine, and this is where most of the practical problems lie.

The objects used as the test particles in a Hubble diagram are often called 'standard candles', thus expressing the hope of their constancy in time and at different locations. Yet this is hardly ever the case, and much of the effort involved goes into their standardization—removal of the various second-order parameters which cause the scatter around the ostensible universal mean luminosity of a given type of object.

Hubble (1929) used this diagram to demonstrate the expansion of the universe: fainter and thus on average more distant galaxies were receding from us with larger apparent speeds. Once the universal expansion was generally established, the test acquired other cosmological uses. There are two regimes in which the Hubble diagram is used today, each with its own goals, methods and problems.

In the low-redshift regime, the Hubble diagram is used in determinations of the Hubble constant. The local geometry is very close to being Euclidean, and thus the effects of the global curvature can be safely ignored. The look-back times to the objects used are small enough so that evolutionary effects can also be neglected. The local universal expansion is practically linear, producing the well-known HUBBLE'S LAW: $cz = H_0 D$, where c is the speed of light in a vacuum, z is the observed redshift (assuming that the peculiar velocity of the object is negligible), H_0 is the Hubble constant and D is the proper distance. Since distances are not directly measurable, even for the nearest galaxies, a proxy quantity is used; in the case of the Hubble diagram, this is often the magnitude of an object of given class, e.g. a Cepheid variable (or, more accurately, the intercept of the CEPHEID PERIOD–LUMINOSITY RELATION), a SUPERNOVA at its peak brightness, etc. If one knows the actual absolute luminosities of the objects used in the test, obtained from some independent calibration procedure, then the slope of the observed relation gives directly the local normalized expansion rate, the Hubble constant H_0. The difficulties in establishing the absolute brightness scale of the objects used for such purposes, and other problems involved in the measurements of H_0, are beyond the scope of this article.

In the more distant universe, the global geometry comes into play, causing the trend to deviate from linearity. The *shape* of the relation becomes a probe of the cosmological parameters; for the standard Friedmann–Lemaitre models, these are the density parameter Ω_0 and the cosmological constant Λ_0. (We note in passing that for many years the value of the COSMOLOGICAL CONSTANT was declared to be zero on purely ideological grounds, and only a single parameter, Ω_0, was used to characterize the global geometry, or equivalently, the deceleration parameter q_0.) Since the shape of the trend does not depend on the absolute value of the luminosities, the normalization and the Hubble constant factor out. The curvature of the trend reflects directly the global kinematics of the universe as observed over cosmological time-scales for true 'standard candles'.

Consider the effect of an increase in the mean density: it causes the expansion to slow down more, and thus the objects at a given redshift are closer and appear brighter. The same effect is accomplished by the negative values of the cosmological constant (which correspond to a positive energy density), and the opposite effect by the positive values of this parameter, which then acts as a repulsive force, accelerating the expansion. These effects become detectable only over very large look-back times, i.e. at relatively high redshifts, requiring the use of objects bright enough to be detected at such large cosmological distances. Moreover, there is a considerable parameter coupling between Ω_0 and Λ_0, as they can have qualitatively similar effects. A large baseline in redshift is also necessary in order to separate their contributions, since they may dominate the changes in the expansion rate at different epochs.

For a source with an intrinsic luminosity L, at a cosmological redshift z, the observed flux is:

$$F = \frac{L}{4\pi D^2 (1+z)^2} = \frac{L}{4\pi D_L^2}$$

where D is the proper distance and z is the source redshift. The quantity $D_L \equiv D(1+z)$ is called the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

luminosity distance. The formula differs from the classical inverse square law by the two powers of the expansion factor, $(1 + z)$: one is due to the energy loss of photons as their wavelengths are redshifted, and one is due to the relativistic time dilation in the photon emission rate, since the source is moving away from us. In the simple Friedmann cosmological models, with a vanishing cosmological constant, $\Lambda_0 = 0$, the proper distance is given by the following formulae:

$$D = \frac{c}{H_0}\frac{z(1+z/2)}{1+z} \qquad \text{for } \Omega_0 = 0$$

$$D = \frac{2c}{H_0}(1 - 1/\sqrt{1+z}) \qquad \text{for } \Omega_0 = 1$$

$$D = \frac{2c}{H_0}\frac{2 - \Omega_0 + z\Omega_0 - (2-\Omega_0)\sqrt{1+z\Omega_0}}{\Omega_0^2(1+z)} \qquad \text{otherwise}$$

where c is the speed of light in a vacuum, H_0 is the Hubble constant and Ω_0 is the density parameter of the universe, the ratio of the mean density to the critical density at the present epoch.

HUBBLE's pioneering vision of determining the global geometry through this and other tests was frustrated by the technology available to him at the time, by not being able to reach out to sufficiently large redshifts where the cosmological effects may be detectable. His quest was then carried out over many years by A SANDAGE and collaborators, as well as many others; for a fascinating historical account, see, e.g., Sandage (1995). Typically, magnitudes of the brightest cluster ELLIPTICAL GALAXIES were used as the standard candles, and the quest was on for finding the ever more distant ones. At low redshifts, suitably defined magnitudes of these objects show an intrinsic scatter of only about 30%, which was considered constant enough. Unfortunately, no conclusive cosmological results were achieved in these studies despite much effort and observing time spent, in part because they did not reach out to sufficiently large redshifts.

QUASARS, discovered in 1963, provided luminous probes of even larger redshifts, but had too much of a spread in intrinsic luminosities and too much variability to be viable for this purpose. Other candidate standard candles tried at cosmological distances include supernovae, the characteristic luminosity (L_*) of the galactic luminosity function in distant clusters, etc.

The observed apparent magnitude of a source is given by

$$m_{\rm obs} = M + 5 - 5\log D_L + K + \Delta m_{\rm sc}$$

where M is the absolute magnitude of the source, which may be affected by evolution effects, and D_L is the luminosity distance defined above. K is the so-called K correction, which accounts for the difference in the detector bandpass in the observer's frame and in the source restframe. It is given by the ratio of the fluxes of the source, with its spectrum integrated over the observed bandpass and its redshifted counterpart, and expressed in the magnitude form. This of course requires the knowledge of the source's spectrum at $z = 0$; any possible evolutionary effects are *not* included. $\Delta m_{\rm sc}$ is an empirical correction used to standardize the candle, i.e., remove statistically some other observable effects which may be correlated with M. In the case of the brightest cluster ellipticals, such corrections include subtle dependences on the cluster richness and morphology; in the case of supernovae, shapes of their light curves are used to derive such corrections.

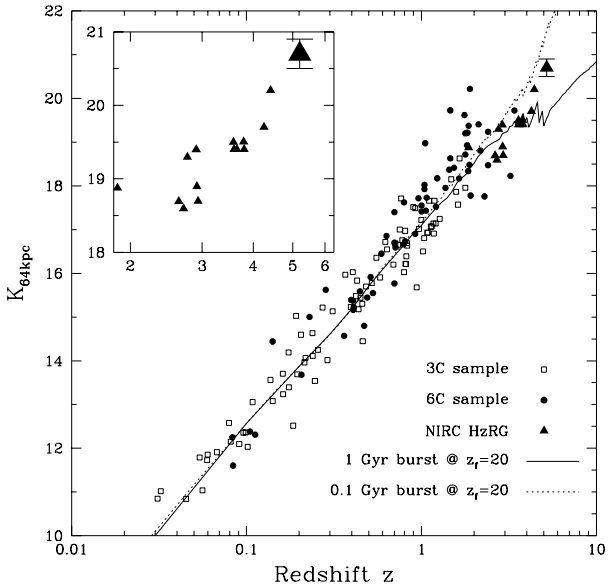

Figure 1. The infrared Hubble diagram (in the K band, 2.2 μm effective observed wavelength) for a set of powerful radio galaxies, reaching out to $z = 5.19$ (indicated with the large triangle). The insert is a zoom-in on the high-z portion of the diagram. Two galactic evolution models are shown, both corresponding to a single burst of star formation starting at $z = 20$, and assuming a cosmology with $H_0 = 65$ km s^{-1} Mpc^{-1}. $\Omega_0 = 0.3$ and $\Lambda_0 = 0$. The diagram shows a remarkably small scatter at any redshift, even though every relevant effect we know of would increase the scatter: the variations in star formation histories and formation redshifts, in the contributions from active nuclei, in extinction, line emission, merging rates, etc. While no one is yet brave enough to try to use this diagram to measure the cosmological parameters, the small observed scatter presents a challenge for theoretical models of powerful radio galaxies and their evolution. (Reprinted with permission from van Breugel W *et al* 1999 *Astrophys. J. Lett.* **518** L61 © The American Astronomical Society.)

As in the case of most other cosmological tests, the use of the Hubble diagram as a probe of the global geometry was severely undermined by the inevitable cosmic evolution of whatever objects are used as the test particles. The light from galaxies comes from their STELLAR POPULATIONS, which must evolve in time, in brightness and in color. By the late 1970s it became clear that the effects of galactic evolution will dominate over the cosmological effects for any type of galaxy at sufficiently large redshifts.

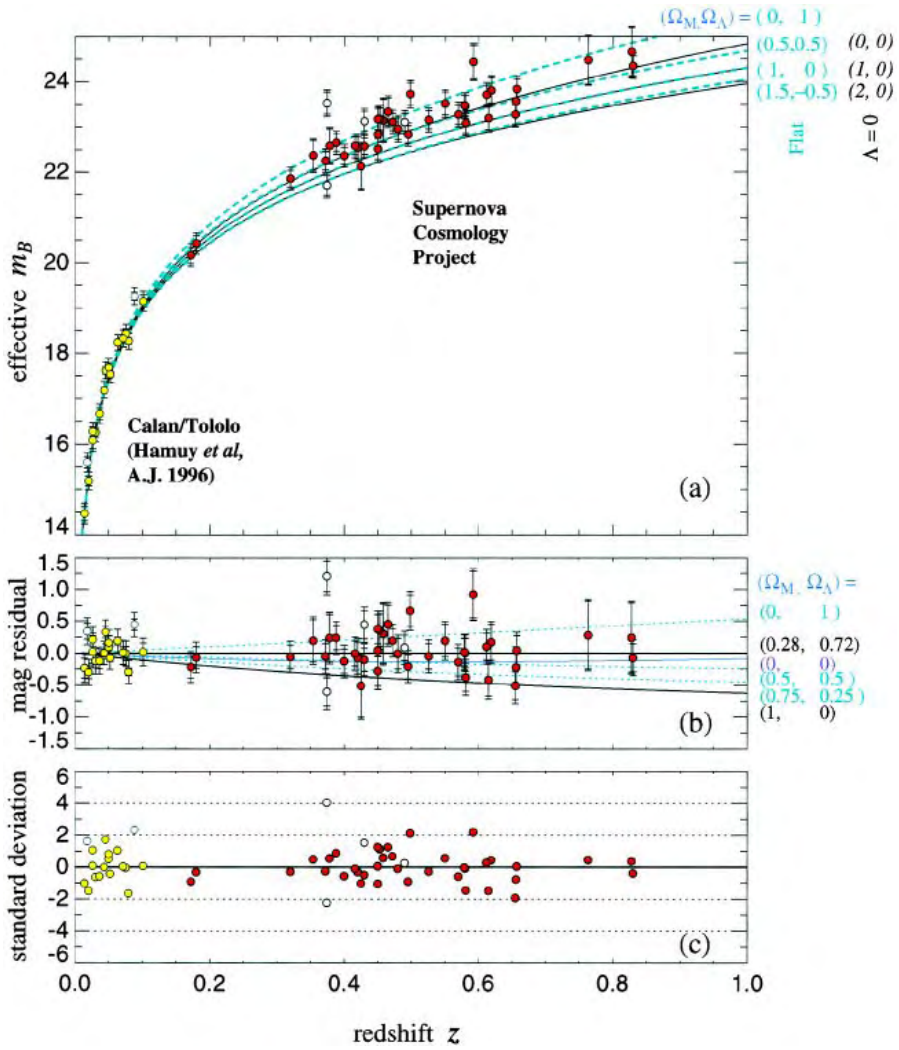

Figure 2. An example of a Hubble diagram for type Ia supernovae, with peak magnitudes corrected using the light curve shapes. Several cosmological models are drawn through the points, with the corresponding values of the parameters Ω_0 and Λ_0 as indicated. The best fit to these data indicates a low-density universe with a positive cosmological constant. The top panel shows the diagram itself. The bottom panel shows the residuals from the best-fit model, and the bottom panel shows the photometric deviations from the model in units of the standard deviations. (Reprinted with permission from Perlmutter S *et al* 1999 *Astrophys. J.* **517** 565 © The American Astronomical Society.)

This is especially true at the observed visual wavelengths, which correspond to the ultraviolet light restframe, which may be dominated by a few luminous, young and short-lived stars. Moreover, galactic merging and interactions, which must have been more frequent at higher redshifts, further complicate the interpretation of observations: galaxies may grow in time, and undergo merger-induced bursts of star formation (see GALAXIES: INTERACTIONS AND MERGERS).

The Hubble diagrams thus became a probe of galactic evolution, where a set of cosmological parameters was often assumed out of necessity in order to measure the rate of galactic evolution. More recently, the Hubble diagram has made a comeback as a potential cosmological tool, as described below.

Even if the evolutionary effects can be controlled, an additional difficulty is the possible (likely?) presence of sample selection effects. Typically, brighter representatives of any class of objects would be found at larger redshifts, as the fainter ones may not make it into a flux-limited sample. Such biases are hard to correct, since one never knows how many objects are not even detected, let alone what is their brightness distribution. Reducing the scatter of observed luminosities at a given redshift (i.e. using a more standard candle) helps, but some bias is always present. Understanding the sample completeness is essential.

In addition, it is sometimes hard to guarantee even

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the homogeneity of the samples, i.e. that the same type of objects are being selected both at high redshifts, and as their ostensible low-redshift progeny. Additional problems include possible effects of GRAVITATIONAL LENSING by the intervening masses, and interstellar extinction corrections, both in our Galaxy and in the distant galaxies used in the test.

Some hope came with technological advances in near-infrared measurements (see INFRARED TELESCOPES). The advantages of infrared observations are considerable. They probe the restframe wavelengths of normal galaxies which are much less affected by a possible flicker of massive star formation. The infrared light is typically dominated by the relatively stable and slowly changing stellar subpopulations such as the red giants. Thus, the effects of galactic evolution effects should be minimized. Infrared observations are also much less sensitive to interstellar extinction.

One example is the infrared Hubble diagram for powerful RADIO GALAXIES at high redshifts (figure 1). The advantages of radio galaxies are that they can be identified at very large redshifts (as of this writing, at $z > 5$), and that they are generally believed to be progenitors of at least some giant ellipticals today. Their chief disadvantage is the presence of a powerful active nucleus, which may be contaminating the observed brightness and affecting the host galaxy in uncertain ways. Perhaps the infrared observations of normal, quiescent cluster ellipticals (known out to $z \approx 1.3$, as of mid-1999), or magnitude intercepts of their fundamental plane correlations may be more promising.

There has been much excitement in recent years about the use of distant supernovae as possible 'standard candles' to measure the global geometry of the universe. At their peak, supernovae of type Ia reach an absolute magnitude $M_B \approx -19.5$, and are thus sufficiently luminous to be detected at redshifts approaching unity, where the effects of cosmic geometry should be readily detectable. Furthermore, the shape of the supernova light curve is found to correlate with the peak luminosity, thus providing a handy observational way to lower the scatter of the peak magnitudes by correcting for this 'second parameter'. Scatter as low as 15% or even less may be achieved (this made type Ia supernovae also a viable tool in the efforts to measure H_0 at low redshifts). Since the physics of the supernova explosions should be universal, this novel standard candle clearly has a lot of promise as a cosmological tool. Note, however, that some evolution in the observable properties of supernovae is possible, e.g. due to the slowly changing metallicities of the stellar populations from which these supernovae originate.

Using this approach, two groups have recently measured the values of the cosmological parameters Ω_0 and Λ_0 (figure 2), with mutually consistent results (Schmidt *et al* 1998, Perlmutter *et al* 1999). Both groups found that the best fit to their observations is consistent with a zero-curvature universe, preferred by the theoretical prejudice of inflation models, but with a positive cosmological constant, which was something of a surprise. If this result is confirmed by future observations and tests, it would be of profound cosmological significance.

It remains to be seen if any other types of luminous objects turn out to be good standard candles, or if new ways of standardizing the old ones are invented. In any case, the Hubble diagrams will remain a useful probe of galactic evolution, and possibly even of the global geometry of the universe.

Hubble Law

The relationship that states that the recessional velocities of distant galaxies are directly proportional to their distances. It is named after the American astronomer Edwin P Hubble (1889–1953) who, in 1929, published his discovery that the redshifts in the spectra of galaxies are proportional to their distances. This was one of the key discoveries in cosmology for it showed that the galaxies are receding and the universe as a whole is expanding.

The relationship between velocity of recession, V, and distance D, may be written as $V = H_0 D$, where H_0 is the present-day value of a constant of proportionality known as the Hubble constant, or Hubble parameter. The law is consistent with a universe undergoing uniform expansion whereby each galaxy (or cluster of galaxies) is receding from every other one with a speed proportional to the separation between them. In such a universe each observer, no matter on which galaxy he is located, sees all other galaxies receding with speeds proportional to their distances, and no one galaxy is the unique center of this expansion. The smooth, idealized, recession of the galaxies from each other (ignoring local variations caused, for example, by the gravitational influence of clusters and superclusters of galaxies) in accordance with the Hubble law is called the 'Hubble flow'.

Hubble Space Telescope

Since its deployment from the Space Shuttle Discovery on 25 April 1990, the NASA–ESA Hubble Space Telescope (HST) has revolutionized observational and theoretical astronomy with a stream of remarkable observations and beautiful images which have stunned astronomers and public alike. Yet, during its first weeks of operation, these dramatic successes seemed a world away.

A number of serious issues came to the fore almost immediately. Warping and deformation of the observatory's huge solar arrays occurred each time that the HST crossed the day–night terminator. The result was a shaking which could not be counteracted by the onboard attitude control system. On occasions, the vibration was so severe that the satellite lost its lock on the guide stars which were expected to provide pointing to an accuracy of a fraction of an arcsecond.

Even worse was the revelation that the initial images captured by different instruments revealed a mysterious halo of light around the stars. It soon became clear that the 2.4 m diameter primary mirror was badly flawed. Investigations revealed that the SPHERICAL ABERRATION was caused by a mirror which had been ground into the wrong shape—it was 2 μm too flat near its edge. The result was that, while the spatial resolution of around 0.1 arcsec was close to specification, the telescope's sensitivity was seriously compromised, since it was only focusing 15% of the incoming light. The flaw had not been noticed prior to launch because the primary and secondary mirrors had never been tested together.

Instead of inaugurating a new golden era of space exploration and discovery, the much-heralded arrival of the world's first large orbital observatory rapidly turned into a public relations fiasco as the myopic telescope and NASA management in general came under heavy criticism.

The immediate answer was to remove the 'fogging' by means of computer processing. However, in the long term, the only solution was to compensate for the faulty optics by installation of a corrective optics space telescope axial replacement (COSTAR) system. This comprised ten coin-sized, adjustable mirrors which were to be inserted into the optical train of three of HST's instruments in order to improve their focusing capability.

The COSTAR was eventually installed during the first servicing mission (SM-1) in December 1993. With the HST captured by the remote manipulator arm and located upright in the Shuttle's payload bay, the astronauts spent $35\frac{1}{2}$ hours of extravehicular activity fitting the COSTAR, replacing the warped solar arrays and installing a modified Wide-Field Planetary Camera.

On 13 January 1994, NASA triumphantly released the first images from the revamped observatory, including a view which showed the central regions of spiral galaxy M100 in unprecedented detail. Senator Barbara Mikulski proudly announced, 'I am delighted to be able to announce today, after the launch in 1990 and the early disappointments, the trouble with Hubble is over!'

The telescope

The EDWIN P HUBBLE Space Telescope is named in honour of the American astronomer who made two major breakthroughs in cosmology during the 1920s. By measuring the distance to the Andromeda galaxy, he became the first person to establish that spiral and elliptical galaxies existed far beyond our own Galaxy. Then, in 1929, he analysed the spectra of galaxies and found a linear relationship between their distances and their REDSHIFTS which suggested that they were all moving away from us, with the furthest galaxies receding at the fastest rate.

The HST was intended to extend astronomical knowledge of the universe by observing from an altitude of about 600 km (375 miles) above the turbulent atmosphere. The idea for such a space telescope was first proposed in 1946 by American astronomer Lyman Spitzer, and was later revived in the 1970s as the Large Space Telescope project. The fate of the project was closely tied to the development of NASA's reusable Space Shuttle, the only launch vehicle which could place the giant telescope into low-Earth orbit and deliver astronauts for regular servicing missions.

Although it began as a NASA project, the EUROPEAN SPACE AGENCY was also keen to participate. This resulted in a memorandum of understanding in 1977 which provided ESA with approximately 15% of the available observing time in return for providing the Faint Object Camera and a pair of solar arrays. This, in turn, resulted in positions for ESA scientists being established at the SPACE TELESCOPE SCIENCE INSTITUTE in Baltimore and the creation of the SPACE TELESCOPE EUROPEAN COORDINATING FACILITY in Garching, Germany.

At the time of its launch, the HST was the largest optical telescope ever placed into orbit. The observatory weighs approximately 11.5 tonnes, and its main body is 13.3 m (43.5 ft) long and 4.3 m (14 ft) in diameter. Two 12 m (40 ft) long solar panels attached on either side of the observatory provide a maximum power output of 4.4 kW. A large aperture door is closed to protect the telescope during servicing missions.

The HST has a Ritchey–Chrétien design, which uses a 2.4 m (94 in) primary mirror made of ultra-low-expansion glass coated with a thin film of aluminum. The mirror collects radiation across the range of wavelengths from ultraviolet to near-infrared. Light is reflected from the primary mirror to a 33 cm (13 in) secondary located 4.6 m (15 ft) in front of it. This reflects the light back through a 66 cm (26 in) hole in the primary mirror to the scientific instruments behind it in the aft shroud section.

The observatory was one of the first satellites to be designed with in-orbit maintenance in mind. In order to aid astronauts during extravenicular activity, the HST has 68 m (225 ft) of handrails and 31 foot restraints on its surface. It also contains 70 orbital replacement units—parts which are designed to be replaced in space.

Apart from providing the option to upgrade the scientific instruments and hardware such as the computer, data recorder or attitude control systems, this also allowed

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

for replacement of the two giant solar arrays which charge the HST's batteries when they are in sunlight. This provided a scientific bonus when one of the first set of arrays was brought back to Earth for analysis after $3\frac{1}{2}$ years in orbit. Subsequent studies of thousands of impact craters on the surface of the array revealed that those with diameters in the range 100–1000 μm were predominantly micrometeoroid in origin, while craters below 100 μm in size were mainly created by space debris.

The HST was originally equipped with five instruments: two cameras, two spectrographs and a photometer.

- The Wide Field and Planetary Camera, developed by the California Institute of Technology and the Jet Propulsion Laboratory.
- The European Space Agency's Faint Object Camera.
- The Goddard High-Resolution Spectrograph for ultraviolet observations, developed at NASA's Goddard Space Flight Center.
- The Faint Object Spectrograph, developed at the University of California, San Diego.
- The High Speed Photometer, developed at the University of Wisconsin.

Over the years, this complement of instruments has been modified due to the initial flawed optics, changing observational requirements and development of improved technology. The High Speed Photometer was replaced during the December 1993 servicing mission in order to make room for the COSTAR. At the same time, the Wide Field and Planetary Camera was also replaced by a version with modified optics (WFPC-2) to offset the HST's spherical abberation. In its wide field mode, this instrument can image an area up to 2.6 arc minutes across, while in its planetary mode, although the field of view is reduced to 1.1 arc minutes, the spatial resolution is improved to 0.04 arcsec.

In February 1997, during a second servicing mission, the Goddard High-Resolution Spectrograph and the Faint Object Spectrograph were replaced by the Space Telescope Imaging Spectrograph, which is designed to take spectra over a wider wavelength range (1050–11 000 Å) than the previous instruments combined. In addition, the Near-Infrared Camera and Multi-Object Spectrometer (NICMOS), gave the observatory the capability of observing in the near-infrared (0.8–2.5 μm) spectral region.

Unfortunately, a higher than expected rate of evaporation by the solid nitrogen coolant in NICMOS resulted in a reduced lifetime for the instrument. Its cameras were switched off after the instrument reached cryogen exhaustion on 3 January 1999. However, the science capabilities of NICMOS are expected to be fully restored after a closed-loop cooling system is installed during the fourth servicing mission (3B) in the summer of 2001.

The next generation of HST instruments includes the Advanced Camera for Surveys (ACS), which will replace the Faint Object Camera. The ACS, which is due to be installed during servicing mission 3B, will operate in three different modes. Although it can be used as a wide field camera, in its high resolution mode it will have ten times the spatial resolution of the WFPC: −2. A third mode, the Solar Blind Camera, will be able to take high-resolution ultraviolet images.

Since all of the scientific instruments will then incorporate their own internal correcting optical system, the redundant COSTAR system will be removed during a fifth servicing mission, around 2004. At the same time, the HST will receive two more instruments—the Wide Field Camera 3, which reuses parts of the original WFPC, and the Cosmic Origins Spectrograph, which will greatly expand the ultraviolet spectroscopic capability of the HST, especially in the far-UV.

Control and communication

Since the telescope is in such demand, and maneuvring in space from one target to another is both difficult and time-consuming, detailed long-term planning is essential. Computer programmers are employed to write the second-by-second instructions that point the telescope, keep it on target and command the scientific instruments.

Programmed pointing instructions are made more complicated by the fact that the observatory follows a circular orbit inclined at 28.5 degrees to the equator. Although its orbital period is approximately 95 minutes, the observatory's motion around the planet means that a particular target above the equator will be occulted by the Earth for up to 45 minutes. The onboard computer overcomes this handicap by instructing the HST to reacquire its target as the OCCULTATION ends. In this way, multiple exposures lasting many hours can be obtained. This problem does not arise for objects above the polar regions, since they are never hidden behind the planet.

The HST uses a number of systems for attitude control and accurate pointing. It has three rate sensor units, each containing two gyroscopes. Frequent failures of these gyros have caused a few headaches for mission controllers, particularly in November 1999, when the observatory went into an automatic safe mode and had to be shut down for two months after four of its gyros stopped functioning. The HST needs at least three operational gyros for accurate alignment of the instruments on its astronomical targets.

The HST also carries four reaction wheels, which move the telescope from one target to another. These only allow the telescope to slew very slowly across the sky—about 90 degrees every 18 minutes. Three fixed head star trackers refine the telescope's position by commanding the reaction wheels to make minor adjustments. At all times, the HST must be orientated away from the Sun so that its sensitive optics are not damaged.

Once in position, the observatory's set of fine guidance sensors are used to pinpoint the particular target by fixing on pairs of guide stars in the telescope's field of view. After locking on to the guide stars, these sensors are able to aim the telescope with an accuracy of 0.01 arcsec

for up to 24 hours. The Fine Guidance Sensors also have a secondary scientific role since they can be used for astrometry, measuring star positions to within 0.005 arcsec (see ASTROMETRY WITH HUBBLE SPACE TELESCOPE). The Guide Star Catalog used by the HST to lock onto celestial targets includes the precise locations of 15 million stars down to magnitude 14.5.

Instructions from the control centre at Goddard Space Flight Center are relayed to the HST via one of NASA's Tracking and Data Relay Satellites (TDRS). The HST receives the data by means of two high-gain antennae, which usually receive programmed instructions from the Earth three times a day.

Until December 1999, scientific data were recorded on a mechanical reel-to-reel data recorder until it could be downloaded to the ground, but this was replaced by a solid state digital version during servicing mission 3A. The observational data are eventually transmitted back to a ground station at White Sands, New Mexico, via a TDRS. From there, the data are sent by satellite relay to Goddard Space Flight Center. After checking that the data have not been lost or corrupted, controllers at Goddard pass them on to the Space Telescope Science Institute in Baltimore where they are stored and processed for scientific analysis.

Responsibility for conducting and coordinating the science operations of the HST rests with the Space Telescope Science Institute, which is operated for NASA by the ASSOCIATION OF UNIVERSITIES FOR RESEARCH IN ASTRONOMY, Inc. (AURA).

A revolution in astronomy

Apart from a brief hiatus from November 1999 to January 2000, when the telescope went into safe mode after the failure of a fourth gyro, the HST has been sending back a stream of data almost continuously for over a decade.

During this period, the observatory has led to an unprecedented series of discoveries that have invigorated all areas of astronomical research. The HST has helped confirm some astronomical theories, challenged others, and, more often than not, come up with complete surprises which leave theorists scrambling for answers.

Apart from the Sun and Earth, only Mercury is inaccessible to the HST's gaze—the planet is always so close to the Sun in the sky that it would be far too risky to point the telescope's sensitive optics in its direction. Many thousands of celestial objects have been studied with the orbiting observatory since its inauguration.

In the solar system, the HST has observed seven of the nine planets and many of their larger satellites, searched for Kuiper Belt objects, studied comets such as Hyakutake and Hale–Bopp, and imaged numerous asteroids. Major advances include the first maps of Pluto, its moon Charon and the large asteroid Vesta, and detailed views of the fragmented Comet Shoemaker–Levy 9 as it collided with Jupiter. Regular monitoring of atmospheric phenomena has revealed cyclonic systems and dust storms on Mars, and chaotic changes on the outer gas giants, including ultraviolet aurorae on Jupiter and Saturn, equatorial storms on Saturn and a transient Great Dark Spot on Neptune.

Within the Milky Way, the HST has unveiled a wondrous menagerie of intricate planetary nebulae; found evidence for brown dwarfs and solitary black holes; studied the changing environment around supernova 1987A as its encircling rings of glowing gas expand outwards and interact; discovered circumstellar disks in which planets may be forming; probed the inner reaches of star forming regions such as the Orion Nebula; found stars incubating inside tall pillars of gas and dust which are being eroded by the radiation from nearby hot stars; and investigated ancient globular clusters.

Nearby galaxies have also come under the HST's scrutiny. In the Andromeda galaxy and the ultraluminous infrared galaxy Arp 220, it revealed not one, but two, luminous core regions. Evidence for massive black holes has been found in the cores of many galaxies, and jets of material have been imaged spewing away from these central power sources. The most massive black hole so far detected, located in the core of elliptical galaxy M87, appears to be equivalent to 3 billion solar masses.

By means of extremely long exposures of the same regions of sky, the observatory has been able to obtain the deepest views yet of the distant universe, looking back more than 90% of the age of the universe, to the era when galaxies were first being formed. The first groundbreaking HUBBLE DEEP FIELD image of the northern hemisphere was assembled from 342 separate exposures by the WFPC-2 over 10 consecutive days in December 1995. A similar deep field view was obtained for the southern hemisphere in October 1998. Both images contained about 2500 galaxies with apparent brightness down to thirtieth magnitude. A subsequent 'long exposure' infrared image of a portion of the deep field—north, taken with NICMOS, uncovered the faintest galaxies ever seen.

Images such as these have provided astronomers with the first clear optical views of the host galaxies in which quasars are embedded. By studying the highly variable shapes and sizes of galaxies in the early universe, new theories have evolved concerning the frequency of collisions and the evolution of spiral and elliptical galaxies. However, while galaxies started to form quite soon after the Big Bang, studies with the HST support the idea that star formation only reached a peak much later, some 7 billion years ago.

Apart from the deep field images, astronomers have also been able to use the HST to probe the distant universe by means of gravitational lenses. Other cosmic puzzles, such as the origin of gamma-ray bursts, the age of the universe and value of the Hubble constant, have also been attacked using the space telescope.

By monitoring the visible afterglow of gamma-ray explosions, astronomers have been able to confirm that at least some of these events occur at cosmic distances, far beyond our Milky Way. Studies of Cepheid variable stars in galaxies up to 65 million light years away have pinned down the Hubble constant to 70 km s^{-1} Mpc^{-1}, with an

uncertainty of 10%. Based on these results, astronomers have calculated that the Universe was born about 12 billion years ago.

Discoveries such as these should keep on coming. Although the HST was originally intended to have an operational lifetime of 15 years, after the successful servicing mission 3A, the telescope's life expectancy has been extended until at least 2010, by which time the Next Generation Space Telescope may be in orbit.
